To Kristen Trombly, OTS, and all future and practicing occupational therapists who creatively strive to restore to the highest level of occupational functioning all people who come into their care.

Catherine A. Trombly Latham

To the occupational therapists of Sister Kenny Rehabilitation Institute.

Mary Vining Radomski

Preface

Imagine:

An occupational therapist enters a hospital room to meet Mrs. B., who sustained a stroke in the past week. The therapist sits down and knows the right questions to ask so that after their brief conversation, the therapist leaves with a general sense of Mrs. B.'s background and priorities and Mrs. B. is assured that someone on her rehabilitation team knows her beyond her current impairments. The occupational therapy evaluation continues later that day with the therapist explaining the occupational therapy assessment process to Mrs. B. and her daughter and ultimately reviewing and interpreting the results based on an appreciation of the strengths and weaknesses of tests themselves and the contextual factors that may have affected Mrs. B.'s performance. The next day, Mrs. B. and her daughter sit down with the occupational therapist to formalize the intervention plan—to discuss Mrs. B.'s priorities in light of evaluation results (from both an occupational therapy perspective as well as the perspective of other rehabilitation disciplines) and intervention options. The occupational therapist reviews what she knows about the efficacy or effectiveness of various interventions. Together, Mrs. B., her daughter, and the therapist establish short-term therapy goals with an eye toward longer-term therapy needs down the road.

This is a glimpse of occupational therapy practice to which we hope this sixth edition of *Occupational Therapy for Physical Dysfunction* contributes: practice composed of occupational therapy services provided within the context of a compassionate therapeutic relationship, informed by expert clinical reasoning that considers “why.” Why use this assessment method over another? Why use this intervention approach over another? Why am I observing these results?

This edition of *Occupational Therapy for Physical Dysfunction* is designed to help occupational therapy students and practitioners acquire the skills necessary to provide occupational therapy services as well as to develop the mindset necessary to do so as a reflective practitioner.

ORGANIZATION

Similar to the previous edition, the sixth edition is composed of six sections with 50 chapters.

Section I describes the historical and social influences on the current practice of occupational therapy for those with physical impairment. This section also lays the foundation for the rest of the textbook and the theoretical foundation for practice by introducing the Model of Occupational Functioning.

Section II presents the areas of assessment for which an occupational therapist working with adults with occupational dysfunction secondary to physical impairment would be responsible. The chapters in this section begin with assessment of the person's occupational roles and competence of performance in those roles, followed by assessment of the person's abilities and capacities that support role performance, and assessment of the environmental and contextual constraints and enablers of performance.

Section III presents three mechanisms of therapeutic change: occupation as therapy, learning, and therapeutic rapport.

Section IV presents therapeutic technologies that enable and support occupational functioning: splinting, wheelchairs, adapted or assistive devices, and physical agent modalities.

Section V elucidates treatment principles and practices of therapy for persons with physical dysfunction. As in earlier editions, this section does not provide recipes for the treatment of people with particular diagnoses, but

rather descriptions of best practice. The professional occupational therapist can choose from these for a particular patient who has his or her own particular goals and manifestation of a diagnosis.

Section VI includes discussions of the practice of occupational therapy for particular, major diagnostic categories, each written by a specialist in that area. These experts alert therapists who are beginning to practice with one of these populations to various commonly encountered impairments that affect occupational functioning and to the specialized assessments and treatments that have been developed for persons carrying the diagnosis. Two new chapters, “Human Immunodeficiency Virus” (Chapter 49) and “Oncology” (Chapter 50), have been added to this section since the prior edition.

NEW FEATURES

This edition also has a number of new features that emphasize the scientific and reflective foundations of clinical practice.

Chapters in Section II (Assessment of Occupational Function) include **Assessment Tables** that summarize the psychometric properties, strengths, and weaknesses of the assessment methods described in the chapter.

Evidence Tables (where evidence exists) are included in chapters in Section IV (Therapeutic Mechanisms), Section V (Treatment of Occupational Function), and Section VI (Treatment to Promote Occupational Function for Selected Diagnostic Categories). These tables summarize research studies that address the interventions mentioned in the chapters and/or Case Examples. They are not an exhaustive compendium of all research, but represent the current best evidence for the effectiveness of the interventions. Readers will find information pertaining to these tables and other features in this volume’s **User’s Guide**.

Finally, the **Case Examples** in this edition have been reformatted to highlight the “whys” of the assessment and intervention process. In general, Case Examples are designed to help students appreciate how various topics described in the chapter relate to and inform occupational therapy practice. Readers will find that the Case Example format in this edition describes the actions of therapy (“Occupational Therapy Process”) along with the therapist’s internal dialogue to explain why he or she approached occupational therapy assessment and/or intervention as he or she did (“Clinical Reasoning Process”).

As in the previous edition, a **Glossary** and boxes highlighting **Clinical Reasoning** (opportunities to develop clinical reasoning skills that go beyond the material that can be looked up in the chapter), **Procedures for Practice**

(how to do a particular assessment or treatment), **Definitions, Research Notes** (examples of application of research, including that from other disciplines, to practice), **Safety Notes** (precautions to be observed), and **Resources** (where to find information and equipment) are included throughout the chapters to showcase and emphasize key concepts.

ANCILLARIES

A website is available at <http://www.thepoint.lww.com/trombly6e>. Students can go to the site to see how an expert would answer the questions posed in Clinical Reasoning Boxes throughout the text. Instructors’ Resources are also available, including Powerpoint slides that provide lecture outlines for each chapter, and an image bank containing all images and tables from the book. Also included online are the **Summary Review Questions** and **References** for each chapter.

A DVD is also included with each copy of this text, to facilitate student learning of core techniques through demonstration. It includes short video clips that help learners visualize and review key aspects of practice, including the measurement of upper extremity range of motion and hand strength, as well as how to fabricate a splint and assist clients as they transfer into and out of a wheelchair.

TERMINOLOGY

Throughout this book, readers will note an amalgam of occupational therapy terminology, derived from the *Occupational Therapy Practice Framework* (AOTA, 2002); International Classification of Functioning (WHO, 2001); *Occupational Functioning Model*; and generic “OT-speak.” We are unapologetic about our aim to help develop multilingual practitioners. If you find yourself needing to think twice to do some translation, get used to it. In practice we must be proficient at adapting our language in appreciation of our audience, understanding that most of us spend our day communicating with people who have never heard of occupational therapy, much less our professional vocabulary.

Also note that we have tried to be intentional about identifying the recipients of services as patients or clients. In acute medical and inpatient rehabilitation settings, the term “patient” reflects a more passive role of the person receiving care; it is also the term used by other professionals on the health care team. The term “client” is used in reference to a person living in the community who is receiving outpatient, home-based, or community-based

services. It reflects the assumption that the person receiving services is ready to assume a more directive role in organizing his or her care.

Sixty outstanding clinical and academic occupational therapists and experienced lay persons contributed to this edition. They each did so with the desire to contribute to the profession of occupational therapy by sharing their knowledge and skills with occupational therapists preparing to enter the field.

Acknowledgements

This sixth edition is published 30 years after the first edition and 35 years after the project first began. The first edition was written in longhand on legal pads—this new edition was electronically processed. During that 35 years, it has taken dozens of people to bring the project to fruition, including contributors, photographers, videographers, models who posed for the photographs, vendors who loaned equipment and/or professional photographs of rehabilitation products, designers, artists, acquisition editors, managing editors, copy editors, art editors, production managers and their crews, typists, and reviewers (formal and informal). I owe great thanks to all of these participants.

Three people in particular contributed to the success of this project and must be acknowledged: Anna Deane Scott, M.Ed., OTR, my first co-editor; Christopher Trombly, my son; and Mary Vining Radomski, Ph.D.(cand.), OTR/L, FAOTA, my current co-editor. Anna Deane first had the idea for this textbook. We co-taught and needed to compile material for our students because there was no comprehensive book devoted to occupational therapy for those with physical dysfunction. She suggested we create that missing textbook, and Williams & Wilkins bought it.

My son Christopher grew up with this project and contributed by playing independently when I needed to work, posing for photographs at various times in his life, eating pizza, and helping out with chores. I am sure he sometimes wished life was different, as did I.

I now leave this project in Mary's capable hands. She graciously accepted co-editorship two editions ago and has brought not only her considerable knowledge about the treatment of cognitively impaired individuals, but also her high work standards, her creative ideas, her network of expert contributors, and her superb administra-

tive skills. I have no doubt that under her leadership this textbook will continue to be an important influence on the practice of occupational therapy.

Lastly, I look forward to developing new occupational roles with my husband, John.

Catherine Trombly Latham

In addition to Jim, Lauren, and Allie Radomski, I gratefully acknowledge the contribution of my Sister Kenny family to the sixth edition of *Occupational Therapy for Physical Dysfunction*. Besides helping with photography, these remarkable therapists, social workers, doctors, and nurses tolerated the inconveniences of the video shoot, shared their expertise and resources, and continually stepped up when I came knocking with "opportunities." I also appreciate the permission to use "Warm Heart" on the cover, painted by Brom Wikstrom, which is part of the Sister Kenny permanent collection (see p. xii). A special word of thanks to occupational therapists Erin Mack, Marilyn Sicheneder (both of TRIA Orthopaedic Center), and Jennifer Theis (Sister Kenny), as well as Cheryl Smith and Rob and Marilyn Beyerl for their help with the DVD. I am grateful to Jennifer Theis for creating the Powerpoint slides that accompany the book. The rehabilitation practitioners and friends of Sister Kenny live out the kind of compassionate excellence that makes me so glad to be an occupational therapist.

I am also grateful to Catherine Trombly Latham for her confidence in me and for her example in all matters of gracious conduct (which include writing and editing). I have yet to figure out how she can be simultaneously visionary, exacting, patient, and empowering, but will give it my best to follow in her footsteps.

Mary Vining Radomski

ABOUT THE COVER ARTIST

Cover and Interior Art: Warm Heart

Artist: Brom Wilkstrom

The cover image for this volume, “Warm Heart,” was painted by Brom Wilkstrom and is part of the Sister Kenny permanent collection. Brom Wilkstrom and his wife, Anne, live in Seattle, Washington. Brom studied art at Seattle Community College and was working as a sign

painter in New Orleans, Louisiana, when he broke his neck swimming and became paralyzed. He now paints with his mouth and teaches in area schools. Brom exhibits his work through the International Association of Mouth and Foot Painting Artists, who also reproduce his work on greeting cards and calendars. Working at the University of Washington’s Burke Museum of Natural History and Culture as an information specialist, Brom is active in many cultural organizations. He has won many awards and his work is included in many prestigious collections.

NEW FEATURES TO HELP YOU BE A SUCCESSFUL OCCUPATIONAL THERAPIST

Occupational therapists who practice competently and ethically do so from a background of evidence that assessments are valid and reliable and treatments are efficacious. The two new table features of *Occupational Therapy for Physical Dysfunction* support evidence-based practice.

ASSESSMENT TABLES At the end of each assessment chapter there is a table to help the therapist select an appropriate measure and to interpret the results. Terms used in these tables include:

- **Reliability** is a measure of an instrument's stability. Interobserver or interrater reliability refers to the outcome when two different individuals administer the instrument to a particular person and achieve similar results. Test-retest reliability, or intrarater reliability, refers to the constancy of results over repeated use of the instrument by the same tester in the absence of change in the person being tested.
- **Sensitivity** is the ability of an instrument to detect clinically important changes.
- **Validity** is the ability of an instrument to measure what it is intended or presumed to measure. Criterion validity is determined by comparing the examined test to an agreed-on *gold standard* (accepted test). Predictive validity is its ability to predict future outcomes.

Assessment Table 6-1
Summary of Assessment of Muscle Tone or Resistance to Passive Movement

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<i>Modified Ashworth Scale</i> (Bohannon & Smith, 1987)	Ordinal scale with score for each motion from 0 (normal muscle tone) to 4 (rigid in flexion or extension). Modification is the addition of one additional rating level (1+).	1–2 minutes per motion tested.	Concurrent validity: $r_s = 0.39$ – 0.49 with quantitative spasticity measures (Allison & Abraham, 1995); $r = 0.50$ with motor and activity scores (Sommerfeld et al., 2004); $r_s = 0.51$ with resistance to passive movement (Pandyan et al., 2003); and $r_s = 0.40$ with the H-reflex (Pizzi et al., 2005).	Inter-rater reliability: $r_s = 0.67$ and 0.73 for elbow flexion and extension, respectively; $r_s = 0.45$ for knee flexion (Sloan et al., 1992); $Kw^1 = 0.49$ – 0.54 for shoulder, elbow, wrist, knee, and ankle joints (Mehrholtz et al., 2005). Test-retest reliability: $Kw = 0.77$ – 0.94 for elbow, wrist, and knee flexors; $Kw = 0.39$ – 0.64 for ankle plantarflexors (Gregson et al., 2000).	Significant reduction in <i>Modified Ashworth Scale</i> scores after treatment with botulinum toxin (Bakheit et al., 2000, 2001); non-significant reduction in <i>Modified Ashworth Scale</i> scores (Pandyan et al., 2002)	Strengths: It is a valid measure of muscle tone or resistance to passive movement (Pandyan et al., 2002); administration time is relatively brief; reliability is better for upper extremity than lower extremity joints. Weaknesses: Only moderate concurrent validity with measures of spasticity. It is questioned as a measure of spasticity (i.e., the neural component of muscle tone). Moderate to good inter-rater reliability; moderate to very good test-retest reliability.

¹Kw = weighted kappa.

STUDENT DVD

features dynamic video clips demonstrating range of motion, manual muscle testing, construction of hand splints and transferring patients.

EVIDENCE TABLES

At the end of each chapter devoted to treatment or a diagnosis is a table listing some of the best evidence concerning the treatments mentioned in the chapter. Terms used in the evidence tables include:

- **Effect size** is a unit-less indication of the strength of the relationship between the treatment and the outcome (Rosenthal, 1984).

There are several representations of effect size, including *r*, Hedges' *g*, Cohen's *d*, and *h*² (eta squared). Effect size, "*r*," is interpreted like a correlation coefficient: 1.0 equals a perfect, strong, relationship and 0 equals no relationship (Rosenthal, 1984). An effect size of *r* = .10 is considered small ; of .30, medium; and of .50 large (Cohen, 1988) (*h*² , eta squared, is interpreted similarly to "*r*").

- **Level of evidence** rating scale used in this textbook is the American Occupational Therapy Association's Evidence Based Project Scale (Trombly & Ma, 2002): Level I [highest] to Level IV [lowest]. The higher the level, the better the evidence that the intervention was the cause of the change reported. The Scale also presents grades relating to sample size, internal validity (how well the study controlled for alternate explanations of outcome), and external validity (how well the study generalizes to persons other than the study participants or to settings other than the study setting). For example, a IC2c rating means that the study was a randomized controlled trial (I), with 20 or fewer participants in each group (C), that had no strong alternative explanation for outcome, but had one or two threats to validity (2), and that the participants do not necessarily represent the population of patients of that diagnosis AND the treatment does not represent current practice OR it was carried out in an unnatural (laboratory) setting (c).
- **Statistical probability** indicates the likelihood that the outcome was due to chance. A probability level of .05 indicates that there are only 5 chances out of a hundred that the outcome occurred by chance (Rosenthal & Rosnow, 1991).

**Evidence Table 24-1
Best Evidence for Occupational Therapy Practice
Regarding NDT/Bobath**

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
NDT for stroke survivors	Effectiveness of NDT in 3 areas: general treatment, upper limb recovery, and lower limb and gait.	726 acute stroke survivors; age range, 15-95 years; mean age cannot be calculated.	Ranged from 2-15 weeks.	Systematic review of 15 trials: 6 randomized controlled trials, 6 non-randomized controlled trials, and 3 case studies.	Of general effectiveness studies (n = 6), 1 found more improvement in NDT group, and 5 found no difference or more gains in alternate group; 1 of 3 studies of upper extremity effectiveness found greater benefit with NDT.	<i>p</i> <0.001 set as statistical significance level for all studies included. Effect sizes were not reported.	Paci, 2003
NDT for upper limb post stroke	Effectiveness of NDT in improving impairment (tone, strength, pain), activity limitation, and participation.	374 stroke survivors 6 weeks to 2 years post cerebrovascular accident; age range, 35-95 years; mean age cannot be calculated.	Ranged from 1 session to 20 weeks of daily 45-minute sessions.	Systematic review of 8 studies: 5 randomized controlled trials, 1 single-group cross-over design trial, and 2 single case studies.	NDT more effective than proprioceptive neuromuscular facilitation but not more than general rehab at reducing muscle tone. No significant effects of NDT on motor control, upper extremity function, or participation.	Improvement in upper extremity tone using RFPs, <i>d</i> = 0.46.	Luke, 2004

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of the Environment on Cognitive Function

During the initial OT assessment, E.B. demonstrated some difficulty with initiating, sequencing, and organizing tasks during the AMP5 and expressed concerns about returning to community and work roles. How might the occupational therapist gain a better understanding of E.B.'s cognitive abilities during therapy? What task and environmental factors might exaggerate or minimize these problems? What other assessments might best help with clarifying occupational performance needs and planning OT treatment?

treatment planning and to determine changes in activity performance over time. The *Interest Checklist* can be used for clients throughout the lifespan, from adolescence through old age.

The revised *Activity Index* (Gregory, 1983) is a self-report assessment that determines a person's interest and frequency of participation in a variety of activities, ranging from card games and theater to quiet hobbies at home. When used in conjunction with the *Meaningfulness of Activity Scale*, it can be used to indicate a client's autonomy, competency, and enjoyment derived from leisure activities (Gregory, 1983). Scores on these combined scales were found to significantly correlate with life satisfaction in elderly persons (Gregory, 1983).

The *Leisure Diagnostic* (Witt & Ellis, 1984) was designed to assess leisure experience the client to rate leisure involvement in leisure activities. See determine a problem scales appear performance after *Diagnostic Battery* have chronic without evidence (Peebles et al. Other assessment of the *Leisure Control* that are (Kloseck, to Resou

SUMMARY REVIEW QUESTIONS

1. Define self-report and direct observation methods of assessment. What are the advantages and disadvantages of these methods when evaluating a client's occupational performance?
2. Distinguish between IADL and basic ADL, and describe one standardized assessment for each.
3. What are three measurement concepts or psychometric properties of standardized evaluation instruments? Define each, and provide an example of how these properties might affect the results of occupational therapy assessments administered in the clinic.
4. What is the relationship between the assessment of occupational performance and development of an occupational therapy treatment plan?

CHAPTER 7—Assessing Abilities and Capacities: Sensation 219

The principles of sensory testing optimize the reliability of the testing results. These are listed in *Procedures for Practice 7-1*. The purpose of these principles is to eliminate non-tactile cues and to ensure that the responses from the patient accurately reflect actual sensation. Because many of the tests require subjective reports from the patient, results can be either deliberately or unconsciously manipulated by the patient to make the deficit appear better or worse. Careful attention to test administration and patient responses can minimize the possibility of testing manipulation by patients. For cases where the patient's responses are questionable and a determination of testing manipulation must be made, therapists may use a forced-choice testing methodology and statistical analysis described by Greve, Bianchini, and Ameduri (2003) in

PROCEDURES FOR PRACTICE 7-1

Principles of Sensory Testing

- Choose an environment with minimal distractions.
- Ensure that the patient is comfortable and relaxed.
- Ensure that the patient can understand and produce spoken language. If the patient cannot, modify testing procedures to ensure reliable communication.
- Determine areas of the body to be tested.
- Stabilize the limb or body part being tested (Fig. 7-4).
- Note any differences in skin thickness, calluses, and so on. Expect sensation to be decreased in these areas.
- State the instructions for the test.
- Demonstrate the test stimulus on an area of skin with intact sensation while the patient observes.
- Ensure that the patient understands the instructions by eliciting the correct response to the demonstration.
- Occlude the patient's vision for administration of the test. Place a screen (Fig. 7-5) or a file folder between the patient's face and the area being tested, blindfold the patient, or ask the patient to close his or her eyes.
- Apply stimuli at irregular intervals or insert catch trials in which no stimulus is given.
- Avoid giving inadvertent cues, such as auditory cues or facial expressions, during stimulus application.
- Carefully observe the correctness, confidence, and promptness of the responses.
- Observe the patient for any discomfort relating to the stimuli that may signal **hypersensitivity** (exaggerated or unpleasant sensation).
- Ensure that the therapist who does the initial testing does any reassessment.

Adapted from: Brand & Hollister, 1993; Callahan, 2002; Reese, 1999.

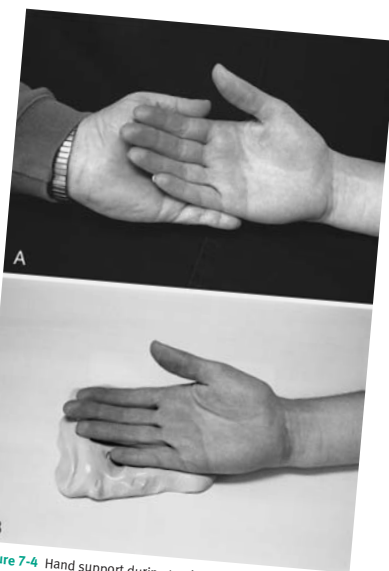

Figure 7-4 Hand support during testing. **A.** Fingers must be carefully stabilized and supported during testing so that motion is prevented, avoiding inadvertent cues to the patient. **B.** A cushion of therapy putty can be used to provide the stabilization.

Figure 7-5 Vision must be occluded during testing. Using a screen such as this is usually more comfortable for patients than closing their eyes or being blindfolded.

CLINICAL REASONING

BOXES give opportunities to solve clinical problems by applying knowledge gained in each chapter to real-life situations.

SUMMARY REVIEW

QUESTIONS let you assess your ability to apply the information presented in each chapter.

PROCEDURES FOR PRACTICE BOXES provide step-by-step directions for applying concepts to practice.

SECTION I: Occupational Function: Definition, Process, and History

CHAPTER 1

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the Occupational Functioning Model.
2. Use the language of the Occupational Functioning Model, the American Occupational Therapy Association's Occupational Therapy Practice Framework (OTPF), and the World Health Organization's International Classification of Functioning (ICF) interchangeably.
3. Organize assessment and treatment planning according to the Occupational Functioning Model.

Conceptual Foundations for Practice

Catherine A. Trombly Latham

Glossary

Ability—Having sufficient power, skill, or resources to accomplish an object (Mish, 2004). A general trait an individual brings to learning a new task (Fleishman, 1972).

Activity, activities—In the Occupational Functioning Model (OFM), activities are considered small units of goal-directed behavior that make up tasks. The Occupational Therapy Practice Framework (OTPF) (AOTA, 2002) defines activity as a class of human actions that are goal directed. In the International Classification of Functioning (ICM), activity is defined as the “execution of a task or action by an individual” and includes everything a person does at any level of complexity from basic physical and mental functions of the person as a whole (e.g., acquisition of knowledge or grasp) to complex skills and behavior (e.g., driving a car or interacting with persons in formal settings) (WHO, 2001).

Activity analysis—A process used to identify the properties inherent in a given occupation, task, or activity, as well as the skills, abilities, and capacities required to complete it. Activity analysis is used to analyze and assess performance, to select occupations to remediate deficient capacities and abilities, or, knowing the person’s skills, abilities, and capacities, to select and modify activity to ensure successful completion of the activity.

Adaptive therapy—Therapy that promotes a balance among a person’s goals, capabilities, and environmental demands by use of assistive technology, adaptation of the environment or methods of accomplishing an activity, and/or redefinition of goals.

Augmented maturation—Therapeutic techniques that use controlled sensory stimulation and activities that promote responses in developmental postures or patterns to develop first-level capacities or developed capacities.

Capacities—Potential attributes that, once developed into abilities and skills, will contribute to occupational functioning. Capacities are the basis of performance.

Context—The circumstances surrounding an act or event (Mish, 2004). In health care, context refers to the whole situation, background, or environment that is relevant to a particular event or personality. In this sense, context has personal, social, cultural, physical, and temporal dimensions.

Environment—Surroundings; the aggregate of physical, social, and cultural conditions that influence the life of an individual (Mish, 2004).

Functioning—An umbrella term encompassing all body functions, activities, and participation (WHO, 2001).

Impairment—Any significant deviation or loss of body structure or physiological or psychological function (WHO, 2001).

Occupation—Everyday life activity (AOTA, 2002, p. 610).

Occupation-as-end—Occupation is the functional goal (activity, task) to be learned or accomplished. Its therapeutic impact comes from its characteristics of purpose and meaning (Trombly, 1995). Through repeated carrying out of an occupation, the patient will relearn the activity, or through adaptation, the activity will be possible for the person, given his current capacities and abilities. Example: Using a stocking aid, the person with a total hip replacement can don his or her stockings.

Occupation-as-means—Occupation that is used as the therapeutic change agent to remediate impaired abilities or capacities. Its therapeutic effect derives from characteristics of purpose and meaning (Trombly, 1995). It is also termed therapeutic occupation (Fisher, 1998). An example is peeling carrots to develop gross grasp by a person who likes to cook.

Occupational dysfunction—Inability to maintain one’s self (i.e., care for self, dependents, and home); to advance oneself through work, learning, and financial management; or to enhance the self by engaging in self-actualizing activities that add enjoyment to life.

Occupational Functioning Model—A conceptual model that guides occupational therapy evaluation and treatment of persons with physical dysfunction. The propositions of the model are as follows: (1) To engage satisfactorily in a life role, a person must be able to do the tasks that, in his opinion, make up that role. (2) Tasks are composed of activities, which are small units of behavior. (3) To be able to do a given activity, one must have certain sensorimotor, cognitive, perceptual, emotional, and social abilities. (4) Abilities are developed from capacities that the person has gained through learning or maturation. (5) These developed capacities depend on first-level capacities that derive from a person’s genetic endowment or spared organic substrate (Trombly, 1993, 1995).

Participation—The nature and extent of a person’s involvement in life situations in relation to impairments, activities, health conditions, and contextual factors. A fundamental property of participation is the complex interaction between a person with impairment and/or disability and the context. Participation consists of all areas or aspects of human life, including the full experience of being involved in a practice, custom, or social behavior (WHO, 2001).

Performance patterns—Patterns of behavior related to daily life activities that are habitual or routine (AOTA, 2002, p. 632).

Performance skills—What one does that has functional purpose, not a characteristic of the person. Performance skills include motor skills, process skills, and communication/interaction skills (AOTA, 2002, p. 632).

How do occupational therapists know what to do when a person with **occupational dysfunction** secondary to a disease or injury that results in physical **impairment** is referred to them? First, they have *specific knowledge* about what the diagnosis means in terms of limitations of bodily structure or function and subsequent probable limitation of occupational performance, and they know the outcome of research on the effectiveness of interventions available—the evidence base of practice. Second, they have *specific skills* for assessing and treating persons with occupational dysfunction secondary to physical impairment. Third, they know *how therapy is organized*—the conceptual foundation for practice. The organization or process of occupational therapy is found in various conceptual models of practice. An occupational therapy model of practice is a way of conceptualizing the interrelatedness of the person, and his or her **environments**, occupations, and quality of life, to guide assessment and intervention. In this chapter, one model, the **Occupational Functioning Model (OFM)**, is described as well as how this model relates to the American Occupational Therapy Association’s (AOTA) Occupational Therapy Practice Framework (OTPF) (AOTA, 2002), and the World Health Organization’s (WHO) International Classification of **Functioning** (ICF) (WHO, 2001).

THE OCCUPATIONAL FUNCTIONING MODEL

The Occupational Functioning Model (OFM) guides evaluation and treatment of persons with physical dysfunction leading to competence in occupational performance. The OFM was derived from clinical practice. The primary belief is that people who are competent in their life roles experience a sense of self-efficacy, self-esteem, and life satisfaction. Research partially supports the idea that competency is related to satisfaction (Robinson-Smith, Johnston, & Allen, 2000). For example, actual performance has been found to strengthen efficacy beliefs in older adults (Resnik, 1998). Competence in occupational performance contributes to development of a person’s identity (Christiansen, 1999; Toal-Sullivan & Henderson, 2004). The goal of treatment, following the OFM, is to enable satisfactory engagement in valued roles whether by restored self-performance or by directing others.

Another assumption of the OFM is that the ability to carry out one’s roles and activities of life depends on basic abilities and **capacities** (e.g., strength, perception, ability to sequence information). This hierarchical organization assumes that lower-level capacities and abilities, such as strength and endurance, are related to a higher-level performance of everyday tasks and activities. This organization

has been preliminarily supported by research (Dijkers, 1997, 1999; Geertzen et al., 1998; Sveen et al., 1999). Only part of the variance associated with function, however, is accounted for by any one ability. For example, Lynch and Bridle (1989) found a moderately strong ($r = -0.65$; $p < 0.01$) negative relationship between the scores of the *Jebsen-Taylor Hand Function Test* (Jebsen et al., 1969) and the scores of the *Klein-Bell ADL (Activities of Daily Living) Scale* (Klein & Bell, 1982). The correlation is negative because better performance on the *Jebsen-Taylor* is indicated by less time (lower score), whereas better performance on the *Klein-Bell* is indicated by a higher score. Filiatrault et al. (1991) found a similar relationship ($r = 0.6$) between the *Fugl-Meyer Motor Function Test* (upper extremity subtest) (Fugl-Meyer et al., 1975) and the *Barthel Index (ADL)* (Mahoney & Barthel, 1965). These outcomes do indicate that sensorimotor control of the upper extremities is related to self-care. But because the r^2 (0.65^2 or 0.60^2) value is only approximately 40%, other unidentified variables must account for the remaining approximately 60% variance associated with ADL. This makes sense because, in addition to upper extremity function, ADL independence requires such skills as sitting and standing balance, perception of positions of objects in space, ability to sequence steps of a procedure, environmental support, and so forth.

It appears that the relationship between two adjacent levels of performance (e.g., capacities and abilities) is stronger than between two nonadjacent levels (e.g., capacities and roles) (Dijkers, 1999). The relationship between levels is strong both at the low end of the model (Pendlebury et al., 1999) and at the high end (Dijkers, 1997, 1999). Pendlebury et al. (1999) found a strong ($r = 0.90$) relationship between deficits in organic substrate and deficits of motor capacities and abilities. In a large sample of persons with spinal cord injury, Dijkers (1999) found a moderately strong relationship ($r = 0.24$ – 0.42) between life satisfaction and roles related to social integration and occupation (work) but not between impairments and life satisfaction ($r = 0.04$ – 0.07). He concluded that “these relationships suggest a causal chain [i.e., one link leading to the next]. . . . the impact of impairment on quality of life is almost entirely through its impact on disability, and the effect of disability is largely through its impact on handicap” (Dijkers, 1999, p. 874). This suggests that the relationship between low-level capacities and abilities and higher-level tasks and roles is not direct. That is, having a particular ability such as strength does not ensure that a person can accomplish a given activity or task (Dagfinrud et al., 2005). Likewise, the ability to accomplish a single activity does not account for role performance. Many capacities contribute to the development of one ability, and many abilities are needed to engage successfully in an activity. When one capacity or ability is impaired, occupational dysfunction does not automatically occur (Rogers & Holm, 1994; Rondinelli et al., 1997). A

person may adaptively use other capacities and abilities to allow accomplishment of the activity.

Research is needed to clarify the multivariate relationships among lower-level abilities and capacities and higher-level activities, tasks, and roles (Trombly, 1993, 1995). Researchers also must verify whether remediation of impaired capacities and abilities results in more complete and more versatile participation in the activities and tasks of importance to people's lives than would learning specific routines of activities in an adapted way (task-specific training). This is a key question for the practice of occupational therapy with persons having physical dysfunction.

Another assumption of the OFM is that satisfactory occupational functioning occurs only within enabling environments and **contexts** particular to the individual. True occupational functioning does not occur in a vacuum or in a controlled situation such as the clinic; occupational functioning is the successful interaction of the person with the objects, situations, and surroundings of his or her home, family, and community. Although the contexts of particular actions and occupations to regain lost abilities and capacities may be controlled at first, therapy is not complete until generalization to the person's particular environment has occurred.

Achievement of occupational functioning after injury or disease is accomplished through occupation as well as adjunctive therapies described in this textbook. In the OFM model, occupation has two natures: **occupation-as-end** and **occupation-as-means** (Trombly, 1995). Occupation-as-end equates to the higher levels of the OFM, at which the person tries to accomplish a functional goal (an activity or task) by using whatever skills, abilities, habits, and capacities he or she has. Occupation-as-means, on the other hand, is *the therapy* used to bring about changes in impaired client factors and performance skills. Occupation-as-means is based on the assumption that occupation holds within itself healing properties that will change organic or behavioral impairments. Both occupation-as-end and occupation-as-means derive their therapeutic impact from the qualities of purposefulness and meaningfulness (see Chapters 12 and 13 for discussion of these concepts).

The constructs of the occupational functioning model shown in Figure 1-1 are described next.

Sense of Self-Efficacy and Self-Esteem

The goal of occupational therapy is the development of competence in activities and tasks of one's cherished roles, which promotes a sense of self-efficacy and self-esteem. Competence refers to effective interaction with the physical and social environments (Fig. 1-2). To be competent means to have the skills that are sufficient or adequate to meet the demands of a situation or task (White, 1959). It

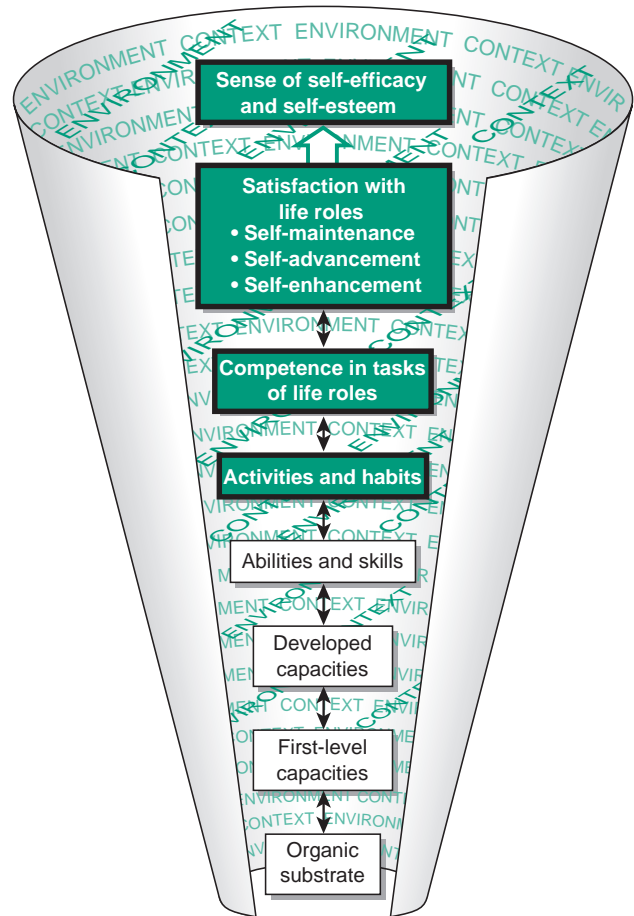

Figure 1-1 Paradigm of occupational functioning model.

does not equate to excellence, normality, or the ability to do everything, and it recognizes that there are degrees of sufficiency and adequacy in people (Mocellin, 1992; White, 1971). Competence reflects people's belief in their own control rather than being controlled by the social or physical environments (Trombly, 1993). Competence develops by enabling a person to engage in graduated, goal-directed activity that is accomplishable by that person and produces a feeling of satisfaction (White, 1959). Occupational therapists help people achieve competence through graded engagement in occupation, vicarious engagement and instrumental learning with immediate and precise feedback, and therapeutic interaction with the therapist (Bandura, 1997; Radomski, 2000; Robinson-Smith, Johnston, & Allen, 2002).

When people feel competent, they are likely to esteem themselves. Self-esteem is that aspect of self-concept that attributes a negative or positive value to the self. Self-esteem is created by individuals' analyses of their competence in socially relevant areas (Gage & Polatajko, 1994). People's levels of self-esteem depend on their confidence,

Figure 1-2 Competency in self-advancement role of contractor's helper.

based on experience, that they can make desired things happen and that others will appreciatively recognize this competence (White, 1971).

Efficacy, as it is used in the OFM, refers both to Bandura's (1977, 1997) concepts of perceived self-efficacy and outcome expectancy and Rogers' (1983) concept of response efficacy. Perceived self-efficacy refers to people's beliefs in their performance capabilities with respect to a specific task (Bandura, 1977, 1997; Gage et al., 1994; Resnik, 1998, 1999). It is concerned not with the skills one possesses but with the judgments of what one can do with those skills. Perceived self-efficacy is influenced through an ongoing evaluation of success and failure with each task people participate in over the course of their lives (Gage & Polatajko, 1994). Response efficacy and outcome expectancy refer to a judgment of the consequences that certain behavior will produce (Resnik, 1998). It is the individual's judgment of how effective his or her response to a given problem will be (Rogers, 1983). The most powerful source of efficacy expectations is past accomplishments in similar situations (Fig. 1-3).

Satisfaction with Life Roles

Being in control of one's life means being able to engage satisfyingly in one's life roles or to voluntarily reassign a role to another. Role performance is a vital component of productive independent living (Hallett et al., 1994). Various thinkers have proposed taxonomies of roles. For example, Reilly (1962) categorized occupational roles according to gender and age, identifying four: preschooler, student, housewife or paid worker, and retiree. She saw play and work roles on a continuum. The OTPF uses the phrase "areas of **occupation**" rather than roles and categorizes these areas as activities of daily living (ADL), instrumental activities of daily living (IADL), education, work, play, leisure, and social participation. The OFM sorts roles into three domains related to aspects of self-definition: self-maintenance, self-advancement, and self-enhancement (Trombly, 1993, 1995), but recognizes that the assignment of roles to a particular category is not absolute. Some roles may be classified in one domain by one person but in another domain by another person, depending on the motivation. For example, volunteering may be classified by one person as a self-advancement role because volunteering promotes skills that will be useful in a worker role. Another person may classify volunteering as self-enhancement because it promotes a sense of satisfaction without expectation of gain. The individuality of motivation underscores the importance of assessing each person from his or her own point of view, letting each define his or her roles and their meaning.

Self-Maintenance Roles

Self-maintenance roles are associated with maintenance of the self and care of the family and home. This domain

Figure 1-3 For this accomplished artist, painting a picture is a task of one of her self-advancement roles (worker). For another person for whom painting is a hobby, it would be classified as a task of a self-enhancement role (hobbyist).

equates to the OTPF areas of occupation of ADL and IADL (Table 1-1). Examples of roles in this domain are independent person, grandparent, parent, son, daughter, homemaker (Fig. 1-4), home maintainer (Fig. 1-5), exerciser, and caregiver.

Self-Advancement Roles

Self-advancement roles are those that draw the person into productive activities that add to the person's skills, possessions, or other betterment. This domain corre-

Table 1-1. The Domains of the Occupational Functioning Model and the Occupational Therapy Practice Framework

Occupational Functioning Model	Occupational Therapy Practice Framework
<i>Competence and Satisfaction with Life Roles and Competence in the Performance of Tasks of Life Roles</i>	<i>Areas of Occupation</i>
Self-Maintenance Roles—To maintain self, family, and home All basic activities of daily living (BADLs) and instrumental activities of daily living (IADLs) associated with self-care All IADLs associated with care of family All IADLs associated with care of home	ADL All personal care IADL Care of others Child rearing Care of pets Communication device use Community mobility Health management and maintenance Home establishment and management Meal preparation and cleanup Safety procedures and emergency responses Shopping Financial management
Self-Advancement Roles—These add to the person's skills, possessions, or other betterment. Examples are: Carpenter Tennis player Volunteer Student Shopper	Education Exploration of formal or informal educational needs and interests Participation in formal or informal education Work Employment interests and pursuits Employment seeking and acquisition Job performance Retirement preparation and adjustment Volunteer exploration and participation
Self-Enhancement Roles—These contribute to personal accomplishment and enjoyment. Examples are: Pianist Shopper Fisherman Tennis player	Play Play exploration and participation Leisure Leisure exploration and participation Social participation Family Peers, friends Community
<i>Abilities and Skills</i>	<i>Performance Skills</i>
Abilities and skills basic to interaction with objects and the physical environment Motor Sensory Cardiorespiratory	Motor skills—skills in moving and interacting with task objects and environment Posture: stabilizes, aligns, positions Mobility: walks, reaches, bends Coordination: coordinates, manipulates, flows

sponds to the OTPF areas of occupation of work and education (Table 1-1) but extends to include the instrumental roles that enable work. Self-advancement roles correspond to the **participation** category of the ICF (Table 1-2). Examples of roles in the self-advancement role domain include worker (Figs. 1-2 and 1-6), student, intern, commuter, shopper, investor, manager, and voter.

Self-Enhancement Roles

Self-enhancement roles contribute to the person's sense of accomplishment and enjoyment (Figs. 1-3 and 1-7). This domain loosely corresponds to the OTPF areas of occupation of play, leisure, and social participation (Table 1-1) and fits within the ICF category of participation (Table 1-2). The OFM would classify activities listed by the OTPF in the education and work categories, namely informal education for personal interest and preparation for retirement, as self-enhancement activi-

ties. Examples of roles in this domain include hobbyist, friend, club member, religious participant, vacationer, golfer, moviegoer, and violinist.

Competency in Tasks of Life Roles

Roles consist of constellations of tasks. For example, the role of homemaker may include the tasks of food preparation (Fig. 1-4) and service, housecleaning, laundry, and decorating (Fig. 1-5). The tasks identified for the same role by different people may be different (Nelson & Payton, 1991; Trombly, 1993, 1995; Yerxa & Locker, 1990). The value ascribed to tasks varies among people of similar situations and may vary from what therapists consider important for patients. Because people have different values, each person must define his or her role by identifying the tasks that he or she believes are crucial to satisfactory engagement in that particular role. The therapist cannot

Figure 1-4 Self-maintenance role: homemaker; task: meal preparation; activity: grilling fish.

assume that particular tasks are or are not important to a person's interpretation of a role.

Tasks consist of constellations of related activities and are therapeutically developed using occupation-as-end, that is, practicing the activities constituting the task in normal temporal order and environmental demand, with or without assistive technology as required.

Activities and Habits

Activities, in this model, are smaller units of goal-directed behavior that comprise tasks (Figs. 1-2 to 1-7). Activities bring together abilities and skills within a functional context. For example, one task of the gardener is pest control. Activities that make up this task include hanging lures, spreading granular insect killer, mixing and spraying liquids, and picking insects off plants. Furthermore, each of these activities consists of even smaller units of behavior, such as opening the package and pouring granular insect killer into a garden spreader. Some activities, such as picking insects off plants, require full attention. Others, called habits, do not. Habits are chains of action sequences that are so well learned that the person does not have to pay attention to do them under ordinary circumstances and in familiar contexts. Physical dysfunction disrupts habits, requiring attention to be paid to the simplest of activities of daily living. This adds to the fatigue experienced by many persons (Wallenbert & Jonsson, 2005). Occupational therapy seeks to help the person sustain or relearn adaptive habits, let go of habits that are no longer adaptive, and develop new habits, given the person's changed abilities and capacities. The OTPF term equivalent to habits is *performance patterns*.

Activities and habits are learned using occupation-as-end, that is, "task-specific training." In task-specific training, functional and meaningful activities are practiced over and over using assistive technology, adaptive methods, or adapted environment to enable performance, if necessary. See Chapter 13 for a more complete discussion of the therapeutic use of occupation-as-end.

Abilities and Skills

Activities depend on more basic abilities (Clark, Czaja, & Weber, 1990; Fleishman, 1972; Fleishman & Quaintance, 1984; Kielhofner, 1997). A person with a great number of highly developed abilities can become proficient at a greater variety of activities. An **ability** is a general trait, such as muscle strength or memory, that individuals bring with them to a new task (Fleishman, 1972). The OFM identifies six categories of abilities and skills: motor, sensory, cognitive, perceptual, socioemotional, and cardiorespiratory. For example, remembering, solving problems, and paying attention are some of the cognitive abilities

that underlie successful activity accomplishment. Actions such as reaching, stooping, grasping, pinching, manipulating, pulling, and pushing are motor abilities that underlie many activities. The OTPF terms these **performance skills** and specifies three spheres: motor, process, and communication/interaction.

In the OFM, abilities are seen as a combination of endowed talents and acquired skills. A skill is the ability to achieve a goal under a wide variety of conditions with a degree of consistency and economy (Higgins, 1991). To accomplish the activity of hanging lures in the previous example of the gardener, the person needs certain abilities, such as coordination, dexterity, and ability to follow directions. The person also needs to be able to translate these endowed talents into the skilled actions required to hang the lures. Carefully analyzed occupation-as-means is used to develop deficient abilities and skills. In the process of repeatedly accomplishing occupations that demand greater levels of the deficient ability or skill, in varying contexts, the patient gains greater levels of that ability or skill. By varying the context, the therapist encourages more robust learning. See Chapter 13 for a more complete discussion of the therapeutic use of occupation-as-means.

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Occupational Self-Analysis

Occupational therapists evaluate a patient's occupational profile. Practice this skill by analyzing your own occupational profile. The following directions are one way to determine the profile.

1. Make an occupational diary by listing awake hours along the left side of a piece of 11 × 8.5 inch paper and listing the days of the week across the top.
2. Fill in activities or tasks you do hour by hour in a typical week.
3. Classify these into role categories: self-maintenance, self-advancement, or self-enhancement.
4. Calculate what percentage of time you engaged in these role categories (hours spent in one role category/total awake hours × 100%).
5. Make another chart. Choose a favorite role. What tasks make up this role for you? Are the tasks the same as those of your classmates who chose the same role?
6. Choose the key task from your answer to Question 5. What activities comprise this task?
7. Choose one activity from your answer to Question 6. What abilities are needed to do this activity?
8. What type of impairments would prevent you from doing the activity as you usually do it?
9. What type of environmental or contextual barriers would prevent or hamper you from doing the activity?

Developed Capacities

Developed capacities reflect the organization of first-level capacities into more mature, less reflexive, and more voluntary responses. For example, to support dexterity, an ability, a person needs independent use of fingers, graded release, and pinch, which are developed capacities that derive from reflexive grasp and automatic release (first-level capacities). This organization is normally acquired through maturation. In therapy, occupation-as-means is used to develop these capacities. Therapeutic demands for gradually more mature and varied responses are made through repeated opportunities to engage in selected occupations. The equivalent OTPF term is client factors, although these appear to include not only the developed capacities of the OFM, but also the first-level capacities and organic substrate of the OFM.

First-Level Capacities

First-level capacities are the functional foundation for movement, cognition, perception, and emotional life based on the integrity of the organic substrate. In the motor domain, first-level capacities are reflex-based motor responses that reflect the organization of primary visual, sensory, and motor systems. Examples include reflexive grasp, reflexive release, primitive reaching, kicking, and stepping. They are the subroutines that Bruner (1973) described as underlying development of all voluntary movement. The ability to recognize a connection between an instrumental, nonreflexive response given consistently within a particular perceptual situation is a first-level capacity of cognition and perception. The fascination of babies with human faces is a first-level capacity of the socioemotional domain.

Organic Substrate

Organic substrate is the structural and physiological foundation for movement, cognition, perception, and emotions, including the primordial central nervous system (CNS) organization in the neonate; the CNS organization that is spared or recovers spontaneously after injury or illness; and the integrity of the skeleton, muscles, sensory and motor nerves, heart, lungs, and skin. If the organic substrate is not present, therapy cannot generate it. If it exists at all, therapy attempts to develop it into first-level capacities through techniques classified as **augmented maturation** (see Chapter 26).

Environment and Context

The words *environment* and *context* are often used interchangeably. In current health care literature, the term *context* is used to encompass all that surrounds and influences

any aspect of human functioning, including the physical environment as well as social, personal, and cultural contexts. *Environment* is defined as the complex of external factors, circumstances, objects, and social and cultural beliefs and practices that influence the life of an individual. Context in the OTPF refers to cultural, physical, social, personal, spiritual, temporal, and virtual aspects of living.

Similar to the OTPF, the OFM model assumes that context and environment surround and permeate all levels of the occupational functioning hierarchy. But the OFM distinguishes between the greater influence of context and environment at the higher levels of the hierarchy and the lesser influence at the lower levels. At the lower levels, the immediate physical and personal contexts influence the actions. For example, organization of a reaching movement was shown to differ when actual, natural objects and utensils were used versus when simulated objects were used (Ma, Trombly, & Robinson-Podolski, 1999; Wu et al., 1998). Cultural and social contexts pertain less to this level. At the higher levels of activities, tasks, and roles, however, all aspects of context—personal, social, cultural, temporal, and physical—interact with the person's abilities to yield occupational functioning for the particular person. Figure 1-1 depicts these ideas within the limitations of two-dimensional representation. Chapters 10 and 35 discuss the influence of personal, social, and cultural contexts on occupational functioning, and Chapters 11 and 36 discuss the influence of physical context.

When the challenges of the environment exceed the capabilities of a person, that person is said to be disabled (Institute of Medicine, 1997). A person with impaired abilities and capacities, however, may be able to accomplish activities and tasks of his or her roles if the environment is adapted to enable that. Therefore, occupational therapy treatment may focus on changing the environment or context rather than on remediating the person's impaired abilities or capacities.

THE PROCESS OF OCCUPATIONAL THERAPY FOR PERSONS WITH PHYSICAL DYSFUNCTION

The process of occupational therapy follows the universal plan for problem solving: identify the problem, intervene, and evaluate the result. The occupational therapist, however, focuses only on problems related to the person's occupational life. What a person needs to do, wants to do, and can do are identified. Discrepancy between what the person needs or wants to do and what he or she can do identifies the problem. The occupational therapist then uses various occupational, adaptive, and adjunctive therapies to intervene. The processes of the OFM and the OTPF are similar (Table 1-3). A more thorough discussion of the OFM process follows.

Table 1-3. The Process of Occupational Therapy

Process	OFM	OTPF (AOTA, 2002)
Goal of Therapy	Satisfactorily engage in self-identified, important life roles through which the person gains a sense of self-efficacy and self-esteem	Engagement in occupation to support participation
Evaluation to Identify the Problem(s)	<p>Top down assessment</p> <p>Identify roles, tasks, and activities the person wants to do or needs to do</p> <p>Observe and analyze the person's performance within usual context; identify inadequate performance</p> <p>Identify impaired abilities or capacities that contribute to inadequate performance and assess level of impairment</p> <p>Identify environmental or contextual enablers or hindrances</p>	<p>Do an occupational profile to understand the client's occupational history, patterns of daily living, interests, values, needs, problems with performance, and priorities</p> <p>Do an analysis of occupational performance by observation within context to specifically identify client's assets and problems</p> <p>Identify targeted outcomes</p>
Plan Intervention	<p>Plan in collaboration with the person or family to determine whether the person wants to engage in either:</p> <ul style="list-style-type: none"> Remediation of impaired abilities or capacities to enhance overall performance, or Restoration of occupational performance through relearning and/or adaptation of method or environment <p>Establish short-term goals that directly relate to the long-term goal of successful role functioning identified by the patient</p> <p>Select interventions that have evidence for effectiveness for the immediate goal</p>	<p>Develop plan with the client to guide action</p> <p>Base therapy on theories, frames of reference, and evidence</p>
Implement the Intervention	<p>Utilize therapeutic mechanisms</p> <ul style="list-style-type: none"> Occupation Occupation-as-end to restore occupational functioning Occupation-as-means to optimize abilities or capacities Therapeutic rapport Learning/relearning <p>Utilize adjunctive therapies to facilitate performance</p> <p>Modify contexts and environments to facilitate performance</p>	<p>Act to influence and support improved client performance of targeted outcomes</p> <p>Monitor and document client's response</p> <p>Review the progress toward targeted outcomes and the intervention plan</p>
Evaluate the Result	<p>Determine whether the targeted outcomes were achieved</p> <p>Determine whether the person was satisfied with his or her achievement</p> <p>Plan for future therapy or referral</p>	<p>Determine success in achieving targeted outcomes</p> <p>Plan future action with client</p> <p>Evaluate the program</p>

Assessment

The hierarchical organization of the OFM indicates that higher level occupational functioning is established on a foundation of abilities and capacities. Assessment *always* follows a top-down approach. That is, the therapist determines what roles and tasks the person was responsible for in life before the accident or disease and what the person is expected to be and wants to be responsible for in post-rehabilitation life, including the context in which the person typically engaged in these valued roles and tasks (Coster, 1998; Mathiowetz, 1993; Mayer, Keating, & Rapp, 1986; Trombly, 1993, 1995). The *Role Checklist* (Baris, Oakley, & Kielhofner, 1988; Oakley et al., 1986), the *Canadian Occupational Performance Measure (COPM)* (Carswell et al., 2004; Law et al., 1998), and the *Client-Oriented Role Evaluation (CORE)* (Toal-Sullivan & Henderson, 2004) are assessments the therapist may use to gather this information. The therapist may also measure the patient's sense of self-efficacy concerning ability to do the tasks required to fulfill particular roles by having the patient assign a number on a visual analog scale that ranges from 0 (not at all confident) to 10 (absolutely certain) for each major task that defines a specific role (Gill et al., 1994). For example, "on this scale from 0 to 10, how confident are you that you can prepare your own lunch without help?" One such assessment is the *Self-Efficacy for Functional Activities (SEFA) Scale* (Resnick, 1999).

When evaluating a patient's competence to accomplish the roles he or she identified as important, the therapist observes the patient attempting to do the tasks and activities of those roles in the most familiar context. The *Assessment of Motor and Process Skills (AMPS)* (Fisher, 2003), the *Klein-Bell ADL Scale* (Klein & Bell, 1982), and the *Barthel Index* (Mahoney & Barthel, 1965; Tennant, Geddes, & Chamberlain, 1996) are examples of observational assessments of tasks and activities. Using an assessment that structures observation of performance and having knowledge of the probabilities established by the diagnosis and age of the person, the therapist detects which of the myriad abilities and capacities assumed to be related to accomplishment of these activities are impaired (the process of **activity analysis** applied to assessment; see Chapter 13) and assesses these abilities and capacities more directly. For example, if the patient's goal is to shave with an electric razor but he appears to lack the grasp strength and endurance to do so, strength and endurance are assessed according to the procedures described in Chapter 5. A person whose abilities and capacities are found deficient may be treated to optimize them, allowing not only shaving but other occupations.

Also to be considered as part of the assessment is whether the environment enables or hinders occupational functioning. Assessments of the home environment have been developed (e.g., *Safety Assessment of*

Function and the Environment for Rehabilitation [SAFER] [Chui et al., 2002] and *Home Occupational-Environmental Assessment [HOEA]* [Baum & Edwards, 1998]), but assessments of other environments have not yet been developed (Letts, Baum, & Perlmutter, 2003). To assess the effects of other physical and social environments typical for the patient on occupational performance, the occupational therapist needs to observe performance under those conditions.

Treatment

Treatment may focus on changing the environment, changing the impaired skills and abilities of the person, or teaching compensatory ways to accomplish activities and tasks. Treatment to improve occupational functioning, then, may start toward the bottom of the OFM hierarchy, focusing on optimizing abilities and capacities; or it may start higher, at the activity level of the hierarchy, focusing on restoring competence in doing the activities and tasks of valued roles that the patient has identified as concerns; or it may start peripheral to the person, focusing on modifying the context or environment. The starting point should acknowledge the problem that the patient has identified as an immediate concern, although treatment may not actually start there. For example, if the patient identified resuming fishing as the goal, the therapist may choose to teach adaptive methods to enable that. If, however, in the experience of the therapist it would be more effective to start treatment by regaining finger dexterity to enable various activities related to fishing (e.g., baiting the hook and removing the fish from the line), the therapist must help the patient understand how treatment of this lower-level ability addresses the stated concern at the task level. In addition, the therapist must ensure carryover of any gained dexterity to the fishing task. Optimizing impaired abilities and capacities is accomplished through remedial therapy in which a change in physiological structure, function, or organization is sought through using occupation-as-means. If remediation of deficit abilities or capacities does not restore occupational functioning, or if economic constraints prevent such thorough treatment, or if the patient is not committed to the extensive work required to recover abilities and capacities, a degree of competence can be restored using **adaptive therapy**. Adaptive therapy seeks to find and promote a balance among the person's goals and environmental demands and his or her current capacities and abilities (Thoren-Jonsson, Moller, & Grimby, 1999). In this type of therapy, the method of doing an activity may be modified, assistive technology may be used to enable completion of the activity, and/or the physical or social environments may be modified. The person may be counseled to reassess the need to accomplish a particularly difficult activity alone and opt to employ another to do it.

Optimizing Abilities and Capacities

It is believed that remediating impaired sensorimotor, cognitive, perceptual, and emotional capacities and abilities to as high a level as a person's organic substrate allows will enable versatile performance of activities. Versatile performance allows the person to adjust to changes in the social and physical environments, whereas if a person learns only one compensatory response, adaptation to new situations is less likely. As in the typical development of these capacities and abilities, therapy engages the patient in circumscribed encounters with the environment using occupation-as-means. Using the example of the man who wanted to shave, the therapist might start treatment by providing a cuff to hold the razor to eliminate the need for grasp (adaptive therapy) and let the patient shave as much as he could. Then the occupational therapist would finish the activity. Day by day, the patient's endurance for shaving would increase, and he would do more of the task on his own (occupation used as a means of remediation). Concurrently, the therapist would engage the patient in other activities that require grasp strength until the patient was able to hold the razor.

Occupation-as-means, that is, activities that provide stretch of soft tissues, active or passive movement to preserve and restore full range of motion, resistance and other stress to strengthen weak muscles, or graduated, increasing levels of aerobic exercise to improve endurance, is used to optimize motor abilities and capacities. The evaluation and intervention techniques for optimizing abilities and capacities are described in Chapters 5, 13, and 21; adjunctive therapies that support this approach are discussed in Chapters 16 and 20; and the application of the approach, in combination with complementary approaches, is illustrated in Chapters 41 to 47. When impairment of the CNS results in the inability to move voluntarily to effect a desired change in the environment, a therapist may use sensory input and developmental postures (augmented maturation) to facilitate change in sensorimotor organization. Or the therapist may use motor learning principles to bring about change in voluntary movement behavior and thereby improve the overall functioning of the client. Two approaches apply motor learning principles and methods to treatment of persons with CNS impairment. These are the Carr and Shepherd *Motor Relearning Programme for Stroke* (1983, 1987) (see Chapter 23) and the task-oriented approach described by Horak (1991) and Bass Haugen, Mathiowetz, and Flinn (see Chapter 22). Both approaches emphasize motor performance using functional tasks, include remediation of performance components and modification of the environment to improve task performance, and stress practice that fits the nature of the task. Both approaches heed the research findings on the effect of context on the organization of movement, which indicate that practicing a skill under simplified, non-context-specific conditions is different

from practicing with an actual object in a context-specific situation (Mathiowetz & Wade, 1995; Trombly & Wu, 1999; Wu et al., 1998). Other approaches use techniques such as controlled sensory input to affect motor output and ontogenetic or recovery-based developmental postures or patterns for both assessment and treatment. The approaches share the idea of the importance of the need for repetition. They emphasize the development of basic movements and postures and assume that when movement is "normalized," skilled movement and occupational performance will occur. The approaches of Bobath, Brunnstrom, Rood, and PNF (proprioceptive neuromuscular facilitation) are described in Chapters 24, 25, and 26.

Restoring Competence

Restoration of occupational functioning depends on developing competence in the valued tasks and activities of the patient's life roles. Competence in tasks and activities is synthesized through successful engagement with the environment. Occupational therapists are skilled in developing graduated encounters with objects and the surrounding physical and social environments to promote successful performance. They are also expert in teaching compensatory methods to accomplish activities. Some therapists use this approach exclusively (Mayer, Keating, & Rapp, 1986). Others believe that first optimizing the impaired abilities and capacities requires less compensation and produces more versatility of performance. There is no research to support one point of view over the other.

When activity, task, and role levels of the OFM are dysfunctional, treatment may aim at making people as independent as possible in spite of any residual impairment. If people must live with an impairment that decreases independent functioning, the occupational therapist will concentrate on helping them find ways to compensate by reorganizing activity patterns or adapting techniques, equipment, or the environment. The goal is independence. People are considered independent when they perform tasks for themselves using assistive equipment, alternative methods, or adapted environments, as required, or when they appropriately oversee completion of activities by others on their own behalf (Moyers, 1999).

Interventions to restore competence in tasks and activities are compensatory. They focus on environmental or contextual modification and on teaching physical, cognitive, and emotional adaptation. The therapist teaches the patient to recognize and use remaining abilities in adapted ways and teaches the principles and concepts of adapted methods so that the person can become an independent problem solver. Therapeutic mechanisms of change include occupation-as-end, teaching-learning, and therapeutic rapport. The assessment and treatment procedures for restoring role performance are described in Chapters 4, 10–15, 18, 19, and 30–37.

CASE

EXAMPLE

Application of the OFM to a Patient with Spinal Cord Injury

Occupational Therapy Process	Mr. J is a patient with spinal cord injury (see Chapter 43 for a description of this condition, including special circumstances such as tenodesis grasp).	Clinical Reasoning—Examples of Therapist’s Internal Dialogue
<p>Obtain Information About the Patient</p>	<p>Diagnosis: fracture/dislocation of C 6–7 of his spine in a diving accident. Status post cervical fusion and laminectomy; medically stable. He exhibits C6 functional level.</p> <p>Interview: Mr. J is 24 years old, a college graduate, who lives with his parents in a second-floor apartment in a small city. He has four older siblings who are all married. He has many friends.</p>	<p>He can become independent in self-care and other tasks and activities important to him if he’s willing to work hard.</p> <p>He will have to relocate to a first-floor apartment or to a building with an elevator. This needs to be discussed soon and a referral made to Social Services.</p> <p>His sociability should make developing rapport with him easy.</p>
<p>Evaluation to Identify the Problem(s)</p>	<p>Interview: In addition to his role as independent person, Mr. J identified self-advancement and self-enhancement roles of worker and sportsman.</p> <p>Mr. J’s worker role was that of computer programmer. The company is holding his job for him. Keyboarding is the major physical task of this role.</p> <p>Swimmer, basketball player, camper, and friend are his major self-enhancement roles. The family is supportive, but they expect Mr. J. to be independent in self-care, with the prospect of resuming work, at discharge.</p> <p>Assessment: The therapist observed Mr. J’s attempts to accomplish the tasks and activities associated with the independent person role and found him dependent in all basic self-care. The therapist noted that he was unable to move his lower limbs, that his upper extremities were weak, and that he was unable to grasp.</p>	<p>Mr. J values his roles as independent person, worker, friend, and sportsman. He appears ready to work to regain those roles.</p> <p>Although he cannot do keyboarding now because of paralysis of his fingers, he should be able to resume his job with adaptations and reasonable accommodations. But he also needs to regain ADL independence and commuter activities and skills to do so.</p> <p>Because of the paralysis, he will need to learn adaptive methods of resuming his sports interests.</p> <p>There is no need to evaluate any other activities until he can do basic self-care activities. It will only be frustrating for him.</p> <p>I am going to introduce him to Mr. L who has a similar disability and who is nearing discharge after gaining many skills and resuming several of his roles. It will let Mr. J see the possibilities for recovery of his own roles.</p>

Evaluation to Identify the Problems (cont'd)	<p>She measured Mr. J's strength and found that the proximal upper extremity musculature rated 4 to 5, with the exception of the triceps, which graded 2 (see Table 5-1, which describes muscle strength grading). Wrist extensors graded 3+ on the left and 4- on the right; wrist flexors and finger and thumb muscles graded 0 bilaterally.</p>	<p>He will need to learn adaptive ischial pressure relief methods and how to use tenodesis grasp.</p>
Implement Intervention	<p>During occupational therapy, Mr. J engaged in</p> <ul style="list-style-type: none"> • occupation-as-means to remediate the weakness of his upper arms and wrists; • occupation-as-end and adaptive therapy to learn adaptive ways to accomplish important tasks and activities and to overcome environmental barriers; • group therapy for social, emotional, and practical problem solving; members are other persons with similar activity limitations. 	<p>I am going to use camping activities and simulated basketball shooting among other activities in his program to strengthen his upper extremities, especially his wrist extensors.</p> <p>I need to determine his openness to using adaptive devices. Relearning basic ADL may be embarrassing for him and may precipitate a depression. I need to pay attention to his emotional responses and discuss this with him.</p> <p>He will benefit from others' problem-solving techniques and stories of adjustment challenges and achievements. His stories will help others.</p>
Evaluate the Result	<p>Because of paralysis of his trunk and lower extremities, Mr. J is required to use a wheelchair, which was adapted to allow propulsion without grasp.</p> <p>Mr. J uses gravity, momentum, and leverage to move his body in the wheelchair and on the bed.</p> <p>The proximal upper extremity musculature recovered to normal strength.</p> <p>Because the triceps remained at less than functional strength, he could not elevate himself off the wheelchair cushion. He learned an adaptive method of relieving ischial pressure to maintain skin integrity.</p> <p>Mr. J's wrist strength improved to 4+ bilaterally, which allowed a functional tenodesis grasp.</p> <p>Mr. J showers using a bath bench and hand-held shower head, which he holds using tenodesis grasp.</p> <p>Has learned to manage his bowel and bladder programs.</p> <p>Is able to dress independently using adaptive methods and devices.</p>	<p>Mr. J was successfully rehabilitated.</p> <p>This is so important. I am glad I sent a picture sheet on adapted pressure-relief methods home with him as a reminder.</p> <p>His time to do this will improve with practice.</p>

Evaluate the Result (cont'd)

He keyboards using universal cuffs with typing sticks tipped with rubber ends. His computer is adapted to allow one-key depression for all operations.

His speed will increase with practice.

He plans on resuming work part time (noon to 4 pm).

This schedule will allow enough time for morning care.

He plans on joining the local wheelchair basketball team

Go, Mr. J!

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Treatment Planning for Mr. J

Mr. J has extensive impairments that prevent him from engaging in the activities and tasks of his valued roles. The occupational therapist, in conjunction with Mr. J, must decide what approach to take in treatment. What are the pros and cons of concentrating therapeutic intervention on restoration of activities, tasks, and roles versus remediation of capacities and abilities? From this deliberation, state a goal your treatment might be directed toward. Which treatments would you use to achieve that goal?

SUMMARY REVIEW QUESTIONS

1. Describe the Occupational Functioning Model (OFM).
2. In what ways are the OFM and the Occupational Therapy Practice Framework (OTPF) similar?
3. What is the overall goal of occupational therapy for persons with occupational dysfunction due to physical impairments according to the OFM? According to the OTPF?
4. Using the OFM as your model of practice, what would you assess first in a patient with stroke: level of spasticity of the upper extremity, ADL, or role history and expectations?
5. Define *ability* and *developed capacity*. Give an example of each. To what levels of the OTPF and the ICF do these correspond?
6. Define *task* and *activity*. Give an example of each. To what levels of the OTPF and the ICF do these correspond?
7. What distinguishes occupation-as-means from occupation-as-end?

ACKNOWLEDGEMENT

I am indebted to my co-editor, Mary Vining Radomski, for her contributions to this chapter, and to my family and friends for posing for the photographs.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Recall the origin of the profession of occupational therapy.
2. Identify historical and social factors that affected the development of occupational therapy for physical dysfunction.
3. Describe the historical roots of various tools of occupational therapy practice for physical dysfunction.
4. Identify economic factors that affect occupational therapy service delivery to patients with physical dysfunction.

CHAPTER 2

Historical and Social Foundations for Practice

Pamela Roberts, Sharon Kurfuerst, and Jaclyn Faglie Low

Glossary

Glossary

Adaptive equipment—Equipment designed to help persons with disabilities compensate for functional limitations; equipment ranges from simple, such as a long-handled reacher for those unable to bend over, to complex, such as computerized environmental control systems.

Battle fatigue—See *War neurosis*.

Critical review—a synthesis of published outcome studies concerning a particular topic or intervention in which the strength of the evidence is critiqued and a summary judgment is made concerning whether the evidence supports or negates the use of the intervention under study.

Habit training—A regimen wherein patients hospitalized with mental illness were expected to follow a rigid daily schedule that included responsibility for personal hygiene, making one's bed, and attending treatment sessions at prescribed times; regimens were designed to help patients develop good habits as an aid to restoration of good mental health and for the therapeutic value of work and routine.

Homeopathy—Medical practice based on treating disorders with minuscule doses of substances that produce the same symptoms as the illness.

Hydrotherapy—Use of water as a therapeutic agent; hydrotherapy incorporated both the prescription of drinking water and the use of bathing to treat illness.

Meta-analysis—A statistical synthesis of published outcome studies concerning a particular research question or intervention. Meta-analysis is a set of statistical procedures for comparing and combining results from different studies (Rosenthal & Rosnow, 1991). The outcome of the meta-analysis expresses the effect of the intervention being studied in statistical terms and may also allow an estimate of the degree of relationship between the treatment and the outcome.

Moral treatment—Treatment approach for mental illness that focused on work as a therapeutic agent rather than restraint and isolation.

Neurorehabilitation—Treatment approach for persons with central nervous system dysfunction; uses specific sensory input to influence motor responses.

Orthotics—External devices fitted to specific body parts to support the body part, immobilize the body part, or facilitate movement of the body part.

Physical agent modalities—Those modalities that produce a biophysiological response through the use of light, water, temperature, sound, electricity, or mechanical devices (AOTA, 2003). Physical agent modalities are preparatory or adjunctive methods to enable a person to engage in activities and tasks of valued roles.

Prospective Payment System (PPS)—A system to pay for Medicare services based on criteria set by the government.

Purposeful activity—Activity used as treatment that is goal directed and that the patient perceives as meaningful or purposeful.

Rehabilitation—An approach to treatment for the person who has a permanent disability; focuses on training in the use of special equipment or techniques to facilitate independence rather than on remediation or correction of underlying deficits.

Third-party payer—A public or private organization that pays for or underwrites coverage for health care expenses. The client and the health care practitioner are considered the first and second parties.

War neurosis, battle fatigue—Physical and emotional responses to combat experiences.

Work hardening—Treatment program aimed at returning the injured worker to productive activity through a structured, interdisciplinary program of increasing endurance, work tolerance, and improved body mechanics.

Work therapy—Work activity with primary purpose of therapeutic benefit rather than productivity.

Occupational therapists today are concerned with their patients' abilities to resume life roles upon discharge from abbreviated hospital stays. Occupational therapists in earlier times questioned whether patients would assume vocational and other responsibilities after prolonged hospitalizations. Although the specific details of the questions have changed over time, the fundamental character of questions about the practice of occupational therapy is the same. How can we best prepare our patients to return to appropriate life roles after a life-changing illness or injury? What are the appropriate tools of practice? How do economic and social constraints affect our practice?

The roots of contemporary concerns are discernible in the experiences of our forebears. This chapter explores the social and historical foundations of physical disability

practice, beginning with an introduction to the founders of the profession. The chapter also addresses the economic factors that have placed constraints on the delivery of occupational therapy services in the United States in the latter years of the 20th century and continuing into the 21st century. Finally, this chapter reviews the origins of common interventions used in practice.

ACTIVITY AS THERAPY—ORIGINS OF OCCUPATIONAL THERAPY

Occupational therapy is based on the belief that **purposeful activity** (occupation) prevents or mediates dysfunction of physical or psychological origin. Writings

attributed to Hippocrates, Galen, and Aesculapius proclaimed exercise, activity treatment, and employment as important therapeutic agents. Centuries later, physicians in European asylums for the insane instituted **work therapy** for inmates. They noted that lower-class patients who were required to perform work tasks while incarcerated recovered more quickly than did idle upper-class patients. The value of physical activity and productive work was central to the **moral treatment** advanced by the French physician Phillipe Pinel in the 18th century and the Tuke family in 18th- and 19th-century England. Moral treatment is the philosophical root of occupational therapy (Bockhoven, 1971; Weinstock-Zlotnick & Hinojosa, 2004).

Ideas about the healthful value of activity were transported to colonial America. Fitness was considered necessary for optimal functioning in occupational roles determined by age, gender, and socioeconomic class. The first hospital chartered in Great Britain's North American colonies included as part of its equipment and supplies spinning wheels, wool, and flax for use by patients. Dr. Benjamin Rush, a signer of the Declaration of Independence, wrote to the managers of the Pennsylvania Hospital in 1797 and again in 1813 in support of the therapeutic value of work for patients (Dunton, 1917).

Attitudes in the United States changed as immigrants with different values and habits swelled the population of the asylums. Mental illness was seen as a permanent condition for which little could be done except to lock the sufferer away. Thus, the use of activity as therapy in institutions for the mentally ill lay dormant for decades. Dunton (1917) surmised that the decline in work as therapy from 1860 to 1890 was related to the demands of post-Civil War conditions.

Hospitals for the physically ill required work of their patients, with jobs done in the service of the institution rather than for their therapeutic benefit. As their recovery progressed, female patients were given the task of caring for sicker patients. In New York City's Bellevue and Charity hospitals, jobs for women required sewing; those for men called for maintenance skills such as carpentry, cleaning, and even rowing a boat to ferry passengers on a twice-daily schedule (Rosenberg, 1978).

Although 19th-century Americans valued work and activity, especially outdoor activity, as vital to good health, the formal idea of occupation as therapy did not emerge until the late 19th and early 20th centuries. Until the introduction of the germ theory of disease and asepsis, traditional medical care was frequently more harmful than helpful. Emphasis on curing disease through bleeding, blistering, and purging to restore the balance of the body's humors was challenged by sectarian or nontraditional approaches to health care. Health reformers advocated education, regular exercise, dress reform, and dietary restrictions in addition to specific curative practices such as **hydrotherapy** and **homeopathy**.

The Growth of the Profession of Occupational Therapy

Professions are made up of practitioners with special skills, knowledge, attitudes, and shared beliefs. Professions are not created instantaneously but evolve over time and within social, cultural, and economic contexts. Identifiable factors influenced the development of occupational therapy as a profession. These include the personalities and experiences of the individuals who recognized the idea of occupation as therapy and the world in which they lived. The late 19th and early 20th centuries were characterized by changes in the effectiveness and ways of provision of health care and influenced by burgeoning emphasis on the relation between chronological age and appropriate roles in life. These factors helped create the conditions in which the ideas and ideals of the founders could flourish.

The Founders and the Near-Founders

In the first decades of the 20th century, individuals in various fields of endeavor began almost simultaneously to practice and promote the use of occupation as therapy. George Barton, an architect with numerous health problems, was convinced that he could help others with similar problems. He opened Consolation House in Clifton Springs, New York, where he provided education, vocational assistance, and workshop activities for convalescents.

Barton assembled five like-minded individuals (Fig. 2-1) to meet with him in 1917 to establish the National Society for the Promotion of Occupational Therapy, which in 1923, was renamed the American Occupational Therapy Association (AOTA). Joining Barton was psychiatrist William Rush Dunton, Jr., a descendent and namesake of Benjamin Rush. Dunton directed the occupations program at the Sheppard and Pratt Institute in Maryland and wrote a number of books and articles on occupation as therapy

Figure 2-1 Six founders of occupational therapy. (Photograph courtesy of the Archives of the American Occupational Therapy Association, Bethesda, MD.)

and on training nurses to provide occupation. His major works included *Occupational Therapy* (1915), *Reconstruction Therapy* (1919), and *Prescribing Occupational Therapy* (1928). He also co-wrote, with Dr. Sidney Licht, *Occupational Therapy: Principles and Practice* (1950, 1957).

Also present was Eleanor Clarke Slagle. She worked with Dunton at Johns Hopkins in Baltimore, where she developed a program called **habit training** for chronically schizophrenic patients. Slagle later went to Chicago, where she directed the Henry P. Favill School of Occupations until it closed in 1920 (History, 1940). Other founding members were Susan Cox Johnson and Thomas Kidner. Johnson, director of occupations for the New York State Department of Public Charities, wrote a textbook on textiles and spent 2 years as a teacher of arts and crafts in the Philippines (Licht, 1967; Johnson, 1917). Kidner, a London-born architect, was the vocational secretary of the Canadian Military Hospitals Commission and a special adviser to the United States government on problems of rehabilitation (Licht, 1967). Isabel Newton, Barton's secretary, was also present. She later married Barton and worked with him as a teacher of occupations to invalids.

Susan Tracy, born in 1864, graduated from nurse training at the Massachusetts Homeopathic Hospital in 1889. She studied manual arts at Teachers College at Columbia University while working as a private-duty nurse. Tracy taught courses in invalid occupations for nursing students. She incorporated her course material into her textbook, *Studies in Invalid Occupations* (1910). In 1916, she introduced an occupational therapy program for general medicine patients at Michael Reese Hospital in Chicago (*Occupational therapy in the general hospital*, 1917, p. 425).

Although she did not attend the organizational meeting, Tracy was one of the five directors of the society listed on the certificate of incorporation. Peloquin (1991) referred to Tracy and Herbert J. Hall as near-founders because of their influence on the profession. Hall was the director of Devereux Mansion in Marblehead, Massachusetts, where he established an experimental workshop.

Rationales for Occupation as Therapy

The early practitioners of occupational therapy validated the idea of occupation as therapy in various ways. Barton emphasized the scientific aspects of occupational therapy in a speech presented at the First Consolation House Conference (March 15–17, 1917). The speech, entitled “Inoculation of the Bacillus of Work,” used numerous medical metaphors, including preparation of the patient, the occupational diagnosis, occupational “applications,” “hypodermics,” and “lumbar punctures” (Barton, 1917). Barton compared occupational dysfunction with medical conditions and interventions. He referred to certain occupations as hypodermics, to be used, in his words, “where superficial stimulation is not sufficient, cases in which one

has to get inside into the blood, or into the muscle itself” (p. 400). For even more severe problems, he termed the appropriate curative occupations “lumbar punctures” (p. 400).

Dunton acknowledged the lack of a scientific basis for occupation as therapy (Serrett, 1985) and proposed principles of occupational therapy to imbue the work with greater precision. His principles emphasized that the work be interesting, focused on cure, tailored to the patient's needs, and culminating in a useful product.

Elizabeth Upham, director of the art department at Milwaukee-Downer College, referred to “the modern science of therapeutic occupations for the handicapped” (Upham, 1917, p. 409). Other authors added their views to the debate. An unsigned history of occupational therapy credited Tracy's book *Studies in Invalid Occupation* as “the first attempt to place occupational therapy on a scientific basis” (History, 1940, p. 31). Hall defined occupational therapy as “the science of organized work for invalids” (*Definitions of occupational therapy*, 1940, p. 37). At an organizational level, the National Society for the Promotion of Occupational Therapy emphasized the scientific aspects of practice by selecting engineer and efficiency expert Frank Gilbreth as an honorary member in 1917 (AOTA, 1967).

Adolph Meyer, a Swiss physician, immigrated to the United States in 1892 and worked as a pathologist at the Eastern Illinois Hospital for the Insane. Later, Meyer became professor of psychiatry at Johns Hopkins University in 1921. From his early work, he was concerned with meaningful activity as the core of treatment. Hopkins (1983) indicates that Meyer described “rhythms of life that must be kept in balance even under difficulty. These were work and play, rest and sleep” (p. 6). He had extensive experiences with leaders in the occupational therapy movement including William Rush Dunton, Jr., Eleanor Clarke Slagle, and Henrietta Price. In 1921, Meyer brought together the fundamental concepts of psychobiology and wrote the paper, “The Philosophy of Occupational Therapy.” In this paper, he emphasized occupation, time, and the productive use of energy with psychobiology interwoven (Meyer, 1977), contributing significantly to the identification of the core tenets of occupational therapy practice.

The Professional Literature

The directors of the National Society for the Promotion of Occupational Therapy selected the *Maryland Psychiatric Quarterly* as its official periodical. *The Modern Hospital* also carried information on occupational therapy. Articles focused equally on physical rehabilitation and mental illness, with authors emphasizing returning people to productive lives. In 1915, *The Modern Hospital* began featuring a monthly column, “Occupational Therapy, Vocational Re-Education and Industrial Rehabilitation.”

A new journal, *Archives of Occupational Therapy*, appeared in 1922. Dunton owned and edited it as well as the *Maryland Psychiatric Quarterly*. *Archives of Occupational Therapy* was renamed *Occupational Therapy in Rehabilitation*. When he retired in 1947, Dunton attempted to transfer ownership of *Occupational Therapy in Rehabilitation* to the American Occupational Therapy Association, but the publisher, Williams & Wilkins, owned the copyright to the journal name and its contents (Bone, 1971). The American Occupational Therapy Association began publication of the *American Journal of Occupational Therapy* in 1947.

The founders and the near-founders contributed to the developing body of knowledge by writing books, many of which became required textbooks. Among them were *Studies in Invalid Occupation: A Manual for Nurses and Attendants* and *Rake Knitting, and Its Special Adaptation to Invalid Workers* by Susan E. Tracy, Dunton's *Occupational Therapy: A Manual for Nurses*, and Barton's *Occupational Nursing: How the Installation of Invalid Occupation Work in Institutions Will Affect the Nursing Profession, and a Practical Example of Its Therapeutic Value* and *A View of Invalid Occupation: An Explanation of the New Idea of Providing Convalescents with Occupation* (Textbooks required, 1920). Additionally, Willard and Spackman's *Occupational Therapy*, first published in 1947, serves as a core text for occupational therapy students and provides a comprehensive overview of the profession from historical perspectives to the value of research.

The first edition of this textbook, *Occupational Therapy for Physical Dysfunction*, written by Catherine Trombly and Anna Deane Scott (1977), was the first textbook specifically written to address specialty practice of occupational therapy for persons with physical disabilities. Since then, numerous textbooks have been written for all aspects of occupational therapy practice.

HISTORICAL AND SOCIAL INFLUENCES ON THE DEVELOPMENT OF THE PRACTICE OF OCCUPATIONAL THERAPY FOR PHYSICAL DYSFUNCTION

Social changes and historical events in the late 19th and early 20th centuries created an environment that fostered the development of occupational therapy for physical dysfunction. Among the social changes were changes in the organizational structure and role of the hospital, the study of human development, the increasing effectiveness of traditional medical care, the professionalization of health care providers, and the independent living movement. The First and Second World Wars provided impetus to train women to provide occupational therapy to the wounded soldiers.

The Development of Hospitals

For centuries, hospitals existed only as institutions of refuge for those without family members to care for them during illness. Little emphasis was placed on curing because there was often little that could be cured. From 1870 to 1910, two factors operated to change the role of the hospital. First, people moved to the cities in response to industrialization and thus were cut off from family support systems. Second, the introduction of aseptic techniques and anesthesia made surgery not only effective but survivable. According to Starr (1982), “The reconstitution of the hospital involved its redefinition as an institution of medical science rather than of social welfare, its reorganization on the lines of a business rather than a charity, and its reorientation to professionals and their patients rather than to patrons and the poor” (pp. 147–148).

Within the hospital, divisions of labor developed to increase efficiency. Hospitals “projected ideals of specialization and technical competence” (Starr, 1982, p. 146). Patients no longer provided their own care. Nursing as a profession emerged within the hospital setting. The population of hospitalized patients shifted from the poor to the middle class.

During the late 19th century, hospitals offered training programs for nursing students. Students did the ward work. Most nurses left the institution for private-duty work after graduation. Middle- and upper-class patients convalesced at home under the care of the hospital-trained professional nurse. By the end of the 1930s, however, the cost of private-duty nursing was prohibitive for most middle-class families (Melosh, 1984). These patients moved to hospitals for care.

Patients in hospitals of the late 19th and early 20th centuries had to work to keep the hospital functioning, so there was no place or time for occupation as therapy. Professional nurses who provided convalescent care in the home may have offered, as did Susan Tracy, invalid occupations to clients, but that was a matter of individual circumstance. It was not until hospitals became curative centers for middle-class patients that there was a place for occupational therapy.

In the mid-20th century, occupational therapists working in general hospitals dealt with a variety of diagnostic categories. Fay and March (1947) discussed grading downward for patients with neurosyphilis, a degenerative disorder, grading from large to fine movements to increase coordination for persons with hemiplegia and paraplegia, adapting activities for persons with Parkinson's disease, and focusing on muscle reeducation and avoidance of fatigue for persons with poliomyelitis. Their description of recommended management of patients with burns will be familiar to contemporary therapists: “the first object . . . is to help overcome the secondary stiffness resulting from immobilization” (p. 135). Therapists were advised to stretch contractures gently and gradually, “since

the scar tissue and the new skin are sensitive and must not be torn or irritated” (p. 135). Rumsey’s (1946) description of the occupational therapy principles for the treatment of peripheral nerve injuries mandated that the involved joint be kept flexible, that involved muscles be contracted and relaxed, and that the treatment plan incorporate both permanent and temporary compensatory techniques and equipment.

Emphasis on Human Development

Another influence on the development of occupational therapy practice was the introduction of concepts about the timeliness of life events. Kern (1983) identified the introduction of standard time, which occurred at the end of the 19th century, as the event that set the stage for emphasis on the temporal aspects of human development. Spokespersons in popular and professional journals began to delineate the ideal sequencing of a wide variety of experiences (Chudacoff, 1989). Emphasis on accuracy in the measurement of time created a framework in which all activities were categorized as being on time, ahead of time, or behind time. This set the stage for theories outlining appropriate times for important life events. Neugarten, Moore, & Lowe (1968) characterized the powerful influence of ideas about age- and stage-related behaviors thus: “There exists what might be called a prescriptive time-table for the ordering of major life events: a time in the life span when men and women are expected to marry, a time to raise children, a time to retire” (p. 22).

Although the study of stage theories of human development was not a part of the preparation of the founders or the early occupational therapists, implicit in the belief systems of the founders of occupational therapy was the idea that role and activity have age and stage specificity. From the beginning, occupational therapists formulated goals that focused on occupational function and selected treatment activities based on “the relation of the age, sex, interests, physical and mental limitations of the patient to the occupation selected” (Occupations for Invalids, 1916).

Historical Events that Influenced the Profession of Occupational Therapy and the Professionalization of Health Care Providers

Just as humans must adapt to various environments and challenges as they pass through the stages of life, so must professions adapt. Several significant periods in the history of occupational therapy practice influenced the profession and practitioners in significant ways. Among them are the two world wars and the period between them.

The rapid growth of occupational therapy was credited in part to World War I (Gutman, 1995). The reconstruction aides were civilian women appointed to help in

Figure 2-2 Craft activities were used in the treatment of military casualties. (Department of the Army. [1951]. *Occupational therapy*. Department of the Army Technical Manual TM 8-291, p. 8. Washington, DC: U.S. Government Printing Office.)

therapeutic efforts for servicemen suffering from **battle fatigue, war neurosis**, or war-related injuries. The occupational therapy reconstruction aides used craft activities that were carefully selected to meet each patient’s physical and psychological needs (Fig. 2-2). The work of one reconstruction aide, Ora Ruggles, is recounted in *The Healing Heart* (Carlova & Ruggles, 1946). The first reconstruction aides sent to France during World War I were stationed near the front lines and were charged with returning to duty as quickly as possible men suffering from war neurosis (Low, 1992). In the postwar years, the concern was for return to productive employment.

Women were selected for training and service as reconstruction aides on the basis of proficiency in a variety of crafts. Although training courses included psychology, specific handicapping conditions, the history of occupational therapy, and hospital etiquette, the use of crafts remained the focus (Emergency Course of Instruction for Reconstruction Aides, n.d.). An Army medical department circular dated March 27, 1918, described the job and the qualifications for appointment: “trained women to furnish forms of occupation to convalescents in long illness . . . to give to patients the therapeutic benefit of activity . . . She shall have a High School Education, or its equivalent.” In addition to the educational requirement, applicants were required to be accomplished in at least three crafts, including basketry, weaving, wood carving, block printing, and needlework.

The seriousness of purpose of occupational therapy was subject to question because the providers of occupational therapy were women and their primary tools were craft activities and their own personalities. Colonel Frank Billings (1918) of the Office of the Surgeon General characterized the work of the reconstruction aides

“as diversional in character, in the form of knitting, in the form of basket weaving, etc.” (p. 1925). He contrasted it with “more purposeful” activities that would serve “training of the soldier for employment after his discharge from the Army” (p. 1925).

This differentiation between women’s work and men’s work culminated in a distinction between bedside activities and vocational activities. Prolonged engagement in bedside activities provided by women reconstruction aides was criticized as promoting dependence and invalidism (Sexton, 1918). Vocational activities conducted by male vocational teachers prepared the men to return to economic productivity.

Following the armistice, many of the short training courses for reconstruction aides that had sprung up in response to the war emergency effort closed. Most of the reconstruction aides returned to civilian life and their former occupations of teacher, artist, or artisan. Some remained as occupational therapists employed in Veterans Bureau hospitals or public health service facilities. Although the reconstruction aides did not have military status during their service time, they were allowed to apply for credit for service time toward civil service appointments (Low, 1992).

Opportunities for occupational therapists working with the civilian population grew with the passage of the 1923 Federal Industrial Rehabilitation Act, which mandated that hospitals providing care to persons with industrial injuries or illness include occupational therapy as “an integral part of its treatment” (AOTA, 1967, p. 10). This did not immediately result in a greater number of occupational therapists working with patients with physical disabilities. In 1937, nearly 80% of occupational therapists worked in mental health settings (Reed & Sanderson, 1983).

The outbreak of World War II increased the demand for occupational therapists to care for wounded servicemen. Occupational therapy literature is replete with descriptions of programs in military hospitals. The activities and equipment described confirm emphasis on remediation of specific physical problems. Vetting (1945) described the equipment and activities of the occupational therapy clinic at the U.S. Naval Hospital at Bethesda: “A large carpentry shop . . . primarily for activities . . . to increase joint motion and muscle strength [Fig. 2-3] . . . will include workbenches designed specifically for patients who must work at shoulder height, adjustable workbenches to be used by patients who need to improve their posture . . . a height comfortable for the wheelchair patients” (p. 134). Other activities described were “Clay modeling . . . for increasing joint motions of the hands . . . floor looms adapted for shoulder and back exercise [Fig. 2-4]” (Vetting, 1945, p. 135). A report on the Naval Hospital at Jacksonville, Florida, described the use of bicycle saws (Fig. 2-5, A & B), bicycle lathes, and foot treadle looms to strengthen lower extremities (Egan, 1945).

Figure 2-3 So-called purposeful activities, such as this sanding activity, were used to restore range of motion and strength of the upper extremities because they lent themselves to adaptations to achieve graded exercise. In truth, they were not meaningful to the patient, and therefore, today, would be considered poor therapy.

As its history evolved, the profession of occupational therapy developed and identified professional models to guide both service provision and research. In the late 1960s, Reilly (1969) challenged the field to distinguish occupational therapy and its purposes from medicine and to build a knowledge base that would support therapeutic

Figure 2-4 Floor loom adapted with weights and pulleys to resist elbow extension. The adaptations could be changed to resist back muscles or arm flexor muscles.

use of occupation. A number of professional models have evolved following this challenge. These models address assessment practices and intervention, reflect on interactions between therapists and clients, and consider these issues in the broader contexts in which the individual, family, and important occupations exist and evolve over time.

Occupational Therapy and Rehabilitation— Challenge to Professional Autonomy

Rehabilitation became a recognized medical specialty in World War II. Although the idea of helping people with handicapping conditions to become productive and useful citizens was evidenced earlier by establishment of curative workshops, histories of rehabilitation link its development not to treatment through activity but to physical medicine. The latter approach developed during the years between the world wars and encompassed uses of “physical and other effective properties of light, heat, cold, water, electricity, massage, manipulation, exercise, and mechanical devices for physical and occupational therapy in the diagnosis or treatment of disease” (Berkowitz, 1981, p. 531).

The first department of physical medicine in an American medical school was established during the 1920s at Northwestern University (Berkowitz, 1981). In 1936, the establishment of a certifying board in physical medicine was proposed before the Advisory Board of Medical Specialties. It was not approved until 1947. By 1949, 234 physicians identified themselves as specialists in this area (Stevens, 1971). Although the two specialties were not identical, the overlapping domains of physical medicine and rehabilitation resulted in the creation in 1948 of a new medical specialty board, the American Board of Physical Medicine and Rehabilitation (Stevens, 1971).

As an Army Air Force physician, Howard Rusk “received orders to minimize his patients’ hospital stays and to return as many people to combat as possible” (Berkowitz, 1981, p. 532), which is reminiscent of the orders under which the reconstruction aides acted. Rusk aimed to establish convalescent centers where the wounded would be sent when their conditions stabilized sufficiently for them to leave acute care and engage in programs of reconditioning and vocational guidance. Rusk and his colleagues envisioned rehabilitation centers serving the special needs of military and civilian patients: “Unlike a general hospital, a rehabilitation clinic could contain the

special facilities needed to train a paraplegic to go up and down a curb or to manipulate a wheelchair” (Berkowitz, 1981, p. 536). Occupational therapists were seen as “an important adjunct in the treatment and early recovery in injury and disease; and [occupational therapy] has an extremely important role in the modern concept of total rehabilitation” (Samberg, 1947, p. 290).

Poor relationships and communication between the physiatrists and vocational rehabilitation agencies slowed the initial growth of rehabilitation centers. In addition, territorial disputes with orthopedic surgeons caused problems. To solidify their place in the health care arena, the physiatrists attempted to assume control of both the registration of occupational therapists and the standards and structure of occupational therapy education. From 1943 through the early 1950s, the board of managers of the American Occupational Therapy Association resisted their efforts. Although successful in retaining professional autonomy, the board of managers and others in leadership positions within the association chose to avoid publicizing the actions of the physiatrists and their responses. They feared many of the rank and file occupational therapists might support the physiatrists’ position because of positive interactions with physical medicine and rehabilitation doctors in military health care (Colman, 1992).

Friedland (1998) proposed that occupational therapists did in fact align themselves with rehabilitation medicine and abandoned commitment to the value of occupation in favor of reductionistic goals of increasing joint range of motion and muscle strength. This emphasis, however, along with concern for returning persons to economic productivity, was evidenced much earlier in writings that included descriptions of equipment to accomplish such goals when crafts were not sufficient (Hickinson, 1934; Taylor, 1929).

In the Rehabilitation Act of 1973, Section 504 prohibited discrimination on the basis of handicap in programs and activities of the federal government or by recipients of federal financial assistance, including work rehabilitation programs. Persons with disabilities were empowered to engage in valued leisure and work roles. As a result, occupational therapists found a greater need for their services in a variety of settings, most notably those services provided in schools and other educational settings. Around this time, the independent living movement was founded and flourished. Shapiro (1993) considered the independent living movement to be “a new civil rights movement.” The need for occupational therapy again flourished because those with disabilities were in need of the skills necessary for community-based living. This movement and the disability studies movement prompted therapists to think innovatively about their work with persons with disabilities (Frieden, 1976). Emphasis again moved away from treatment of deficit conditions to enabling engagement in valued occupational roles. In 1978, Gail and Jay Fidler discussed the role of

purposeful activity in self-actualization: “Doing is viewed as enabling the development and integration of the sensory, motor, cognitive, and psychological systems; serving as a socializing agent, and verifying one’s efficacy as a competent contributing member of one’s society” (Fidler & Fidler, 1978, p. 305).

In 1986, the National Council on the Handicapped published an assessment of federal laws and programs affecting persons with disabilities that included legislative recommendations. In 1990, the Americans with Disabilities Act (ADA) was signed into law (Smart, 2001). The ADA has five sections including employment, transportation, public accommodations and services, telecommunications, and a miscellaneous section addressing issues such as access to wilderness areas.

TOOLS OF PRACTICE

The evolution of a profession requires practitioners to be open to new tools and approaches, although transitions are rarely smooth. Professional identity may be threatened by methods perceived as radical departures from the early ideals. Incorporation of new techniques or technologies may generate territorial disputes with other professionals.

Work Programs

Work programs were part of the early history of occupational therapy. For many years, sanatoria for the treatment of tuberculosis were major employers of occupational therapists. Patients moved through a graduated regimen from bed rest to light activity to vocational training, a program easily recognizable as **work hardening**.

Work programs for other injuries simulated actual job conditions as much as possible. Goodman (1922) described a work program for industrial injuries: “[the clients] would be in the atmosphere of work all the time” (p. 200). The director of occupational therapy at a curative workshop for orthopedic conditions and industrial injuries reported on the program of physical and occupational therapy: “Our patients report for treatment at 8:00 in the morning, so that they will continue the habit of starting out early, thus making it easier for readjustment to work later on” (Taylor, 1929, p. 337). Concerns about malingering by injured patients are longstanding. Spackman (1947) noted complications arising from industrial compensation programs: “The trouble occurs in instances when it is not financially profitable for the patient to return to work” (p. 227).

More recently, the profession has returned to “work hardening” (Hanson & Walker, 1992) and has incorporated ergonomics into practice (Jacobs, 1999). Many of

the clients seen today in work-hardening programs are laborers or unskilled workers; back injury is the most common reason for referral (Hanson & Walker, 1992). In addition to addressing the reconditioning needed for return to work, occupational therapists are widely engaged in injury prevention programs, using ergonomic and task analysis.

Use of Crafts and Exercise

Although expertise in activity analysis and selecting activities specific to treatment goals has been a hallmark of occupational therapy from the beginning, occupational therapists in many settings were concerned about the adequacy of handicrafts to prepare patients for occupational function. According to an editorial in a 1918 issue of *Maryland Psychiatric Quarterly*, activities used in therapy “may appear trivial” (Occupational aides, 1918, p. 27). Hall (1917), who served several times as the president of the National Society for the Promotion of Occupational Therapy, commented, “The occupations that are employed therapeutically range all the way from work in the service of the institution to virtual play in the construction of rather useless articles of the so-called arts and crafts order” (p. 383).

Practicing therapists recognized the limitations of their traditional approaches. Decrying the scarcity of crafts that required finger extension, Taylor (1929) reported, “Mechanical means are often necessary because of the limitations in occupations” (p. 337). She was equally concerned about activities for lower extremity function: “The problem ahead of us in the use of occupational therapy for functional restoration is to readapt and make jig saws, looms, etc., so that all physical exercises may be obtained through occupations” (p. 337). After describing adaptations of the loom, bicycle saw, and treadle saw for lower extremity strengthening, one director of occupational therapy noted, “As ankle flexion is usually limited, I am going to mention two ways of getting it by mechanical appliances” (Hickinson, 1934, p. 34). The first way was a cot with a pulley at one end. The patient lay on his or her side, and “a band around the patient’s foot is fastened to the cord over the pulley, and a weight attached. Flexion of the foot uses the flexor muscles to pull up the weight, which may be gradually increased” (Hickinson, 1934, p. 34). The second way was described thus: “The foot may be strapped in the ankle circumductor, and the circumductor turned entirely by pulling the foot away from the pedal. [The term circumductor suggests a device that moves the ankle through full circumduction.] The handle is not used except to start. This makes a heavy exercise” (Hickinson, 1934, p. 34). Subsequent attempts at developing equipment for specific muscle patterns included such inventions as the Extensoricisor, which was described as “an apparatus to provide progressive resistive exercises for the

finger extensor muscles” (Heather, Smith, & Walsh, 1962, p. 10).

Mosey (1970) noted that following World War II, “Occupational therapists were uncomfortable with their operating principle that it was good for disabled people to keep active and busy doing the things they enjoyed” (p. 235). Emphasis on crafts gave way to exercise, and practice became specialized. One of the specialized areas was the treatment of patients with poliomyelitis. Treatment, which was based on the work of Sister Elizabeth Kenny, was directed toward maintaining or improving muscle strength and joint range of motion. Exercises and activities aimed at restoring or increasing motion at specific joints required that occupational therapists be proficient in joint measurement. The first volume of the *American Journal of Occupational Therapy* included articles on joint measurement (Hurt, 1947a, 1947b, 1947c) and a printed paper goniometer with directions for cutting it out and assembling it (Goniometer, 1947). Over time, information on specific exercise techniques and equipment appeared in the professional literature.

Gradually, thinking within the profession has shifted from the earlier focus on component level therapy to functional performance, to the nature and experience of occupation within a person’s life (Hasselkus, 2004). This rediscovery of our roots and rethinking of occupation has allowed occupational therapy to view practice beyond the rehabilitation clinic to the home and the community, and to serve clients beyond those with identified deficits to those who may experience occupational dysfunction because of life circumstances (e.g., aging, retirement, locating to a new community) or to groups or communities (AOTA, 2004).

Other professions have begun to see the value of meaningful occupation and are incorporating it into their practices (Basler, 2005), including the process of activity and task analysis, which occupational therapists have claimed with pride as unique to our profession. This trend will influence the profession’s commitment to research and education of the public concerning the profession’s expertise and contributions concerning meaningful activity as a therapeutic agent.

Adjunctive Treatment of Vision and Visual Perceptual Deficits

Historically, several people were instrumental in including remediation of visual perceptual deficits into the practice of occupational therapy. Goldstein (1942) discussed visual spatial problems with brain-injured adults following World War I. Bender, Held, Reitan, Teuber, Werner, and others improved evaluation tools to assess visual spatial organization. Hebb studied the effects of sensory deprivation on normal adults, which showed the problems with thinking and reasoning and visual perceptual difficulties (Heron

& Hebb, 1961). These studies were important for recognizing that organization of sensorimotor processing was necessary for the development of higher cortical functions. During the 1960s and 1970s, Frostig and Horne's visual perceptual programs (1965) were popular in occupational therapy practice for learning disabled children. Kephart's perceptual motor program was also widely used in the education setting (Kephart, 1960). In 1961, Ayres stressed the development of body scheme with emphasis on cognitive, visual training, and tactile and proprioceptive procedures. Ayres also recognized the importance of the vestibular system and its influence on the organization of sensory input, especially the visual system. Occupational therapists today focus not only on visual perceptual deficits but also on the role of vision and how it relates to function in daily activities. Gianutsos (1997) reported that nearly half of persons admitted to rehabilitation after brain injury had visual system deficits. Vision deficits often result in a decreased ability to function in daily activities, which leads to greater reliance on family, friends, and other social systems. Occupational therapists have incorporated the screening and treatment of visual disorders into practice preparatory to restoration of occupational functioning (Aloisio, 1998; Gianutsos, 1997).

Physical Agent Modalities

By the late 1970s and early 1980s, occupational therapists working with patients with physical disabilities began to incorporate other less traditional modalities into their treatments. To facilitate joint and muscle function, they used paraffin baths, hot and cold packs, ultrasound, and electrical stimulation. These approaches and others selected to produce changes in soft tissue were known collectively as **physical agent modalities**.

In 2003, the American Occupational Therapy Association (AOTA) reissued a position paper on the use of physical agent modalities. The techniques in question were labeled as adjunctive modalities (AOTA, 2003, p. 650) to convey that use of these techniques was considered adjunctive or supplemental to purposeful activity in meeting patients' objectives. The position paper mandated that use be restricted to "a practitioner who has documented evidence of possessing the theoretical background and technical skills for safe and competent integration of the modality into an occupational therapy intervention plan" (AOTA, 2003, p. 650).

Because, as late as 1997, a survey of occupational therapists revealed that most users of physical agent modalities had no formal training in either theoretical basis for use or technique (Cornish-Painter, Peterson, & Lindstrom-Hazel, 1997), occupational therapy education programs now incorporate specific instruction in physical agent modalities into their curricula and continuing education opportunities for clinicians are available.

Adaptive Equipment

Adaptive equipment for performing occupation-as-means and tasks and activities of daily living was first described for a patient at Michael Reese Hospital in Chicago. The patient was paralyzed by a gunshot wound. Susan Tracy strapped a polishing pad to the man's right hand and taught him to polish articles placed in front of him by moving his arm. The benefit of this was realized when, as the author reported, "This man had not been able to put anything into his own mouth for 4 months, but, with the aid of a second leather palm [Fig. 2-6] which holds a fork or spoon, he can now feed himself" (Occupational therapy in the general hospital, 1917, p. 426).

Some 30 years later, Haas provided directions for making a knife-and-fork combination (Haas, 1946). Haas published a booklet, *Equipment Aids for Those Having One Hand* (Haas, 1947, p. 1). He recommended the use of clamps, vacuum cups, and clips for stabilizing projects and proposed attaching fine sandpaper to tools to increase friction and prevent slipping (Haas, 1947).

In the years following World War II, much adapted equipment addressed the needs of disabled veterans. An unsigned article in a 1945 *Occupational Therapy and Rehabilitation* issue was illustrated with photographs of aids designed to permit war veterans with amputations to drive. The adaptations were designed by the war engineering board of the Society of Automotive Engineers, and the information was provided to occupational therapists so they could advise their patients (Simple devices enable veterans to drive motor vehicles safely, 1945).

Patients with poliomyelitis had long convalescent periods in which activities were limited by poor endurance and disability. Occupational therapists developed activity programs to provide mental stimulation without overtaxing damaged neuromuscular systems. McFarland and Lukins (1946), respectively a physician and an occupational

Figure 2-6 A universal cuff that holds eating utensils and typing or phone dialing sticks to enable more independent performance of some occupational tasks. This adaptation is still in use.

therapist, described a mouth-stick page turner for patients in respirators and included instructions for fabrication. MacLean (1949) described the development and adaptation of arm slings, lapboards, adjustable tables, and built-up armrests to improve functional abilities. For the next several years, adaptations to meet the needs of patients who had had poliomyelitis were frequently featured in occupational therapy literature.

New products were regularly introduced to occupational therapists in the *American Journal of Occupational Therapy*. A 1952 column of products and techniques included a collapsible reacher for the bed or wheelchair patient (Have you tried?, 1952). In 1969, Lowman and Klinger compiled and classified the extant adapted equipment into one publication that improved the selection and prescription of adapted equipment, although many of the specific devices were still made by occupational therapists. Contemporary occupational therapists have access to extensive, commercially available collections of adaptive equipment for almost every disabling condition. Today's challenges are found in selecting equipment that will achieve the goal and that is reliable, affordable, and acceptable to the patient, both functionally and cosmetically.

Orthotics

Orthotics for upper extremities were an extension of occupational therapists' design and manufacture of adaptive equipment. An article by Slagle (1938) was illustrated with a photograph of a patient identified as having a brachial plexus injury wearing an airplane splint "to rest shoulder muscles" (p. 378). The patient is engaged in an activity identified as Egyptian card weaving with the stated purpose of providing "motion of grasp, wrist and elbow flexion" (p. 378). No indication is provided that the splint is itself part of the occupational therapy program.

Writing on the management of patients with arthritis, Sammons (1945) reported, "Splints are frequently used to prevent flexion deformities of the hands or spinal rigidity in faulty position in rheumatoid spondylitis" (p. 18). The author referred to the use of a cock-up splint for wrist drop, but no information was provided as to whether the occupational therapist was involved in the fabrication or fitting. In a chapter on treating persons with physical injuries, Spackman (1947) referred to a cock-up splint but did not give information on construction, application, or management. Hand surgeon Sterling Bunnell outlined a sequence of care for hand injuries, with occupational therapy initiated once the wound had healed and continuing until the patient was "ready for work" (Bunnell, 1950, p. 148). His article was illustrated with photographs of a variety of commercial splints with an address from which they could be ordered (Fig. 2-7).

Fabrication of orthoses was addressed in 1952. The chief of occupational therapy at the Veterans Adminis-

Figure 2-7 One of Bunnell's splints; this one was called a "knuckle bender."

tration Hospital in Portland, Oregon, reported on the use of plastic to fabricate splints for patients with poliomyelitis. She included principles of a well-designed splint and directions for making several splints, including an opponens cuff and a foot-drop splint (Boyce, 1952). Silverstein (1953) described clinic-made adaptations of several of Bunnell's hand splints. She noted, "It became possible . . . to adapt these splints to fit hands of unusual sizes or peculiar deformities . . . to supply these new splints quickly and at a much lower cost than previously . . . Familiarity with the mechanics of the devices allowed alteration of the splints as the patient's condition improved" (Silverstein, 1953, p. 213).

Neurorehabilitation Techniques

As patients with head injury and stroke achieved higher rates of survival, interest in treating the sequelae of neurological insults developed. In 1948, Berta Bobath's article "The Importance of the Reduction of Muscle Tone and the Control of Mass Reflex Action in the Treatment of Spasticity" was published in *Occupational Therapy and Rehabilitation*. Subsequent writings on the management of adult hemiplegia by the Bobaths appeared in physical therapy journals.

Herbert Kabat, a physician, was among the first to introduce ideas about neuromuscular mechanisms into treatment techniques. In 1950, Kabat and occupational therapist Dorothy Rosenberg described a program aimed at "accelerating the development of voluntary motion in severely paralyzed muscles . . . [by] using reinforcement techniques for guided resistive exercise utilizing primitive mass movement patterns, certain reflexes, synergistic motions, symmetrical bilateral motions, etc." (Kabat & Rosenberg, 1950, p. 6). Patients with a variety of neurological disorders were admitted to the Kabat-Kaiser Institute for medical care, physical therapy, occupational therapy,

and vocational counseling. Physical therapists helped patients establish individual motions before occupational therapists began working on movement combinations necessary for self-care. Carroll studied the efficacy of Kabat's reinforcement techniques in the treatment of hemiplegia. The techniques she used were "(1) the tonic neck reflexes, (2) the stimulation of synergists, (3) the use of resistance, and (4) rhythmic stabilization" (Carroll, 1950, p. 212). Relating inconclusive results to a limited treatment time and interruptions because of medical complications, Carroll recommended that occupational therapists "devise a variety of techniques which are based on these principles and which may lead to better results in the total rehabilitation of the hemiplegic patient" (p. 213).

In the third of a three-part series, "Proprioceptive Facilitation Elicited Through the Upper Extremities," Ayres described the selection and adaptation of "simple, normal, life-like activities" (Ayres, 1955, p. 121) using proprioceptive facilitatory mechanisms. Margaret Rood, trained as both physical therapist and occupational therapist, based her work on use of sensory input to influence motor output. Although she was not a prolific writer, her work influenced occupational therapy education (Cohen & Reed, 1996). Signe Brunnstrom, also a physical therapist, presented her theory and techniques to occupational therapists in a 1961 article, "Motor Behavior of Adult Hemiplegic Patients: Hints for Training" (Brunnstrom, 1961). Subsequent publications by occupational therapists and professionals from other disciplines provided readers further explanations of neuromuscular mechanisms and applications of theoretical information to clinical practice. Street (1963) discussed the theories of Rood, Sherrington, and others and the clinical implications of techniques for inhibiting or facilitating antagonists. In the abstract of her 1968 article, "A New Look at the Nervous System in Relation to Rehabilitation Techniques," Moore said, "More recent concepts concerning learning, plasticity and facilitatory and inhibitory systems in the nervous system are covered" (Moore, 1968, p. 489).

Contemporary research indicates that neurological functions occur concurrently at many levels of the nervous system rather than in the rigidly hierarchical model of earlier theorists. Although new information is increasing its influence on practice, occupational therapists have not discarded the works of these earlier theorists and practitioners. Techniques introduced by Kabat, the Bobaths, Brunnstrom, and Rood are still in evidence in many clinical settings and are included in this textbook.

ECONOMIC FACTORS AFFECTING HEALTH CARE SERVICE DELIVERY

Three interrelated factors affect the delivery of health care service, including occupational therapy for patients with physical dysfunction. These are governmental policies and

laws concerning health care financing, third-party payer reimbursement policies and practices, and the requirement of accountability for effectiveness of service.

Governmental Policies and Laws

Access to occupational therapy services is affected by regulation and reimbursement. According to the Centers for Medicare and Medicaid Services (formerly the Health Care Financing Administration), private insurance funds approximately one third of total health care services, of which 15% is for older Americans (Federal Interagency Forum on Aging-Related Statistics, 2004). Public funds, including Medicare, contribute approximately 54%; Medicaid covers 10% of health care; out-of-pocket costs account for approximately 19%, with another 4% from other funds such as foundations (Healthcare Financing Administration, 1998; Federal Interagency Forum on Aging-Related Statistics, 2004). Managed care organizations or private insurance primarily cover children and adults under the age of 65 years who are not disabled. Depending on state law, those who are injured on the job are frequently covered under workers' compensation. Those who are uninsured may be eligible to apply for state assistance under the Medicaid system or may need to pay privately for health care services. People who are under the age of 65 and are disabled may be able to apply for state or federal assistance. Health care from the Veterans Administration is available for veterans of the United States military service. In 1966, Medicare was enacted as a means of providing health coverage for the elderly (age 65 and older) and the disabled. Older adults who meet eligibility criteria may subscribe to Medicare for their health care benefits or they may receive coverage from a managed care organization or may use a combination of benefits.

In 1983, Congress implemented the Medicare Prospective Payment System (PPS) for acute care hospitals in an effort to contain costs and standardize care. Acute care hospital PPS is based on 490+ diagnostic related groups (DRGs). Since the enactment of the DRGs, temporary exemption has been in effect for rehabilitation hospitals and units, children's hospitals and units, alcohol and drug programs, long-term care, cancer specialty hospitals, and psychiatric hospitals and units. The impact of the DRGs was significant. Hospital lengths of stay became shorter and discharges to all types of post-acute care providers rose. Current Medicare program post-acute care policy is focused on providing care based on types of providers, with the key post-acute care institutional providers being inpatient rehabilitation facilities, skilled nursing facilities, and long-term care hospitals. Each of these sites provides post-acute care to Medicare beneficiaries. The Balanced Budget Act (BBA) enacted (Balanced Budget Act of 1997, section 4421, Public Law 105-33) and mandated PPS for nursing facilities, rehabilitation hospitals and units, and home

health agencies. Skilled nursing was included in the PPS in 1998 that based payment on a per diem allowance. Home health was included in 2000, and payment for that was based per episode of care. Inpatient rehabilitation was included in 2002, and payment was based on per discharge. Psychiatric hospitals and units were included in 2005.

For current occupational therapy practice, regulatory and reimbursement requirements are the basis for service delivery in institutional settings. Services are provided throughout the continuum of care, which may include emergency room, intensive care unit, acute care hospital, transitional care, inpatient rehabilitation, skilled nursing, home health, outpatient rehabilitation, assisted living, day care, inpatient psychiatric care, and long-term residential care. Standards reflect current practices and are administered through regulatory agencies such as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the U.S. Department of Health and Human Services (DHHS), fiscal intermediaries, and the Commission on Accreditation for Rehabilitation Facilities (CARF). Occupational therapy provided in institutional settings is required to adhere to the regulations that serve as guidelines for safety and quality of care. These regulations have specific requirements to which the occupational therapist and occupational therapy assistant must adhere to ensure regulatory compliance and optimize reimbursement. For example, services must be prescribed by a physician and provided under a physician-approved plan of care; services must be performed by a qualified occupational therapist or occupational therapy assistant under the supervision of an occupational therapist; and services provided must be reasonable and necessary for the individual's illness or injury. In addition to these requirements, regulations can also place limits on the amount of therapy intervention, including the amount of time services are provided and the overall length of service provision, requiring the therapist to outline and provide a plan of care within these guidelines.

It is important for occupational therapy professionals to be aware of legislative or regulatory activities that may impact the practice of occupational therapy. For example, yearly in the *Federal Register*, revisions to payment policies under the Physician Fee Schedule are published. These revisions impact reimbursement for health care services including the delivery of occupational therapy.

Influence of the Policies of Third-Party Payers

Third-party payers have had significant influences on the delivery of occupational therapy services. Howard (1991) indicates that “reimbursement policies reflect societal influences and are shaping occupational therapy in several ways. Control has shifted to third-party payers, allowing

them to define occupational therapy; use of the medical model is being rewarded by reimbursement; the language used to discuss the profession has changed to accommodate the insurance and other industries; and values that dominate society are being reinforced” (p. 875). These influences have been most notable in the past 10 years, during which an influx of new health plan products and insurers has been noted (Institute for the Future, 2003).

One of the largest payers of occupational therapy services is Medicare, a federally administered health insurance program for people age 65 and older, those of all ages with end-stage renal disease (ESRD), and those under age 65 with certain qualifying disabilities. Divided into two parts, Medicare A and Medicare B, this program helps to cover inpatient care in hospitals and skilled nursing centers, as well as some aspects of hospice and home health care, and outpatient services, including physician visits and those medically necessary services provided by occupational therapy practitioners (Centers for Medicare and Medicaid Services, 2005b). In 1997, the Balanced Budget Act (BBA) resulted in the most dramatic changes in payment for Medicare services delivered in post-acute care settings ever achieved by a single piece of legislation (Cotterill & Gage, 2002).

As a result of the BBA, there was momentum in health care to shift services to post-acute care settings, including skilled nursing facilities, inpatient rehabilitation units, and home health. These settings saw the implementation of the Prospective Payment System (PPS), a system of payment affecting services delivered to Medicare A beneficiaries. Under the PPS, post-acute health care providers are paid a daily rate, which includes all services provided to the client, including occupational therapy services. No longer can the cost of occupational therapy services be billed to the client separately.

This shift in payment structure to a prospective payment method means that a health care provider must anticipate the services that a client will need for a defined period of time and then request payment at the corresponding rate. Monitoring of the amount of time and the overall intensity of therapy delivered to Medicare A clients has become more stringent to effectively manage the overall cost of care delivery. As a result, the health care workforce, including occupational therapists and occupational therapy assistants, has been dramatically impacted. For example, in early 1998, several long-term care companies embarked on large workforce reductions as a reaction to the reimbursement changes and flooded the market with occupational therapy practitioners (Brachtesende, 2005). In response to the increased availability of therapists already in the market, academic programs experienced dips in enrollment in occupational therapy and occupational therapy assistant programs (Brachtesende, 2005). Today, post-acute care providers have learned to effectively and efficiently manage service delivery under

the new reimbursement system, and the demand for occupational therapy services and occupational therapy service providers for Medicare A beneficiaries has undergone a noticeable upswing.

For Medicare B beneficiaries, including those who receive traditional outpatient services from either an independent outpatient provider or a hospital-based outpatient department, those who receive home health services, and those who are permanent residents of long-term care facilities, there have also been notable changes since the implementation of the BBA. Rehabilitation services are limited by the beneficiary cap placed on outpatient rehabilitation services, including occupational therapy. Medicare B covers 80% of the costs of therapy up to the financial limitation, or cap, and then the beneficiary must either use another insurance payer or pay privately for additional occupational therapy services (Centers for Medicare and Medicaid Services, 2005b). These financial limits have impacted the delivery of occupational therapy services by forcing some therapists and their patients to focus primarily on the most essential components of therapy, including only working on basic skills such as simple ADL activities and functional mobility (Mattson, 1999). Those clients who are most severely disabled and those with chronic conditions have also been negatively impacted as a result of the Medicare B caps and have been forced to either privately pay for additional occupational therapy services or find alternative interventions.

Another government-administered health insurance program is Medicaid. Medicaid is designed to assist low-income individuals and families who fit into specific eligibility groups that are established by federal and state law (Centers for Medicare and Medicaid Services, 2005a). Although funded by the federal government, Medicaid is administered individually by states. Each state is permitted to establish its own guidelines for both Medicaid eligibility and the coverage of services (Centers for Medicare and Medicaid Services, 2005a). Requirements can vary significantly from state to state for both recipients and service providers. Occupational therapy services may or may not be covered under Medicaid. When services are covered, the conditions warranting care are specifically identified, and there may be requirements regarding the frequency and duration of occupational therapy services for which Medicaid will pay.

In the last two decades of the 20th century, the number of Americans covered by managed care plans increased dramatically. By the mid-1990s, three quarters of those with health insurance coverage were enrolled in some form of a managed care insurance plan (Glied & Zivin, 2002). Much of the growth of these plans has been the result of increased demand for health care cost containment, a drive toward improving access to health care for all who need it, and closer scrutiny regarding the quality of care that is delivered and paid for (Frakes, 1997).

Managed care is a broad term for a variety of health care coverage arrangements where the goal is to manage and control the cost of medical care and related health care services (Krieg, 1997). It has a strong focus on prevention and wellness and uses a primary physician to help direct or “manage” the health care resources that are utilized by the client. Health Maintenance Organizations (HMOs) and Preferred Provider Organizations (PPOs) are the two primary types of managed care plans. From the inception of managed care in the 1920s, managed care has been primarily provided by private insurance companies (Krieg, 1997). More recently, government-funded health care programs, such as Medicare and Medicaid, have seen a dramatic rise in their costs and have developed their own managed care systems to help control costs and more appropriately direct the care received by beneficiaries (Krieg, 1997).

The shift in the health care climate to one of greater cost control, more efficient service delivery, and better overall management of health care resources has resulted in a plethora of changes in third-party reimbursement, which have impacted the delivery of occupational therapy services. Occupational therapy providers have seen an increase in paperwork to demonstrate compliance with payer requirements. Service intensity and duration are often dictated by the payer. Recipients of occupational therapy services may need to pay privately for additional services beyond what their insurer covers, thus requiring occupational therapy practitioners to use time with their clients effectively to insure desired clinical outcomes are achieved in the most efficient manner. Regardless of practice domain, occupational therapists and occupational therapy assistants must pay careful attention to the specifications of their client’s payer source to ensure that services rendered are reimbursed timely and appropriately. The case examples in the chapters of this textbook provide practical examples of how occupational therapists plan treatment while keeping these reimbursement limitations in mind.

Accountability for Effectiveness

Requiring accountability for effectiveness has led to an emphasis on evidence-based practice throughout the medical establishment. As with other factors that have influenced occupational therapy, accountability is not a new concept in occupational therapy. In 1929, Marjorie Taylor, director of the department of occupational therapy at Milwaukee-Downer College and advisory director of the Junior League Curative Workshop in Milwaukee, exhorted: “The therapists must bend all their energies to rapidity of functional gain with every patient. In no other field is the pressure of time felt so keenly, or the loss of money through inexact or unintelligent treatment so

great” (Taylor, 1929, p. 335). Although the fees charged for her program were \$2.50 per day for combined treatments in occupational therapy and physical therapy, her message is both familiar and vital to occupational therapists today.

Today, the costs of therapy must be carefully assessed. Neither the government, through Medicare and Medicaid, nor the private insurance companies are willing to pay for unlimited or ineffective treatment. Whereas formerly therapists had the freedom to keep a patient under treatment until that person had obtained all benefit from therapy, now therapists are told by the insurance companies how many treatments they will be reimbursed for. Therapists are also required to demonstrate to the payers how the treatment improved the patient’s functional status. Therapists must select interventions that are most likely to make a significant difference in the patient’s occupational functioning. The government and the insurance carriers expect that evidence exists concerning the effectiveness of interventions. As Hasselkus said in 2002, we have entered a new therapy world called the world of evidence-based practice.

Evidence-based practice is the conscientious, explicit, and judicious use of current best evidence to make decisions about the care of individual patients (Sackett et al., 1997; Sudsawad, 2005). Although therapists did not use interventions that lacked evidence previously, the evidence was not scientific (Hasselkus, 2002). “Evidence” consisted of authority statements, a single small study, a published manual, or our own or our colleagues’ experiences (Hasselkus, 2002). Now, scientific evidence is required.

Evidence-based practice involves the searching for and gathering of evidence pertinent to the therapeutic problem, the evaluation of the validity of the evidence to establish a causal relationship between the treatment studied and the outcome, the determination of best evidence available pertinent to the particular patient and intervention, and finally, the application of the evidence to the patient. Clinical experience guides that application. Clinical experience is not supplanted by scientific evidence; it makes the judgment of when and for whom the evidence applies.

Evidence-based practice requires the generation of outcome studies. As part of the effort to organize and increase outcomes research in occupational therapy, the American Occupational Therapy Association (AOTA) and the American Occupational Therapy Foundation (AOTF) funded the Center for Outcomes Research and Education (CORE) at the University of Illinois at Chicago in 1999 (Kielhofner et al., 2004). Evidence-based practice is facilitated by organized syntheses of extant evidence. In 2004, AOTA and AOTF, joined by the Agency for Healthcare Research and Quality of the United States Department of Health and Human Services, sponsored an International

Conference on Evidence-Based Occupational Therapy. Therapists from 13 countries convened for 3 days to develop an international plan for the identification, review, and synthesis of scientific information and methods of making this information available to practicing therapists and students. The OTseeker database (www.otseeker.com), which was developed in Australia, was chosen as the database to become the repository of the occupational therapy evidence.

The authoritarian support for interventions, considered adequate for the first half of the 20th century, was supplanted by a growing, but still small, body of scientific evidence in the latter half of the 20th century. In the 21st century, single studies and authoritarian support are no longer adequate. Now, several studies synthesized into a **critical review** or **meta-analysis** are sought to support the effectiveness of a given intervention or class of interventions. Evidence-based occupational therapy is a worldwide effort. Individual occupational therapists as well as national organizations are contributing to the effort to generate, organize, and synthesize evidence. Examples of evidence to support assessments and interventions used in occupational therapy for physical dysfunction are included in each chapter of this textbook.

PAST, PRESENT, AND FUTURE: WILL THE QUESTIONS BE THE SAME?

Occupational therapists have met many challenges throughout the course of the profession. Today’s occupational therapists are discovering that challenges once met reappear, sometimes in familiar form and sometimes in different guise. Treatment planning for short hospital stays and limited reimbursable visits are formidable tasks for occupational therapists trained in more traditional fee-for-service practices and are as daunting as the challenges our predecessors faced in preparing patients to return to productive lives after long hospitalizations. The types of diagnoses that occupational therapists see have changed with advances in health care. New technologies and treatment techniques are incorporated into practice. The value of occupation has been reinforced by research on the recovery of brain function after injury (Liepert et al., 2000), the demonstrated effects to prevent dysfunction among elders (Clark et al., 2001), the emphasis of the health care community on activity and participation (World Health Organization, 2001), the adoption by other professions of activity as therapy (Basler, 2005; Kowalske et al., 2000; Walker, 2002), and other evidence that supports occupational therapy’s basic premise. Building the evidence base for the effectiveness of interventions used by occupational therapists for persons with physical dysfunction is the current focus of the profession.

SUMMARY REVIEW QUESTIONS

1. What is the basic premise of occupational therapy?
2. What social movement and historical events promoted the use of occupation as therapy?
3. How do practices of the 19th-century health reformers relate to occupational therapy in the 20th century?
4. What economic factors have affected occupational therapy practice?
5. How did adjunctive interventions, such as adaptive equipment and orthoses, enter the practice of occupational therapy for physical dysfunction?
6. Were work programs new to the practice of occupational therapy in the last decade of the 20th century? If not, what was their origin?
7. Why did early therapists have concerns about crafts as an effective modality to remediate specific physical deficits? What did they do? Is that still a concern?
8. What are physical agent modalities and when and by whom are they used?
9. What is evidence-based occupational therapy? Why is it important to practice from a base of evidence?
10. What are the economic factors affecting health care service delivery today?
11. What influence does government and third-party reimbursement have on occupational therapy practice?

ACKNOWLEDGEMENT

The authors recognize the contributions of Jean Spencer, Ph.D., OTR, FAOTA, and Catherine Trombly, Sc.D., OTR/L, FAOTA, to this chapter.

CHAPTER 3

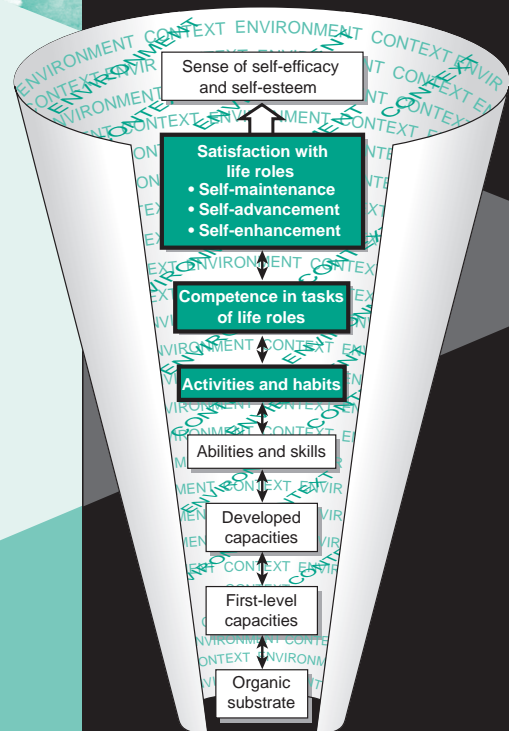

Planning, Guiding, and Documenting Practice

Mary Vining Radomski

LEARNING OBJECTIVES

After studying this chapter, the reader will begin to be able to do the following:

1. Describe four lines of clinical reasoning that shape provision of occupational therapy services.
2. Effectively document occupational therapy services.
3. Differentiate between anticipated therapy outcomes and long- and short-term goals.
4. Consider a variety of treatment approaches in planning therapy.
5. Make a commitment to maintaining his or her professional competence.

Glossary

Accreditation—A determination by an accrediting body that an eligible health care organization complies with established standards (JCAHO, 1999).

Commission on Accreditation of Rehabilitation Facilities (CARF)—Founded in 1966, CARF is a national organization whose mission is to promote the quality, value, and outcome of rehabilitation services through a consultative accreditation process that centers on enhancing the lives of persons served (CARF, 2004).

Comorbidities—Medical problems typically unrelated to the treatment diagnosis that affect the anticipated outcome and/or the treatment approach.

Continuum of care—A system of services of varying intensity that address the ongoing or intermittent needs of persons with disabilities, ranging from acute medical intervention to rehabilitation to subacute rehabilitation to home health services to outpatient treatment to community wellness opportunities (CARF, 2004).

Episode of care—A discrete interval of service provision related to the achievement of specific therapeutic goals. Patients typically participate in many episodes of care during the recovery and rehabilitation process.

Evidence-based practice—Methods and mindset that integrate research study evidence into the clinical reasoning process (Tickle-Degnen, 2000).

Goal—Narrowly defined end result of therapy to be achieved in a specified time (Bryant, 1995). Goals are usually designated as long or short term.

Joint Commission on Accreditation of Healthcare Organizations (JCAHO)—Founded in 1951, JCAHO is an independent, not-for-profit organization dedicated to improving quality of care in various health settings (JCAHO, 1999).

Length of stay—Total number of days between the date the patient is admitted to the hospital and the date he or she is discharged.

Outcome—Anticipated end result of therapy, given the client's characteristics, expected length of stay or therapy duration, and resources (funding, social support).

Plan of care—A document prepared by all members of the rehabilitation team (including the patient) that describes the interdisciplinary treatment goals, interventions, and time frames for a specific episode of care.

The caliber of the clinician's thinking about each step in the occupational therapy process will set the stage for either inspired intervention or treatment that is rote, uninteresting, and ineffective. One might argue that the ongoing behind-the-scenes thinking about assessment and intervention (known as clinical reasoning) is at least as important as what happens between the client and therapist in a typical 30-minute session.

Clinical documentation chronicles clinical reasoning about occupational therapy diagnosis (Rogers & Holm, 1991), intervention plans, actions, and results. For many clinicians (often including this author), documentation is the price paid for otherwise interesting work. Documentation, however, can be the vehicle through which clinicians think out loud: a map for planning treatment and a compass for monitoring results and shifting course.

This chapter is structured around three interrelated dimensions of occupational therapy practice: thinking, doing, and documenting. Note that Table 3-1 summarizes the ways in which clinical reasoning informs these three aspects of providing occupational therapy services and introduces the case example format used throughout the textbook. The chapter concludes with a discussion of the ways therapists use the processes of thinking, doing, and documenting to improve their clinical competence.

CLINICAL REASONING

Clinical reasoning is the thinking process by which therapists collect and use information to make decisions about care of an individual client (Rogers, 1983). Clinical reasoning is ongoing. It begins as the therapist first reads a patient's referral; extends through assessment, intervention, and discharge; and continues as the clinician reflects on the process and results of intervention with this patient as he or she plans therapy for another patient. Clinical reasoning in practice typically does not occur as a tidy progression of thoughts; it may appear cyclic or even chaotic as therapists dance back and forth between hypothesis testing and storytelling throughout their involvement in patients' care (Hagedorn, 1996). Note how the same internal questions and self-reflections in Table 3-1 are repeated at various junctures in the delivery of services.

As therapists make decisions and plans for assessment and treatment, they simultaneously employ at least four lines of clinical reasoning.

- *Scientific reasoning* refers to the logical thinking about the nature of the client's problems and optimal course of action in treatment (Mattingly, 1991; Rogers, 1983). Therapists employ scientific reasoning when they consider the reliability and validity of assessment tools and

Table 3-1. Clinical Reasoning Underlying the Process of Delivering Occupational Therapy Services

Service Delivery	Clinical Reasoning Objectives	What the Therapist . . .		
		Does	Thinks (examples of internal questions and self-reflections)	Documents
Screening	Understand the patient’s diagnosis or condition	Obtain and review background information	<ul style="list-style-type: none"> • What do I know about the patient’s medical diagnosis? • What impairments, activity limitations, and participation restrictions are typical for individuals with this diagnosis or condition? • Do the patient’s records and information from referral sources suggest that occupational therapy services would be appropriate for this patient at this time? 	Informal notetaking and record keeping
Assessing occupational functioning	Know the person	Interview, listen, write	<ul style="list-style-type: none"> • What do I need to know about this patient’s current and past occupational functioning? • What does the patient’s past tell me about his or her priorities, strategies, and resources under the present circumstances? • Which of the patient’s current concerns relate to his or her occupational functioning? • What seem to be the patient’s main priorities regarding his or her occupational functioning? 	Daily contact notes
	Appreciate the context		<ul style="list-style-type: none"> • Are there social, cultural, and personal contextual factors that may affect the evaluation or intervention process? • Who should I talk with to better understand the patient’s situation, occupational functioning, and/or needs? • Where is the patient in his or her recovery relative to onset of the condition? • What is the projected duration of this episode of care? • What sorts of resources are available to support the occupational therapy process? • What other medical, rehabilitation, and therapy services have been or are involved in the patient’s care? • What have been the outcomes of past or current services? 	
	Reflect on competence	Consult others (as needed)	<ul style="list-style-type: none"> • Do I have adequate experience, education, and training to provide occupational therapy services to this patient? • If not, should I share responsibility with someone who can provide coaching or assistance? • Should this patient be referred elsewhere for services? 	
	Develop provisional hypotheses		<ul style="list-style-type: none"> • What physical, cognitive, and contextual barriers may be interfering with the patient’s occupational function? 	
	Consider the evaluation approach	Select evaluation tools and methods	<ul style="list-style-type: none"> • Do I want to observe function to make inferences about impairment? • Do I want to assess specific impairments to make inferences about function? • How can I use existing information from other disciplines to inform questions about barriers to occupational functioning? 	
Consider the evaluation tools		<ul style="list-style-type: none"> • Are there standardized assessments that will help specify the nature of the barriers to occupational functioning? • What forms of evaluation or specific tools will put the patient most at ease, given what I know about his or her background? 		

continued

Table 3-1. (continued)

Service Delivery	Clinical Reasoning Objectives	What the Therapist . . .		
		Does	Thinks (examples of internal questions and self-reflections)	Documents
	Interpret observations	Administer evaluation; observe; take notes on performance	<ul style="list-style-type: none"> • How closely am I adhering to administration instructions for standardized assessments? • Does the patient seem to understand the instructions? • What physical, cognitive, and sensory processing capacities are challenged by this assessment? • What strategies or approaches does the patient use to perform the assessment? 	
	Synthesize results	Write up evaluation findings	<ul style="list-style-type: none"> • How does the patient's performance compare to that of others? • To what extent could the patient's performance have been affected by unrelated factors (fatigue, medication, pain, distraction, etc.)? • Do patterns emerge in the patient's performance across task or assessment? 	
Planning intervention	Develop intervention hypotheses		<ul style="list-style-type: none"> • What seem to be the most salient barriers (physical, cognitive, emotional, contextual) to the patient's occupational functioning? 	Intervention plan
	Select an intervention approach or model		<ul style="list-style-type: none"> • What intervention approach or model has the strongest evidence of effectiveness in the rehabilitation research literature for patients similar to my current patient? 	
	Reflect on competence	Consult others (as needed)	<ul style="list-style-type: none"> • Do I have adequate experience, education, and training to provide occupational therapy services to this patient? • If not, should I share responsibility with someone who can provide coaching or assistance? • Should this patient be referred elsewhere for services? 	
	Consider the patient's appraisal of performance	Discuss evaluation impressions and findings with patient and possible course of intervention	<ul style="list-style-type: none"> • To what extent does the patient understand and/or agree with my hypotheses regarding barriers to his or her occupational functioning? • Given what I suspect are underlying barriers to occupational functioning, what does the patient seem to want to achieve in therapy at this time? • Are there any constraints on the length of time that I am able to provide services to this patient? 	
	Consider what will occur in therapy, how often, and for how long	Specify treatment activities, time frame, and intensity	<ul style="list-style-type: none"> • What specific techniques or activities should be used in therapy, given the approach I've selected and what I know about the person? • What does the literature suggest about the optimal time frame, intensity, and duration of therapy needed to achieve results? • If there is no scientific evidence in this area, what do experienced clinicians recommend about time frame, intensity, and duration? 	
	Ascertain patient's endorsement of intervention plan	Discuss with patient and modify as necessary	<ul style="list-style-type: none"> • What are the indicators that this patient understands the intervention plan that I've proposed? • What are the indicators that this patient (and/or significant others) endorse the plan as proposed? 	

continued

Table 3-1. (continued)

Service Delivery	Clinical Reasoning Objectives	What the Therapist . . .		
		Does	Thinks (examples of internal questions and self-reflections)	Documents
Delivering treatment and monitoring progress	Assess the patient’s comprehension	Provide instructions for therapy, exercises, tasks, and activities	<ul style="list-style-type: none"> • Does the patient seem to understand what I am saying? • Am I using language or expressions that likely make sense to this person? 	Daily contact notes
	Understand what the patient is doing	Observe patient’s performance	<ul style="list-style-type: none"> • What specific actions is the patient taking? • What do the actions infer about how the patient is thinking or processing? • Why does the patient appear to be performing in this manner? 	Weekly and/or monthly progress notes
	Compare actual performance to expected performance	Discuss with patient; modify the treatment plan as needed	<ul style="list-style-type: none"> • To what extent does this patient’s performance support my hypotheses regarding the nature of his or her barriers to occupational functioning? • Is the patient’s performance improving at the rate I anticipated? If not, why? • To what extent is the patient complying with home recommendations, exercises, and activities? 	Home programs
	Know the person		<ul style="list-style-type: none"> • What does the patient’s performance tell me about who this patient is? • How should these insights further shape the intervention plan? 	
	Appreciate the context		<ul style="list-style-type: none"> • Are there other possible factors that are interfering with the patient’s occupational functioning? If so, what might they be? • Does the patient seem to understand what I am saying? • Am I using language or expressions that likely make sense to this person? 	
	Consider alternatives to current services		<ul style="list-style-type: none"> • Is the patient making enough progress toward his or her occupational therapy goals to warrant continuation? Are the goals still appropriate? • Would services from other providers be beneficial? 	
Discontinuing occupational therapy services	Anticipate present and future patient concerns	Write and discuss recommendations	<ul style="list-style-type: none"> • Given what I know about the diagnosis or condition, who he or she is, and his or her progress to date, what should this patient continue to do (or discontinue) to optimize his or her occupational functioning? 	Home programs
	Analyze the patient’s comprehension		<ul style="list-style-type: none"> • Does the patient seem to understand what I am saying? • Am I using language or expressions that likely make sense to this person? • What other people in the patient’s life also need to understand this information? 	Referral
	Decide if or when the patient should return for therapy	Plan for follow-up	<ul style="list-style-type: none"> • Do I expect the patient’s occupational functioning to change at some point in such a way that therapy should then be resumed? If so, when would it make sense to reevaluate the patient’s need for occupational therapy services? 	Discharge summary

continued

Table 3-1. (continued)

Service Delivery	Clinical Reasoning Objectives	What the Therapist. . .		
		Does	Thinks (examples of internal questions and self-reflections)	Documents
			<ul style="list-style-type: none"> • Are there resources to pay for follow-up occupational therapy services? • Does the patient seem to understand under what circumstances to contact me again, or should we schedule a time at which he or she will return? • Are there other services in the community that this patient should be accessing at this point? 	

when they use the patient’s medical and occupational diagnoses and research evidence to shape the intervention plan (Rogers & Masagatani, 1982; Rogers & Holm, 1991).

- *Narrative reasoning* refers to thinking in story form to place the client’s functioning in the context of his or her background and broader experience (Schell & Cervero, 1993). Therapists employ narrative reasoning when they try to understand the meaning of disability in the patient’s life in order to link his or her goals and values to the therapy process (Mattingly, 1991).
- *Pragmatic reasoning* refers to thinking about logistics and practical aspects of delivering services to clients within a given setting or organization (Schell & Cervero, 1993). Therapists employ pragmatic reasoning when they consider norms of the department or expectations related to **accreditation**, personnel, or reimbursement factors as they provide occupational therapy services (Schell & Cervero, 1993).
- Ethical reasoning refers to idealistic thinking about what should be done on behalf of a specific individual (Rogers, 1983). A therapist employs ethical reasoning when he or she synthesizes research evidence, an appraisal of his or her competence, practical aspects of service delivery, and the patient’s goals and values to answer the following question: “What, among the many things that could be done for the patient, ought to be done?” (Rogers, 1983, p. 602).

Clinical reasoning is a dynamic process, simultaneously influenced by client and therapist characteristics, experience, and background (Rogers & Holm, 1991; Roberts, 1996; Sviden & Hallin, 1999; Unsworth, 2001). For example, a middle-aged therapist with elderly parents and an equally experienced therapist with young children may arrive at different assessment conclusions and develop different treatment plans for an 80-year-old patient recovering from a pelvic fracture because of their different life experiences. Similarly, the characteristics of settings in

which occupational therapists work shape clinical reasoning (Rogers & Holm, 1991). Physical, financial, and personnel resources influence assessment tools and methods, and multidisciplinary teams establish informal rules about the boundaries of each discipline’s contribution (Rogers & Holm, 1991). Clearly, clinical decisions are shaped by many factors, including the clinician’s professional expertise, the client’s background and preferences, and research evidence (Rappolt, 2003). **Evidence-based practice** minimizes the influence of personal and environmental biases in the clinical reasoning process.

Evidence-Based Practice

Evidence-based practice (EBP) is “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. [It integrates] individual clinical expertise with the best available external clinical evidence from systematic research” (Sackett et al., 1997, p. 2). Evidence-based practice includes both method and mindset. The method is made up of seven steps: (1) write an answerable clinical question; (2) gather best evidence to answer the question, including clinical assessment findings, systematic reviews from the literature, and primary studies; (3) evaluate the validity and clinical usefulness of the gathered evidence; (4) synthesize the findings; (5) communicate with various stakeholders, including client and family, about evidence as it relates to assessment or treatment; (6) apply findings to practice; and (7) monitor, evaluate, and document the results (Sackett et al., 1997; Tickle-Degnen, 2000). Many resources are available to clinicians, including systematic research reviews and tools for implementing EBP methods (see Resources 3-1).

Beyond the methodology, evidence-based practice reflects habits of thinking and doing that pervade the way the clinician delivers services (Cusick & McCluskey, 2000; Holm, 2000). Although evidence-based practice

www.otseeker.com

is increasingly emphasized in the literature, it may not yet have fully infiltrated day-to-day occupational therapy practice. Many treatments do not lend themselves to controlled clinical trials, and subjects in well-designed studies tend to be unrealistically homogeneous and do not have the confounding problems or severity of impairments typical of many rehabilitation patients (Whyte, 1998). Clinicians cite insufficient time (Philibert et al., 2003;

Rappolt, 2003) and difficulties understanding research (Gervais et al., 2002) as barriers to using evidence to inform practice. Many therapists put more emphasis on knowledge gained from clinical experience and consultation with others than on research literature (Dubouloz et al., 1999). They rely on previous experience and patients' input to guide decisions, using research primarily to confirm the effectiveness of practice to non-clients (Dubouloz et al., 1999).

Leaders in our profession have unambiguously charged occupational therapists to “wake up to the world of health care research and to use findings from this world of research in addition to more familiar sources of evidence to guide treatment planning” (Ottenbacher, Tickle-Degnen, & Hasselkus, 2002, p. 247). This requires individual clinicians to adhere to the ethical standards of our profession (American Occupational Therapy Association [AOTA], 2000) and take personal responsibility to know and then fully inform clients of the nature, risks, and potential outcomes of any intervention (Holm, 2000). As they adopt an evidence-oriented mindset, occupational therapists will be able to describe why they are using particular assessments and recommending particular interventions (Cusick & McCluskey, 2000) and enable clients, families, and payers to make informed decisions about occupational therapy services.

**CLINICAL DOCUMENTATION**

Clinical documentation in occupational therapy provides a chronological record of the patient's status and condition related to occupational functioning and details the course of therapeutic intervention (AOTA, 2004a). It reflects the clinician's reasoning and serves as the basis for judging the appropriateness, effectiveness, and necessity of intervention (AOTA, 2004a).

Occupational therapists contribute information to medical records in a number of formats: source-oriented medical records, which are organized in sections according to the department providing care; integrated medical records in chronological order; and problem-oriented medical records, which are organized according to four components, namely database, complete list of problems, plans for each problem, and progress notes (Robertson, 1997). SOAP notes are typically used to report progress in problem-oriented medical records (Robertson, 1997). (SOAP is an acronym for the four parts of a progress notes: subjective, objective, assessment, and plan.) Obviously, occupational therapists contribute documentation that complies with the structure of the medical records established for their specific work settings.

In the course of their daily work, occupational therapists produce a number of reports, including daily contact notes, evaluation summaries, weekly or monthly progress notes, and discharge summaries (Table 3-2).

Table 3-2. Overview: Types of Occupational Therapy Documentation

Documentation	Purpose	Typical Formats	Contents	When to Document
Contact, treatment, or visit note	Brief account of an individual session	Short narrative note, checklist, or flow sheet	<ul style="list-style-type: none"> Amount of time spent evaluating or treating the client Brief characterization of intervention (e.g., ADL instruction, strengthening, compensatory strategy training) Description of client response relative to short-term goals 	After each evaluation or treatment session
Evaluation report	Detailing of assessment findings, interpretation of results, estimated outcomes of intervention, goals, time frame, and treatment plan	<ul style="list-style-type: none"> Therapist's observations and findings recorded on a fill-in-the-blank form Handwritten or dictated and typed report 	<ul style="list-style-type: none"> Background information on the client (age, sex, diagnosis); summary of medical history, secondary problems, and comorbidities; precautions and contraindications Referral source, services requested, date of referral Date(s) of evaluation sessions and amount of time Pre-morbid or prior level of functioning in occupational function; self-report of problems and priorities (Occupational Profile [AOTA 2002, 2004]) Assessment results: scores, observations, summary, and analysis of assessment findings (Analysis of Occupational Performance [AOTA, 2004]) Intervention plan: projected outcomes of therapy, goals, and time frame; statement of client participation in goal setting for therapy; general description of treatment plan (including treatment approach and recommended frequency of treatment sessions) 	After completing the assessment, synthesizing the results, and collaborating with client about therapy goals
Progress report	Summary of progress toward functional goals, interventions employed, updated goals, and treatment plan	<ul style="list-style-type: none"> Fill-in-the-blank form or checklist with section for handwritten comments Flow sheet (as used with clinical pathways) Handwritten or dictated and typed report 	<ul style="list-style-type: none"> Dates of service and dates of progress period Number of treatment sessions during progress period Overview of activities, techniques, modalities used Summary of instruction provided to client or family Description of adaptive equipment issued or recommended Client's response to intervention specific to therapy goals Recommendations regarding continuation of therapy Revised goals and time frame for achievement Revised treatment plan (treatment approach, recommended frequency of sessions) Statement of client participation in goal setting for therapy 	Daily, weekly, or monthly, depending on setting
Discharge report	Review of occupational therapy assessment, intervention, and outcome	<ul style="list-style-type: none"> Fill-in-the-blank form or checklist with section for handwritten comments Flow sheet (as used with critical pathways) Handwritten or dictated and typed report 	<ul style="list-style-type: none"> Dates of referral, service initiation, and discontinuation Total number of evaluation and treatment sessions Summary of client's progress toward each therapy goal Overview of interventions employed specific to each goal Description of maintenance program and discharge instructions Recommendations for follow-up, maintenance programs, referrals to other services or agencies 	After the last session in an episode of care

 Hygiene: Level of Assist: 5 Supervision, Set-Up or Standby Prompting
 Bathing: Level of Assist: 4 Minimal Assistance
 Toileting: Level of Assist: 4 Minimal Assistance

Level of Patient Participation: Passive Participation

Patient Safety Awareness: Verbalizes Safety Precautions

Adapted Equipment in Use: ADL: Raised Toilet Seat, Reacher and Tub seat/ch

Progress Toward Targeted Outcomes:
 Patient, Family and Caregiver response to intervention:
 Patient progressing as planned toward targeted outcomes; continue current plan

Therapist Current Recommendations for Discharge:
 Home with Family Assistance

THERAPEUTIC EXERCISE: (10427)
 THERAPEUTIC ACTIVITIES / FUNCTIONAL TRAINING: (Ther Act 14909)
 EQUIPMENT: (Equip:10436)
 MANUAL THERAPY: (Manual:14945)
 MODALITIES: (Modalities:14951)
 NEUROMUSCULAR REEDUCATION: (Neuro ReEd:14938)
 HAND: (Hand:15375)
 STRAPPING / TAPING: (14955)
 SPLINTING / FABRICATION: (14956)
 ORTHOTIC FIT / TRAIN: ***
 DEVELOPMENT OF COGNITIVE SKILLS: ***
 SENSORY INTEGRATION: ***
 SELF CARE / HOME MANAGEMENT: (14958)
 COMMUNITY / WORK REINTEGRATION: (14958)
 WHEELCHAIR MANAGEMENT / PROPULSION: ***
 SPECIAL PROGRAMS: (10426)
 WORK CONDITIONING / HARDENING: ***
 WOUND CARE: (WOUND:14954)
 AQUATIC THERAPY: (14960)
 ASSISTIVE TECHNOLOGY ASSESSMENT: ***
 No further Therapy planned at this time.
 Patient seen for *** only, to be discharged.

Figure 3-1 This screen shot of occupational therapy documentation in a electronic medical record depicts how clinicians use drop-down boxes to select descriptors of intervention and patient performance. (Epic Systems Corporation © 1999–2005. Reprinted with permission.)

Documentation formats include computerized records, checklists, forms, and narrative notes. (See Fig. 3-1 for an example of an occupational therapy daily progress note from a computerized medical record.) Regardless of format, to communicate in these documents, therapists must be clear about their target audience (McGuire, 1997; Robertson, 1997). That is, who will read this note and what do they need or want to know about the occupational therapy work with this patient? Clinicians aim to provide succinct descriptions of functional status, anticipated outcome, and progress to date, so that a single document meets a number of stakeholders' information needs. The reading audience may include members of the treatment team, who want to know how best to collaborate; the third-party payer, who wants to decide whether to pay for services; the accrediting agency, such as the **Joint Commission on Accreditation for Healthcare Organizations (JCAHO)** or the **Commission on Accreditation of Rehabilitation Facilities (CARF)**, which want to determine whether quality services are provided at your institution; the legal system, which wants evidence in malpractice litigation; and the

patient and significant others, who want to understand the care (Robertson, 1997).

McGuire (1997) outlined six principles that reflect excellent standards for occupational therapy documentation. She suggested that clinical documentation addressing these principles meets the information requirements of a variety of stakeholders, including Medicare, the largest third-party payer in the United States. After stating each principle, I briefly summarize McGuire's recommendations for clinical documentation (Fig. 3-2).

1. Focus on function. Clinicians describe the patient's previous or premorbid level of function in key areas, review his or her current status, and/or provide estimates of potential improvements or outcomes as a result of therapy.
2. Focus on underlying causes. Clinicians combine their understanding of the patient's medical condition with results of their assessments to identify specific impairments that restrict or limit occupational performance (McGuire, 1997).

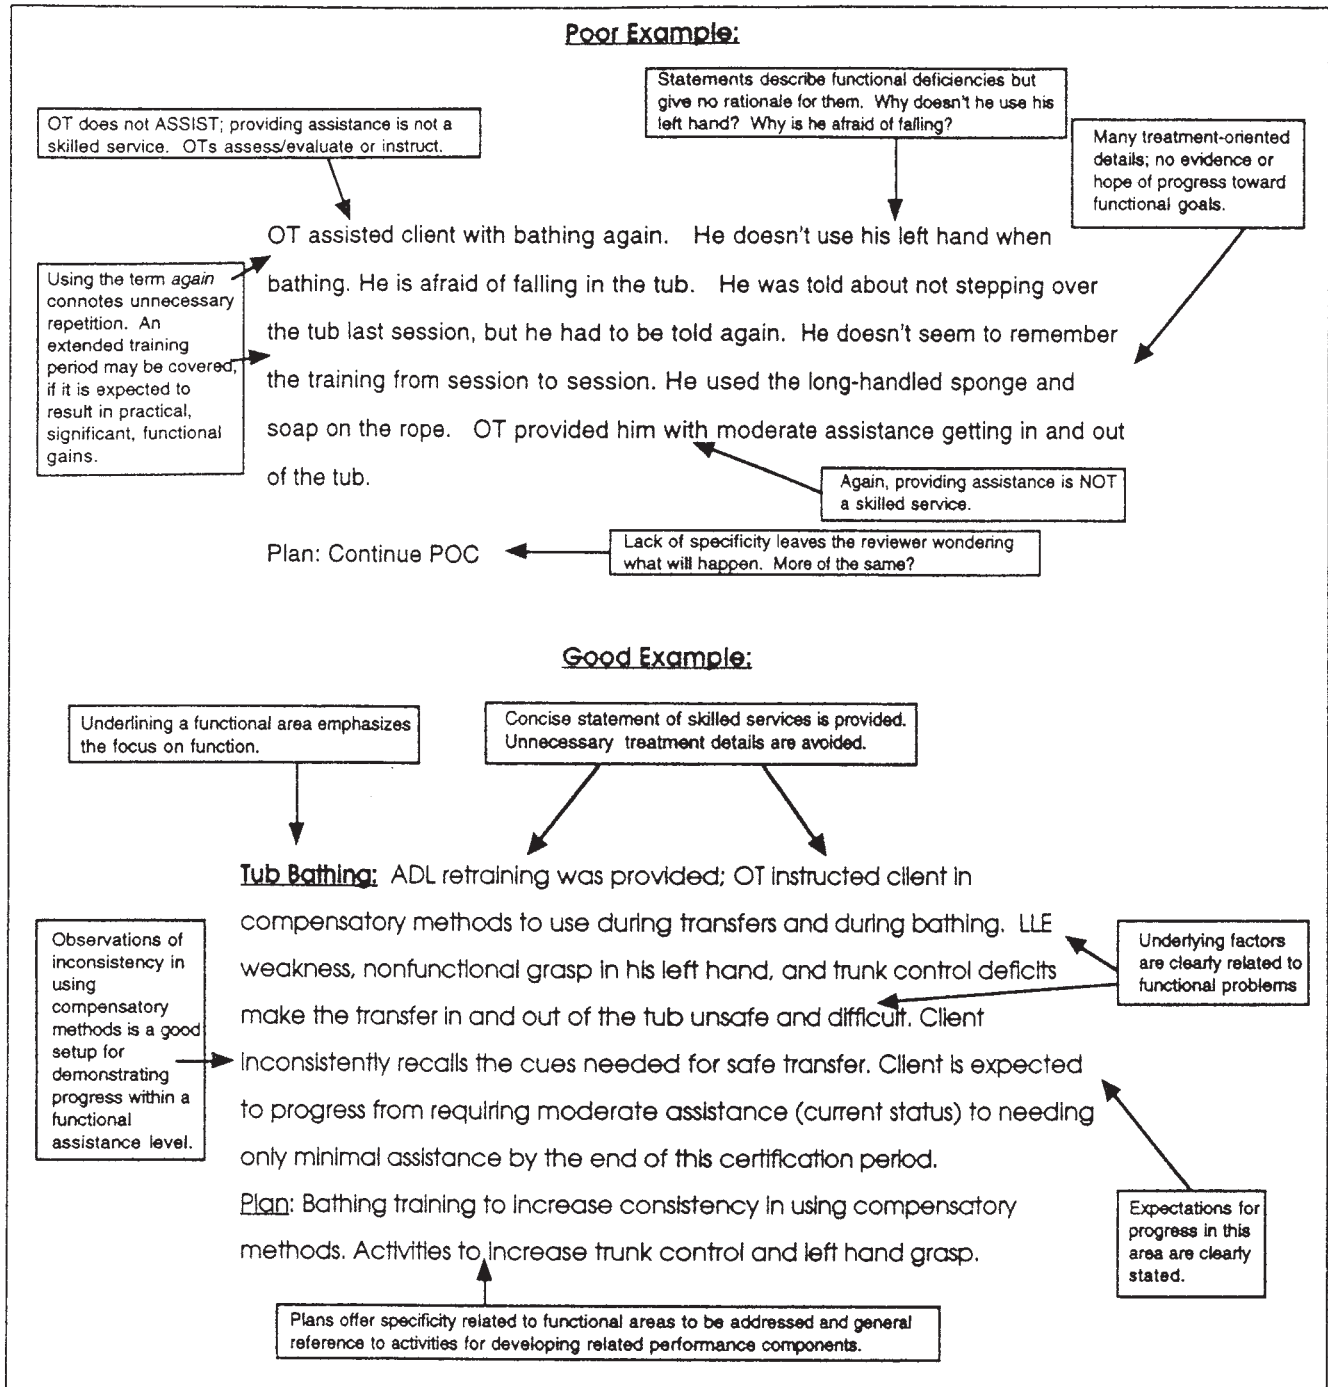

Figure 3-2 Features of effective progress notes. (From: McGuire, M. J. [1997]. Documenting progress in home care. *American Journal of Occupational Therapy*, 51, 444. Copyright 1997 by The American Occupational Therapy Association, Inc. Reprinted with permission.)

3. Focus on progress. Clinicians describe patients' progress toward goals according to objective measures, details of careful observation, and/or standardized levels of independence. (Definition 3-1 describes standardized definitions for levels of assistance used by the Centers for Medicare and Medicaid Services.)
4. Focus on safety. Many stakeholders look to the occupational therapist to provide information about the patient's safety and competence in self-

DEFINITION 3-1

de·fin·i·tion

Standardized Levels of Assistance as Defined by the Centers for Medicare and Medicaid Services

Definitions for Levels of Assistance for ADL Self-Performance Items (from RAI used in skilled nursing facilities)		Definitions for Levels of Assistance Based on FIM™ (from IRF-PAI used in inpatient rehabilitation facilities)	
Independent	No physical or cognitive help, set up, or supervision	Complete Independence	The patient safely performs all the tasks described as making up the activity within a reasonable amount of time and does so without modification, assistive devices, or aids.
Supervision	Oversight, encouragement, or cueing provided 3 or more times during 7-day period	Modified Independence	One or more of the following may be true: the activity requires an assistive device or aid, the activity takes more than a reasonable amount of time, or the activity involves safety (risk) considerations.
Limited Assistance	Resident highly involved in activity, received physical help in guided maneuvering of limbs or other non-weight-bearing assistance	Supervision	The patient requires no more help than standby, cueing, or coaxing, without physical contact; alternately, the helper sets up needed items or applies orthoses or assistive/adaptive devices.
Extensive Assistance	Although resident performed part of activity, over last 7-day period, help of the following type(s) was provided 3 or more times: weight-bearing support; full staff performance during part (but not all) of last 7 days	Minimal Assistance	The patient requires no more help than touching and expends 75% or more of the effort.
Total Dependence	Full staff performance of the activity during entire 7-day period. There is complete non-participation by the resident in all aspects of the ADL task.	Moderate Assistance	The patient requires more help than touching and expends 50–74% of the effort.
		Maximum Assistance	The patient expends between 25 and 49% of the effort.
		Total Assistance	The patient expends less than 25% of the effort.

management, self-advancement, and self-enhancement roles.

- State expectations for progress or explain slow progress or lack of progress. Occupational therapists must “document a continued expectation that the patient’s condition will continue to improve significantly in a reasonable and generally predictable amount of time” (McGuire, 1997, p. 441). Therapists need to document setbacks that delay progress, such as medication changes, medical complications, and social disruptions.
- Summarize needed skilled services. Occupational therapists avoid detailing the specific therapeutic interventions used during a given treatment session or period but emphasize the provision of skilled services. Skilled services include evaluations; direct intervention, such as training in techniques or strategies; task modification; selection or construction of equipment or orthotics;

and instructions to the patient or caregiver about maintenance programs.

PROVIDING OCCUPATIONAL THERAPY SERVICES

Clinical reasoning and documentation shape and reflect each aspect of providing occupational therapy services, including screening, assessing, planning, intervening, monitoring, and discontinuing treatment.

Screening

People are referred for occupational therapy if they have impairments, activity limitations, or participation restrictions; are at risk in these areas; or need help promoting health (Moyers, 1999). A physician's order or referral is a prerequisite to beginning services covered by third-party payers.

Screening is defined as reviewing information relevant to a prospective patient to determine the need for further evaluation and intervention (Moyers, 1999). Therapists gather this information through chart review and a brief interview.

Chart Review and Brief Interview

Occupational therapists review relevant documents in the patient's medical record before beginning assessment or treatment. Other team members' assessments (e.g., the physician's history and physical, social service or psychology intake notes, nursing assessments) help the therapist create a preliminary clinical image related to disease, severity of illness or disorder, comorbidities, age, sex, and personal and social background (Rogers & Holm, 1991). After the chart review, the occupational therapist typically introduces himself or herself to the patient and/or significant other, informs them of the referral, and briefly describes the nature of occupational therapy and the anticipated services. The purpose of this conversation is to ensure the appropriateness of the referral and obtain preliminary agreement to participate. The conversation may take place during the first few minutes of the initial assessment session, as with outpatients or patients receiving home care, or be a brief encounter in the patient's hospital room, with the assessment scheduled to take place later.

Documentation Requirements: Referral to Occupational Therapy Services

A physician's order should include the following information: the patient's diagnosis (underlying disorder, disease, or injury that contributes to occupational dysfunction);

the treatment diagnosis (the likely impairment contributing to occupational dysfunction); the actual or estimated date of recent change in the level of function; a request for evaluation or treatment; the date; and the physician's signature (Allen et al., 1997).

If the screening suggests that the referral to occupational therapy is inappropriate or the patient or family defers participation, the clinician records that orders were received and a screen was performed and explains why further assessment and treatment appear unwarranted.

Assessing Occupational Function: The Four Elements

Various aspects of occupational therapy assessment have been detailed elsewhere in this text (see Chapters 4 to 11). The discussion that follows sets the four elements of assessment (interview, observation of function, evaluation, and synthesis of results) in the broader schema of providing occupational therapy services, emphasizing the clinical reasoning dimensions rather than specific tools or methods.

Interview

Using a structured interview, the clinician identifies the client's needs and goals in the context of his or her life (Fisher, 1998). Fisher extolled the value of this aspect of the assessment process: "This step is critical, and it must occur, even under the pressures of cost containment, reduced duration of care, staff cuts, and increased accountability. In fact, there is some evidence that taking more time, initially, to establish client-centered performance will result in overall outcomes being enhanced and overall costs reduced" (Fisher, 1998, pp. 515–516).

Observe Function

The occupational therapist observes the patient performing one of the activities described as important and problematic to generate hypotheses regarding underlying impairments or inefficiencies that interfere with function. For example, while observing a patient with stroke get dressed, the clinician looks for cues that point to underlying causes of performance problems (hypothesizing, for example, that difficulty locating socks, shirt, and shoes is due to left neglect).

Evaluate with Selected Tools and Methods

Based on observations of functional performance and resultant hypotheses regarding underlying causes, therapists use selected evaluation tools and methods to verify and

quantify the existence of impairments or inefficiencies. In fact, clinicians evaluate only those client factors (AOTA, 2002), impairments, or inefficiencies suspected of impeding occupational function, rather than casting a wide net to identify all possible deficits.

Synthesize Results

Occupational therapists study assessment findings to draw conclusions about the patient's competence and quality of occupational function. The patient's strengths and weaknesses, likely underlying causes or explanations for performance problems, and potential barriers and enablers to improved functioning become the basis of the hypothesis for treatment (Opacich, 1991). The hypothesis for treatment reflects the therapist's understanding of the patient's problems. Although it may change as treatment gets under way, the hypothesis for treatment guides the selection of the treatment approach (Opacich, 1991).

Documentation Requirements: Record Keeping and Notes

Occupational therapists typically take notes regarding patient performance during the assessment. Sometimes these forms or protocols ultimately go directly into the medical record. Worksheets are also used for data collection (with the typed or handwritten summary produced for the medical record upon completion of the assessment). Some occupational therapy assessments and intervention plans are completed after just one evaluation session, in which case the therapist generates the documentation described in the next section. When the assessment spans multiple sessions, daily contact notes are recorded in the medical record.

Planning Intervention

After formulating a hypothesis for treatment, the occupational therapist plans intervention. Clinical reasoning is involved in estimating outcomes, setting goals, and selecting treatment approaches and methods.

Estimate Outcomes and Set Collaborative Goals

An **outcome** of therapy is an anticipated end result, given a specific set of parameters (Bryant, 1995). Outcomes are chosen in part according to expected **length of stay** or anticipated number of outpatient or home-based sessions and the type of funding available. The contemporary rehabilitation environment often requires clinicians to identify key expected outcomes for and with persons served, measure these outcomes, and determine how outcomes

can be achieved in a resource-wise or cost-effective manner (Cope & Sundance, 1995). Interdisciplinary rehabilitation teams typically establish a **plan of care** for a given **episode of care** that delineates the overall patient-specific outcomes, with each discipline setting goals that contribute to these core outcomes.

The Occupational Therapy Practice Framework (AOTA, 2002) suggests that the overarching outcome of occupational therapy intervention is to enable recipients of our services to engage in occupations that allow them to participate in valued roles within their home, school, work, and/or communities (AOTA, 2002). This may be achieved through improvements related to: (1) function (remediation of impairments); (2) occupational performance (independence in activities of daily living [ADL], work, and play); (3) health and well-being (symptom status improvement and prevention of disability); and (4) quality of life (purposeful participation in community life, emotional well-being, balance of activity and rest, and life satisfaction) (Moyers, 1999). Global outcomes of occupational therapy intervention can also be identified according to resumption of self-maintenance, self-advancement, and self-enhancement roles (Trombly, 1993, 1995). In selecting and projecting outcomes of treatment, occupational therapists are urged to look beyond functional independence or relearning of physical skills as the superordinate aims of occupational therapy (Radomski, 1995) and help patients attain wholeness, autonomy, meaning, and purpose in their daily lives (Crabtree, 2000).

Predicting outcomes of therapy forces clinicians to answer two key questions in intervention planning: (1) In what broad ways will this client's life, health, and functioning improve as a result of therapy at this point in the recovery or adaptation process? (2) How long will it take to realize these benefits? The answers require an appreciation for the **continuum of care** and a realization that not every dysfunction, impairment, or inefficiency can or should be addressed within a given episode of care. For example, resumption of self-maintenance roles may be an appropriate occupational therapy outcome for a stroke patient with good family support who is expected to receive inpatient rehabilitation for 2 to 3 weeks. On the other hand, resumption of self-advancement roles would probably not be an appropriate outcome of inpatient rehabilitation. Occupational therapy services to promote work readiness can likely be provided more cost effectively when the individual is an outpatient. Furthermore, resumption of work roles typically occurs after the patient achieves medical stability, approaches maximal restoration of function, and begins the adjustment process, none of which is likely to occur within a month of a stroke. Treatment planning based on anticipated outcomes of therapy not only reflects good stewardship, but it is also required by accreditation bodies, such as CARF (2004).

Table 3-3. Example of Establishing Short-term Goals

Long-Term Goal: Independence in Lower Extremity Dressing	
Examples of Short-Term Goals Based on Impairments	Examples of Short-Term Goals Based on Task Analysis
<ul style="list-style-type: none"> • Trunk flexion and BUE forward reach adequate for LE dressing • Cognitive-perceptual skills adequate for positioning clothing during LE dressing • Endurance adequate for safety and independence during LE dressing • Demonstrate compensatory methods and appropriate use of adaptive equipment for safe, independent LE dressing 	<ul style="list-style-type: none"> • Client will be able to properly place trousers over feet for donning. • Client will be able to spontaneously dress LLE before RLE. • Client will be able to pull up trousers from a standing position. • Client will be able to demonstrate proper and long handled shoe horn and complete LE use of sock donner dressing in 5 minutes without SOB.

BUE, both upper extremities; LE, lower extremity; LLE, left lower extremity; RLE, right lower extremity; SOB, shortness of breath.

Long- and Short-Term Goals

Once the occupational therapist and patient/family member conceptualize global outcomes of therapy, they work backward to establish a sequence of long- and short-term goals to get there (Cope & Sundance, 1995). A **goal** is a measurable, narrowly defined end result of therapy to be achieved in a specified time (Bryant, 1995). Long-term goals reflect what will be achieved by the time the patient is discharged from treatment or discharged to the next level of care on the continuum (Moorhead & Kannenberg, 1997). In occupational therapy, long-term goals always relate to expectations of the patient's functional skills and/or resumption of roles. Short-term goals are the small steps that cumulatively result in long-term goal achievement. Short-term goals are based either on expected improvements specific to client factors (AOTA, 2002) or impairments that ultimately contribute to improved function or on the patient's improved ability to perform portions of the functional task (McGuire, 1997). Table 3-3 compares these two types of short-term goals. A patient's occupational therapy goals are always linked to a predicted outcome and typically complement the work of other rehabilitation disciplines. Procedures for Practice 3-1 illustrates how long- and short-term goals support realization of outcomes. Definition 3-2 describes how to use goal attainment scaling to measure progress.

Collaborating with Clients to Set Goals

Collaborative goal setting between clients and therapists, an accreditation requirement of CARF (2004) and JCAHO (1999), presents benefits and challenges to both patients and therapists. Ponte-Allan and Giles (1999) suggested that the nature of goal setting may be linked with actual outcomes of therapy. They compared patients whose goals were functional, independence-oriented statements with patients whose goals were general, less functional

statements or who made no goal statements at all. Although there were no differences in age, sex, side of lesion, or levels of disability at admission, patients who had functional goals had higher discharge scores on the Functional Independence Measure™ for grooming,

PROCEDURES FOR PRACTICE 3-1

Linking Long- and Short-Term Goals to Anticipated Rehabilitation Outcomes

P.B. is a 20-year-old man with C8 tetraplegia beginning multidisciplinary inpatient rehabilitation. The following examples of outcome and long- and short-term goals are not meant to be exhaustive lists of intervention plans but rather to illustrate the linkage between global outcome projections and therapy plans.

- Projected outcome of rehabilitation stay: In 8 weeks, P.B. will resume self-maintenance roles, requiring no more than occasional physical assistance from family members to manage in the home environment.
- Examples of long-term occupational therapy goals (to be achieved in 8 weeks):
 - 1) P.B. will perform upper body dressing independently and require no more than moderate assistance for lower body dressing.
 - 2) P.B. will use adaptive equipment to feed himself independently.
- Examples of short-term occupational therapy goals (to be achieved in 2 weeks):
 - 1) P.B. will don a pullover shirt with no more than general verbal cues.
 - 2) P.B. will participate in the evaluation of various types of adaptive equipment for self-feeding and use selected aids to feed himself independently after set up by therapist.

DEFINITION 3-2

de·fin·i·tion

Goal Attainment Scaling

Goal attainment scaling is a method for evaluating the effectiveness of therapy that produces a quantitative index of patient progress over time and a means by which one patient's progress can be compared with other patients in the same program (Ottenbacher & Cusick, 1990). Goal attainment scaling was developed for use in the mental health field (Kiresuk & Sherman, 1968) and has been used to measure change as a result of cognitive rehabilitation (Rockwood, Joyce, & Stolee, 1997) and brain injury rehabilitation (Joyce, Rockwood, & Mate-Kole, 1994; Trombly, Radomski, & Davis, 1998; Trombly et al., 2002).

For each goal, a 5-point behaviorally defined scale is constructed as exemplified below. Ottenbacher and Cusick (1990) provided an excellent summary regarding how quantitative outcome data can then be calculated and interpreted.

Problem area: Patient relies on other people to make transportation arrangements for her.

Predicted Attainment	Score	Goals
Most favorable outcome	+2	Patient accurately makes her own transportation arrangements without supervision or assistance.
Greater than expected outcome	+1	Patient accurately makes her own transportation arrangements with occasional cueing.
Expected outcome	0	Patient accurately makes her own transportation arrangements with ongoing supervision.
Current status	-1	Patient is provided with information about transportation arrangements made for her.
Least favorable outcome	-2	Patient is unable to successfully use transportation information provided for her.

upper and lower extremity dressing, and toilet and tub transfers. Despite the potential benefits, collaborative goal setting is challenging for newly disabled patients. Patients typically have relatively passive roles during the acute medical management of their disabling condition or illness but, upon transfer to the rehabilitation unit, are expected to actively participate in planning a process about which they are utterly unfamiliar. Patients understandably have difficulty identifying and articulating goals because to do so requires that they anticipate future functioning, tasks, and skills not needed in their current setting (Struhkamp, 2004). Patients' expectations of therapy depend on their previous experience in similar situations, background, experiences of friends and relatives (Wade, 1999), state of health and mind, and long-held priorities and values.

Collaborating with patients in goal setting is a critical counterbalance to therapist-biased expectations and priorities in treatment planning (Procedures for Practice 3-2); it reflects a philosophy of care rather than simply a periodic conversation between therapist and patient (Cott, 2004). This practice philosophy requires that therapists tolerate the stress that can occur during goal setting (Foye et al., 2002) and remain attentive and flexible as patients' goals change throughout the recovery and adaptation process (Donnelly et al., 2004). Therapists appreciate that most patients must be taught how to participate in goal setting

(Nelson & Payton, 1997), probing for concerns, goals, and ideas. Asking a patient, "What are your occupational therapy goals?" is likely to be met with a perplexed look and a vague response. As one patient put it, "Asking one question about goals on an initial evaluation is probably not adequate" (Nelson & Payton, 1997, p. 582). Clearly, the time and energy invested in collaborative goal setting not only benefits patients but contributes to the empathic partnership that holds so much reward and satisfaction for therapists (Gahnstrom-Strandqvist et al., 2000).

Select Treatment Approaches and Methods

In Chapter 1, Trombly describes two broad therapy approaches that aim to improve clients' effectiveness and satisfaction with occupational roles: remedial therapy and adaptive therapy. Before proceeding with intervention, occupational therapists consider the patient's strengths and weaknesses based on assessment findings to select a treatment approach that will achieve expected outcomes and meet collaborative goals for therapy. In so doing, clinicians consider the extent to which a given treatment approach places demands on the patient's metaprocessing abilities (self-awareness, self-monitoring, and motivation), therapy time needed to improve occupational function, and potential for generalization of results.

PROCEDURES FOR PRACTICE 3-2

Suggestions for Collaborating with Clients to Set Meaningful Occupational Therapy Goals

- Incorporate life history information into the assessment process so that you are able to get a glimpse of what the patient has found meaningful and important during the course of his or her life events (Spencer, Davidson, & White, 1997). Awareness of the patient's personal context enables the clinician to discuss, frame, or propose possible therapy outcomes and goals in ways that the patient will understand.
- Appreciate that patients' ability to identify and advance their goals for therapy will be influenced by where they are in recovery and adaptation process. Individuals who are acutely ill or whose hospitalization has insulated them from the real-world impact of newly acquired disabilities will often be unable to anticipate the challenges that await them in the community. Outpatients or home-based clients are typically more able to articulate needs and hopes for therapy because of their experiences with performance gaps.
- Consider the broad continuum of care (inpatient to home health to outpatient to work reentry) as you aim to match the "right" goals with the "right" time frame by asking, "what does the person both value and need from occupational therapy at this point in his or her recovery?"
- Appreciate that most patients are unfamiliar with occupational therapy services and what we have to offer them and, therefore, are unable to independently generate goals for therapy. The therapist sometimes facilitates collaborative goal setting by proposing a menu of possible goals to address in therapy and modifying that list with the patient.
- Acknowledge the influence of cognitive function on a person's capacity to set meaningful goals. For a person to establish a meaningful goal, he or she must first accurately appraise his or her current status and compare it to past or premorbid performance. The individual must be able to imagine what is both possible and likely (given present condition and status) and how much time and effort is required to attain what is envisioned. Solicit input from family if the patient seems unable to independently determine or communicate his or her goals for therapy.
- If you are unable to arrive at consensus of broad therapy outcomes, try to agree on short-term goals. For example, a patient who is 3 months post brain injury wants only to work toward resuming his career as an air-traffic controller, a broad outcome the clinician views as unrealistic. Instead of haggling over what the future may or may not hold for this individual (which dampens energy, hope, and motivation), the patient and therapist agree that, to return to work, he needs to be able to independently get ready each morning, and begin their work there.

Remedial Therapy

Remedial therapy aims to restore an impaired capacity or ability with the expectation that this improvement will bring about general change in the patient's activities, tasks, and roles. For example, a therapist may base the treatment plan for a patient with an incomplete C8 spinal cord injury on the premise that, if upper extremity strength is optimally restored, the patient will not only become independent in grooming but also be more efficient with meal preparation and work tasks. Remedial approaches typically address body structures and functions (World Health Organization, 2001), which comprise client factors in the Occupational Therapy Practice Framework (AOTA, 2002). In general, remedial therapy places low demands on metaprocessing, but because it aims to fix underlying impairments, it may be somewhat slow to affect occupational function. A remedial approach is often emphasized when patients are in the early stages of recovery and rehabilitation.

Adaptive Therapy

Adaptive therapy is used when (1) a remedial approach does not result in full restoration of a patient's premorbid capacities and abilities or (2) the patient wants to optimize

his or her level of independence while continuing to work toward restoration of fundamental capacities and abilities. For example, an inpatient with hemiplegia receives remedial therapy to improve upper extremity strength and function after a stroke but also learns one-handed dressing techniques (adaptive therapy) to facilitate independent discharge to home. Adaptive therapy entails three possible therapy actions: changing the context, reestablishing habits and routines, and acquiring compensatory skills and strategies.

CHANGING THE CONTEXT

Context changes focus on changing factors that are external to the patient to improve occupational function (e.g., changing the demands of the task or environment, changing the tools used, changing the social supports or expectations). For example, using a range timer, which automatically turns off the stove at a predetermined time, may allow a person with memory impairment to cook without an undue safety risk. Installing grab bars in a patient's bathroom may dramatically increase the patient's ability to carry out self-maintenance tasks. Negotiating changed work responsibilities with an employer may enable a newly injured worker to keep his or her job.

Changing the context generally places low metaprocessing demands on the patient and can result in rapid improvements in occupational function, especially changes to physical aspects of context. The effects of intervention, however, are often task specific and do not necessarily generalize to other activities, tasks, and roles.

REESTABLISHING HABITS AND ROUTINES

With enough repetition and consistency, people perform many daily occupations efficiently and accurately with little or no conscious attention (that is, automatically). For example, most people have a consistent procedure for morning hygiene and dressing that rarely changes from one day to the next. These routines or habits let people expeditiously carry out frequently performed activities with minimal attentional load. After a disabling injury or illness, many patients need assistance either to reestablish existing routines or to create new ones that better match changed capacities and abilities. (Chapter 29 has a detailed discussion of how habits and routines are reestablished or created.)

Patients need to be motivated or at least compliant enough to carry out a consistent series of steps necessary to reestablish habits and routines, but they do not necessarily need insight into their deficits and an understanding of the rationale of this approach. Because there is virtually no expectation of generalization (e.g., reestablishing a morning self-care routine will have no effect on the efficiency with which one does the laundry), patients should work on reestablishing habits and routines in the environment in which those routines will be used.

ACQUIRING COMPENSATORY SKILLS AND STRATEGIES

Occupational therapists teach patients new skills and strategies that allow them to compensate for permanent or temporary impairments. For example, a person with lower extremity weakness or paralysis acquires new skills for moving from the wheelchair to bed. An individual with multiple sclerosis learns energy conservation strategies that allow her to optimize her productivity; a person with brain injury learns techniques that help him get to appointments on time despite ongoing memory impairment. (Chapter 14 discusses how people learn new skills and strategies.)

Learning new skills and strategies generally takes longer to affect occupational function than, for example, changing elements of the physical context. Acquiring the skills to transfer in and out of a wheelchair, however, may have benefits that generalize to a variety of activities and tasks, thus enabling performance of a number of occupational roles. To benefit from this approach, patients must appreciate the importance of the new skills and strategies, be motivated to participate in training, and be capable of recognizing opportunities in which the new skills and strategies can be used.

Determining the Optimal Treatment Approaches

Occupational therapists use diverse sources of evidence in identifying the most appropriate intervention plan for a specific client, including client perspectives and research evidence (Lee & Miller, 2003). Clinicians evaluate the available research evidence to determine the extent to which a specific research study and/or evidence review are relevant to the patient and clinical circumstances. They judge its quality based on classes of the evidence, such as randomized controlled studies, case-control research, case series, and expert opinion (Whyte, 1998). Furthermore, they evaluate the validity of a study's results by asking the following questions (Sackett et al., 1997): (1) Were patients randomly assigned to experimental and control conditions, and was the randomization concealed? (2) Were all patients who started the study accounted for at its conclusion? (3) Were patients' outcomes analyzed in the groups to which they were randomized? (4) Were the patients and clinicians blind to the experimental and control conditions? (5) Did all treatment groups receive comparable treatment except for the treatment under study? (6) Is my patient similar to those enrolled in the study?

The rehabilitation literature does not always conclusively point to a single treatment approach for a given set of problems. In such cases, Radomski and Davis (1999) suggest that clinicians weight the amount of treatment time and effort devoted to various intervention approaches based on the best available evidence and the patient's capacities, abilities, goals, and resources. They proposed the concept of a treatment fraction—the deliberate distribution of treatment efforts across appropriate treatment approaches to achieve goals. For example, with a woman acutely recovering from Guillain-Barré syndrome, the treatment fraction might look something like this: 40% of therapy efforts directed at remedial therapy (intervention focusing on improving strength and endurance); 35% directed at acquiring skills and strategies, such as learning modified self-care methods and energy conservation strategies; and 25% directed at changing the context (helping the patient make her home more accessible). When she returns to therapy as an outpatient, the treatment fraction changes: 20% of the therapy time is devoted to remedial therapy; 20% is devoted to changing the context (helping the patient's family shift roles and responsibilities around the patient's changing abilities); 25% is devoted to acquisition of skills and strategies; and 35% is devoted to reestablishing habits and routines. The distribution is dramatically different for a client with Alzheimer's disease; the therapist may choose to devote 80% of therapy time to changing the context (adapting the home environment and coaching significant others regarding how to respond when their loved one is confused) and 20% to establishing behavioral routines. Although no hard and fast rules exist for the correct weighting of therapy time and efforts, the

treatment fraction illustrates the importance of deciding how to spend therapy resources in pursuit of the patient's goals rather than exclusively subscribing to one approach or mindlessly shifting focus session by session.

Required Documentation: Evaluation Note

An occupational therapy evaluation note is added to the medical record when assessment and treatment planning are complete. Table 3-2 shows the purpose of this document and what must be included.

Implementing Intervention

Once therapists collaboratively determine therapy outcomes, goals, and approaches, treatment begins. Clinicians continue to make decisions regarding how the treatment is best delivered (one-on-one or group treatment) and by whom. The exception is when a clinical pathway dictates a predetermined therapy course that dovetails with intervention of other team members (see Definition 3-3).

How Treatment Is Delivered: Individual or Group Sessions

Occupational therapy occurs during one-on-one sessions with the patient or in dyads or small groups. Although clinicians must be sensitive to costs associated with providing services, they base scheduling decisions on each patient's unique needs and goals rather than solely on the clinician's convenience or efficiency.

Individual Treatment

Clinicians typically schedule individual sessions for assessment and reassessment. Individual sessions are also appropriate when patient privacy must be protected, such as during dressing training or when the patient seems particularly vulnerable or in need of emotional support. Patients who are easily distracted, such as those in early phases of recovery from brain injury, are also best treated individually.

Group Treatment

Groups typically consist of patients engaged in parallel activities, such as performing individualized exercise regimens at the same time and place, or in collaborative activity, such as preparing a meal together. Patients tend to be grouped according to similar goals, treatment, or education needs or similar diagnoses, conditions, or limitations. Beyond its value from an economic standpoint, group treatment offers many benefits to patients. Group therapy can facilitate the exchange of social support and

encouragement among patients as they derive hope for their own futures from observing others master similar challenges.

Who Delivers Treatment

Economic trends in health care require that the most appropriate person perform therapy tasks to optimize efficiency (Russell & Kanny, 1998). Occupational therapists make decisions about who will carry out the treatment plan (occupational therapist, occupational therapy assistant, and/or occupational therapy aide). Occupational therapists orchestrate the treatment plan and are ultimately responsible for service delivery (AOTA, 2004b). They typically spend their time conducting evaluations, identifying problems, planning solutions, and supervising implementation (Dunn & Cada, 1998; Glantz & Richman, 1997). Occupational therapy assistants spend most of their time delivering direct service and documenting results (Dunn & Cada, 1998; Glantz & Richman, 1997).

Required Documentation: Daily Contact Notes

Each time the patient is seen for assessment and treatment, the clinician documents the contact (Table 3-2).

Monitoring Progress

Clinicians constantly monitor clients' response to intervention and their progress toward goals. At regular intervals, typically weekly for inpatients and at least monthly for outpatients, clinicians formally reassess status relative to goals, analyze barriers and enablers to progress, evaluate effectiveness of the treatment approach, and make decisions about continuing, modifying, or discontinuing treatment. If short-term goals are met but long-term goals are not, the short-term goals are upgraded (Moyers, 1999). If short-term goals are not met or performance has leveled off, the therapist examines and possibly modifies the treatment approach, reflects on the caliber of his or her skills with the treatment methods, looks for transient explanatory factors, consults with experts, and/or considers discontinuing therapy.

Required Documentation: Weekly and/or Monthly Progress Notes

Progress notes document the formal examination of the patient's progress toward treatment goals (Allen, 1997). For outpatients with Medicare, therapists also must complete monthly recertification forms detailing the patient's progress toward goals, which must be signed by the patient's physician every 30 days.

Discontinuing Therapy

Therapy is discontinued when goals have been met, the patient's performance has leveled off or deteriorated in such a way that he or she is not benefiting from services, or the individual chooses to stop. Ideally, the patient and family participate in discharge planning, which entails setting up a maintenance program, referring to other services, and/or planning for follow-up.

- Set up the maintenance program. Patients and families receive instructions that allow them to extend the benefits of treatment after discharge. Therapists typically provide written and oral information regarding continued exercise, recommended equipment, and strategies or techniques that optimize function.
- Refer to other services. Many patients who discontinue occupational therapy at one site continue treatment at another level of care. For example, often persons receiving inpatient rehabilitation receive additional occupational therapy in long-term care facilities, through home health agencies, or as outpatients. To continue intervention seamlessly, therapists pass information along to the next tier of intervention. Therapists may also identify areas of need that are outside their scope of practice or competence and refer patients to appropriate disciplines or specialists.
- Plan for follow-up. Implicit in intervention plans geared to addressing the right issues at the right time in a patient's recovery and adaptation is the expectation that the therapist will not treat all possible problems during a given episode of care. A scheduled occupational therapy follow-up session is a mechanism by which the clinician can screen for the need for more services. A follow-up session is necessary when the patient improves, regresses, or anticipates changed needs or goals or when the social or environmental context changes (Moyers, 1999). Some clients are ambivalent about discontinuing occupational therapy, recognizing lack of progress but fearing abandonment and stalled recovery or deterioration. Planned follow-up assures patients that occupational therapy services will be available to them if needed in the future.

Required Documentation: Home Program, Referrals, and Discharge Summary

Not only are written home programs and referrals provided to the patient and referral source, these reports are also added to the medical record. The discharge summary provides an overview of services provided, outcomes, and recommendations. Allen (1997) suggested that creating this document can be a reflective process for the clinician, who considers goals met or not and factors contributing to or interfering with progress.

USING PRACTICE EXPERIENCE TO IMPROVE COMPETENCE

You, as an occupational therapy professional, are ultimately responsible for assessing, improving, maintaining, and documenting your own competence to practice (AOTA, 1999; Youngstrom, 1998). As Holm (2000) reminded us, high standards of competence are inextricably linked to high ethical standards. Competence has many dimensions, including knowledge, critical reasoning, interpersonal abilities, performance skills, and ethical reasoning (AOTA, 1999). Like occupational therapy services, continuing competence entails assessment, goal-directed action, and documentation.

Self-Assessment: Reflecting on Practice

The cornerstone of continuing competence is reflection on yourself and your practice. Therapists deliberately and regularly take stock of their status and determine their growth edges. Clinicians interested in growth ask for feedback from peers and formally review their own performance. Schell (1992) recommended that clinicians annually outline their strengths, areas needing improvement, accomplishments of the past year, and goals for the coming year (see Procedures for Practice 3-3 for suggestions).

Goal-Directed Action

Having assessed your professional strengths and weaknesses, you have many ways to improve your competence, including the following:

- Participate in your professional national and state occupational therapy associations. During volunteer service, you will encounter other occupational therapists who are committed to their profession and their own growth.
- Become a research-sensitive practitioner (Cusick & McCluskey, 2000). Make research evidence a vital part of the way that you provide services.
- Because even the most dedicated therapists make them (Schierton, Mu, & Lohman, 2003), commit to learning from your mistakes. Reflect on your errors or inefficiencies and consider what you would do should you face similar circumstances in the future. Be willing to discuss what you learn in this process with others.
- Establish a mentoring relationship. Mentors benefit from the relationship as they expand into new areas of practice, and proteges benefit from coaching and intellectual stimulation (Smith, 1992).

PROCEDURES FOR PRACTICE 3-3

Analyzing Your Competence

Clinicians use the answers to the following questions (based on AOTA Standards of Competence [1999] and Code of Ethics [2000]) to guide their responses to unfamiliar diagnoses, conditions, or problems. They determine whether they are competent to provide independent assessment and treatment or supervised assessment and treatment or if they should refer the patient to someone with more expertise.

1. Knowledge
 - Do I have adequate and up-to-date theoretical knowledge about this diagnosis, condition, or problem?
 - Do I have knowledge regarding any legislative, legal, or regulatory issues specific to this client's diagnosis, condition, or problem?
 - Do I have knowledge of any contraindications or precautions associated with treating this diagnosis, condition, or problem?
2. Critical Reasoning
 - Will I be able to recognize the appropriate response to treatment?
 - Will I be able to recognize potentially harmful primary or secondary effects of treatment?
 - Will I be able to decide how to respond to untoward responses to treatment?
3. Interpersonal Abilities
 - Am I competent to discuss the pros and cons of various methods to assess and treat this diagnosis, condition, or problem with the client?
 - Am I competently able to collaborate with other professionals specific to this diagnosis, condition, or problem?
4. Performance Skills
 - Is specialized training or certification required or recommended for treating this diagnosis, condition, or problem?
 - Am I skilled at using modalities, devices, or technology related to treating this diagnosis, condition, or problem?
 - Is the patient at risk of harm associated with inappropriate treatment of this diagnosis, condition, or problem?
5. Ethical Reasoning
 - Is my motivation to assess or treat this patient influenced by potential personal gain or profit?
 - Is there any conflict of interest related to my decision to treat or assess this patient?

- Keep a journal to document information and questions; to reflect on ideas, concerns, and beliefs; and ultimately to identify learning needs (Tryssenaar, 1995).
- Start a journal club at work in which clinicians regularly read and discuss research articles relevant to occupational therapy practice.
- Volunteer for medical record reviews and audits. By reviewing the documentation of others and submitting your documentation to the same scrutiny, you will learn how you can make your documentation clearer and more useful.

Documentation

Crist, Wilcox, and McCarron (1998) recommended that occupational therapists use “transitional portfolios” (p. 729) to plan and document their professional competence. More than a resume or a curriculum vitae, the transitional portfolio houses artifacts of completed and

exemplary work (e.g., certificates of attendance, awards, articles), in-process projects and plans for professional development, and a reflective journal with ideas, goals, feelings about one's reading, research, and work experiences. Clinicians may avail themselves of resources such as the Professional Development Tool (which includes self-assessments, professional development plans, and portfolio template) developed for members of AOTA (AOTA, 2003). By systematically collecting and organizing information and artifacts specific to accomplishments, progress, and goals, occupational therapists take responsibility for their present and future professional competence.

In summary, occupational therapists feel competent when clients achieve results that translate into meaningful improvements in their daily lives (Gahnstrom-Strandqvist et al., 2000). Such results can be achieved as clinicians combine their knowledge of evidence with their insights regarding patients' values and goals to plan and implement intervention that is not only effective but rewarding for patient and therapist alike.

CASE

EXAMPLE

Clinical Reasoning and Clinical Competence

Occupational Therapy Intervention Process

Patient Information

N.T. is a 71-year-old man who is 15 months post onset of right cerebral vascular accident and flaccid left hemiplegia. Shortly after his stroke, N.T. received intensive inpatient rehabilitation services and, upon discharge to his home, participated in outpatient occupational therapy 3 times per week for 2 months. He was discharged from outpatient occupational therapy having achieved independence in self-care and home-making activities. N.T. and his wife left Minnesota shortly thereafter for their winter home in Phoenix but have since returned.

He was referred back to outpatient occupational therapy because of concerns about left shoulder pain and subluxation. He presented with a 2-fingerwidth left shoulder subluxation, decreased shoulder passive range of motion (-20° external rotation, -25° shoulder flexion and abduction), and pain at extremes. He reportedly was not routinely wearing a sling while walking but indicated that he tried to keep his left upper extremity supported when sitting. He also reported that he tried to perform the self range-of-motion exercises that he learned after his stroke, but pain often interfered. He described his typical level of shoulder pain as varying between 6 and 8 on a 1–10 scale.

N.T. and his therapist decided to use a conservative approach to address his current shoulder problems. The therapist ordered a hemi-sling, taught him to don and doff it, and recommended N.T. wear it when walking. The therapist referred N.T. to physical therapy for ultrasound treatments, which were immediately followed by passive range-of-motion exercises in occupational therapy. N.T.'s wife attended 2 sessions and learned how to perform passive range of motion on her husband's shoulder. The therapist also helped N.T. implement strategies positioning the left upper extremity at bedtime and taught him ADL techniques that minimized the strain on his shoulder. Now after 6 sessions and 3 weeks of outpatient occupational therapy, N.T. has gained 5° in shoulder range of motion, but pain continues to interfere with daily activities as well as sleep. There has been no change in shoulder subluxation.

Clinical Reasoning Process

Objectives

Appreciate the context

Develop intervention hypotheses

Examples of Therapist's Internal Dialogue

"It is unfortunate that N.T. has developed shoulder problems, but I know that that's a fairly common problem after stroke. I thought that his pain might lessen if he simply got in the habit of wearing a sling again and if we could improve his shoulder range of motion. His wife seemed to quickly pick up on my instructions regarding how to handle the upper extremity and how to perform pain-free passive range-of-motion exercises. But I am concerned that N.T. is still having significant shoulder pain."

"I've been treating patients with stroke for over 3 years now, and based on my experience with other patients, I would've expected some improvement in N.T.'s shoulder pain by this point. I think that we should change the intervention plan."

Select an intervention approach

“The lead occupational therapist on my team suggested I consider trying neuromuscular electrical stimulation (NMES) on N.T.’s shoulder. I found a handful of outcome studies on PubMed and read the abstract of a systematic evidence review from the Cochrane Database. Although the 3 studies had methodologic problems (not one involved a randomized control group or standardized treatment protocol), my reading suggests that, at best, NMES might improve subluxation and decrease pain and, at worst, do no harm. It’s frustrating that I can’t find unequivocal direction from the literature, but between my reading and my conversations with the lead therapist, I would like to propose this course of action to N.T.”

Reflect on competence

“N.T. is interested in trying NMES but I need to think through whether or not I’m the right person to provide this intervention.

- I understand the rationale and research evidence for using this modality and it seems like an appropriate method of intervention, given N.T.’s pain and shoulder subluxation. (Scientific Reasoning)
- N.T. appears to understand what NMES involves and seems committed to attend sessions over the next month. I’m assuming he can continue to arrange transportation to his therapy. (Narrative Reasoning)
- I read the procedures, watched other therapists, and practiced applying electrodes. I am confident I can do this. However, my supervisor reminded me to check licensure requirements, and it is clear that I do not have the formal training required by the State of Minnesota to use physical agent modalities like NMES. (Pragmatic Reasoning)
- Even though I think I have the knowledge and technical skills to provide this intervention, I will need to make arrangements for another therapist to do so because of the state licensure requirements. I am going to continue to explore what I need to do to get the necessary credentials for the future.” (Ethical Reasoning)

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Using Types of Clinical Reasoning as a Self-Check of Competence

Consider the case example with just one change of circumstances. Let us assume that the therapist has recently just met the state licensure requirements for using physical agent modalities but has yet to use NMES on a patient. Describe at least one competency concern in the areas of Scientific, Narrative, and Pragmatic Reasoning as well as how you recommend that the therapist address that concern.

SUMMARY REVIEW QUESTIONS

1. Describe specific aspects of occupational therapy documentation that you think are critical information for the following target audiences: referring physician, physical therapist on the interdisciplinary team, payer, and family member.
2. Summarize ways a clinician's bias may affect clinical reasoning during each phase of providing occupational therapy services.
3. Draft two long-term and two short-term occupational therapy goals for a hypothetical client with multiple sclerosis whose anticipated outcome of therapy is to return to clerical work.
4. Write a brief statement (fewer than 25 words) that you could use to describe occupational therapy to a new client as a prelude to collaborative goal setting. Compare descriptions with classmates and then share with family and friends who know little about occupational therapy.
5. Compare and contrast the treatment fractions of two patients receiving occupational therapy services: a patient with a progressive condition like amyotrophic lateral sclerosis and a patient with an acute traumatic brain injury.
6. Describe what competence looks like in action specific to knowledge, critical reasoning, interpersonal abilities, performance skills, and ethical reasoning. Describe what incompetence looks like for each area.

SECTION II: Assessment of Occupational Function

CHAPTER 4

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Understand the nature and importance of assessment in occupational therapy.
2. Evaluate roles, competence, and occupational functioning, beginning with clients' perception of their occupational performance issues.
3. Understand the measurement criteria necessary for reliable and valid assessments for use in occupational therapy practice.
4. Describe and select appropriate validated assessments of competence in occupational performance (roles, tasks, and activities).

Assessing Roles and Competence

Susan E. Fasoli

Glossary

Activities of daily living (ADL)—Activities or tasks that a person does every day to maintain personal care. Also referred to as basic activities of daily living (BADL).

Instrumental activities of daily living (IADL)—Complex activities or tasks that a person does to maintain independence in the home and community.

Leisure—Activities or tasks that are not obligatory, are intrinsically motivating, and are done for enjoyment.

Life roles—Areas of occupation associated with self-maintenance (e.g., ADL, IADL), self-advancement (e.g., work, education), and self-enhancement (e.g., leisure) that involve specific tasks and activities (see Chapter 1).

Occupational performance—Ability of individuals to satisfactorily perform purposeful daily activities (occupations). This involves the dynamic transaction among the client, the context or environment, and the activity.

Reliability—The ability of an assessment to consistently measure performance and to differentiate among clients under various conditions (Finch et al., 2002).

Validity—The extent to which an instrument measures what it is intended to measure (Finch et al., 2002).

Work—An area of occupation that includes activities needed for engaging in remunerative employment or volunteer pursuits (AOTA, 2002).

Participation in the occupations of everyday life is a vital part of human development and the lived experience (Law, 2002). Occupational therapists provide services to optimize the **occupational performance** of persons who have or are at risk for developing occupational dysfunction. This chapter describes many assessments of occupational performance and competence in valued life roles, tasks, and activities. Later chapters discuss assessment of the abilities and capacities (components of occupational function) required to carry out the tasks and activities involved in various life roles.

The goal of occupational therapy is to enable individuals to achieve competency and satisfaction in their chosen life roles and in the activities that support function and participation in these roles. Such competency and satisfaction can be achieved through personal independence or by directing others, such as an attendant. Occupational performance is the ability to carry out basic **activities of daily living (ADL or BADL)**, **instrumental activities of daily living (IADL)**, education, **work**, play or **leisure**, and social participation (American Occupational Therapy Association [AOTA], 2002). Whenever a person has a health disorder, injury, or disease that results in a physical impairment, independence in these areas of occupation may be jeopardized. The evaluation of occupational performance often begins with a semi-structured interview to assess the client's needs, problems, and concerns regarding role participation and competence in daily living tasks and activities (AOTA, 2002). During this interview, the therapist gathers valuable information from the client and family members about the tasks and roles that are most important to them and about activities that the client can and cannot do. After identifying the client's areas of difficulty in occupational performance, the therapist completes further assessments (either impairment based or

disease specific) to clarify the factors that limit performance. If the limiting factors can be improved or eliminated by direct intervention, the therapist chooses an intervention approach that is appropriate for the problem. If, however, the limiting factors are not amenable to change, the therapist teaches the individual to compensate for these limitations by adapting the task or by changing the environment in which it is performed.

It is important to recognize that occupational performance, or the ability to carry out activities during daily life, depends on the individual's culture, gender, roles that he or she wishes to undertake, and environment (Law, 1991; Trombly, 1995a). Thus, occupational performance is a personal concept. The individuality of a person's roles and his or her day-to-day functioning make it both difficult and time consuming to assess all aspects of occupational performance. Therefore, it is important for the occupational therapist to carefully select evaluations that best measure a client's occupational performance needs. As outlined by Trombly (see Chapter 1), assessments should be done using a top-down approach that begins with an evaluation of roles, tasks, and activities. Life roles include self-maintenance (e.g., caregiver, home maintainer), self-enhancement (e.g., friend, movie-goer), and self-advancement (e.g., worker, student) (Trombly, 1995b).

This top-down approach to assessment includes consideration of the environment in which a person lives. Assessment does not ignore the more basic abilities, or performance skills, that enable occupational performance, such as strength, endurance, problem solving, or depth perception. Rather, it begins with a function-based assessment of the tasks and activities that the client needs, wants, or is expected to accomplish and is having difficulty performing (Law et al., 1998). Looking at this process from the

perspective of the World Health Organization's International Classification of Functioning, Disability and Health (ICF) (WHO, 2001), occupational therapists first assess activities and participation, evaluating impairments in body functions (i.e., performance skills) as needed to explain difficulties in performance. By beginning with a focus on the clients' needs and considering their roles and the environment in which they live, therapists acknowledge the values and goals that these individuals bring to occupational therapy. This approach reflects a change in philosophy to a client-centered approach, recognizing that it is the person who is engaged in therapy who should articulate the goals of therapy and drive the rehabilitation process (Law, 1998).

MEASUREMENT CONCEPTS

Several important measurement concepts must be considered when choosing evaluations to assess roles and competence in occupational therapy. These concepts include whether the assessment is a standardized measure with established **reliability** and **validity**, its responsiveness to change, its level of measurement and clinical utility, and whether it involves direct observation or self-report.

A standardized measure is a published assessment tool that provides detailed instructions on test administration and scoring and has published results of reliability and validity (Finch et al., 2002). A reliable assessment is one that consistently measures the attribute under study, no matter who is scoring (inter-rater reliability) or when the assessment occurs (test-retest reliability). A valid assessment is one that measures what it purports to measure. Most evaluations of occupational performance have content validity, meaning that the test items comprehensively represent the area being tested. Some items of a valid assessment, however, may be more important than others. For example, when assessing homemaker competence during meal preparation, “can use the stove safely” is more critical in many ways than “can stir batter.”

Use of the non-standardized checklists commonly found in the clinic is not recommended because of their inherent lack of reliability and validity. Because the tasks listed in non-standardized checklists are rarely operationally defined, the same methods are not necessarily used to evaluate task performance across clients and therapists. This is critical to establishing reliable and valid outcome measures. In today's demanding health care environment, it is essential that occupational therapists choose assessment tools that have strong evidence of reliably and validly evaluating changes in client performance.

An assessment that includes a wide range of test items will be more responsive to detecting impairments in occu-

pational performance. The responsiveness of an assessment refers to its ability to detect the minimal clinically important difference (MCID) or change in performance over the course of therapy. For a therapist working on a day-to-day basis with a client to improve her ability to dress, the assessment should be sensitive enough to allow progress to be noted when different areas of the body can be dressed or different articles of clothing applied. Responsiveness is directly related to the number of items on an assessment and to the number of categories on the scoring scale. An assessment with 50 items is likely to be more responsive than one with 10 items. The level of measurement also contributes to the test's responsiveness or sensitivity in detecting clinical change. For most evaluations of roles, tasks, and activities, the level of measurement is ordinal, that is, the scores are rank-ordered to indicate the client's performance. For example, scores might range from 1 (dependent, is unable) to 7 (independent, is able). The range of ordinal scores varies depending on the assessment scale. A scoring system that uses a 1–7 Likert-type scale is likely to be more responsive to changes in performance than one using a 1–3 scale.

Periodic reevaluations are performed to monitor the client's response to therapy. At a minimum, it is important to record the level of performance at admission and discharge because these records may be used for program evaluation, to justify service to third-party payers, in legal actions, or when determining whether a patient will be discharged home or to an extended-care facility. Discharge evaluations can also aid transitions from one level of care to the next (e.g., rehabilitation hospital to home-based therapy) by providing valuable information about the client's abilities and occupational performance needs.

The clinical utility of an assessment tool is another important consideration. Clinical utility refers to all of the practical factors of an instrument, such as its cost, the training required, availability of a manual with clear instructions, and the ease of administration and interpretation. In most occupational therapy settings, managers prefer to use assessments that are time efficient and provide information useful for planning and evaluating treatment.

Assessment of roles and competence by occupational therapists can take place in many different environments, such as a hospital, rehabilitation center, workplace, school, or community setting. It is important to note that the setting in which an assessment is performed can affect a client's performance. Research indicates that the results of an assessment performed at one location (e.g., rehabilitation center) do not necessarily predict performance in another location (e.g., home) (Brown et al., 1996; Rogers et al., 2003). For example, Park, Fisher, and Velozo (1994) reported that process skills were better when older adults completed IADL tasks in the familiar environment of their homes rather than the occupational

therapy clinic, while motor skills remained stable across settings. This research supports evaluation of a client's performance in the environment in which tasks ordinarily occur, whenever possible.

Standardized assessments gather information about occupational performance from either direct observation or self-report by the client or family members. Observation of activities that the client identifies as important is the most direct method of assessing competence in occupational performance. This method is preferred for accuracy, detection of inefficient or unsafe methods, and determining the underlying reason(s) that a particular task cannot be performed. Direct observation of the wide range of occupational performance areas, however, can be time consuming and costly (Law & Letts, 1989). Self-report of one's competence in occupational tasks and roles through interview is often the easiest, fastest, and least expensive method of assessing functional abilities.

There is a concern, however, that self-reports and interviews may not accurately reflect what the person can do. Studies that compared self-report ratings with direct observation of functional performance have yielded conflicting results. Some researchers reported high agreement between these two methods, especially for daily self-care tasks (Collin et al., 1988; Harris et al., 1986); others found that clients consistently overrated their abilities (Edwards, 1990; Sagar et al., 1992). If a client reports questionable data and does not permit direct observation, the therapist should verify the report with others who have knowledge of his/her actual performance. False information is not necessarily the result of a conscious intent to deceive but may reflect the fact that the client is in a health care facility and does not have an accurate sense of his or her abilities. In these cases, proxy reports and interviews with family members or caregivers can provide additional information about client performance from the family's perspective. Although self-report and direct observation in the environment where the task ordinarily occurs are preferred, the assessment methods chosen for a particular client ultimately will depend upon the nature of the disability, the supportiveness of the client's environment, and the time constraints encountered during rehabilitation.

Competence in occupational performance areas (e.g., ADL, IADL, leisure, work) is evaluated over time, based on the client's identified needs and interests. Assessments of self-care and personal mobility are usually done early because they form the basis for planning restorative therapy and/or adaptation to optimize ADL. As recovery continues and discharge plans are considered, further evaluations are used to assess a client's ability to manage home and childcare responsibilities, gain access to home and community, engage in leisure activities and family recreation, or return to valued education or work pursuits.

The assessments discussed in this chapter are generic measures that can be used to evaluate occupational

performance in clients with a variety of diagnoses and levels of disablement. Refer to the chapters that follow for specific measures that assess the effects of a particular disease or condition (e.g., orthopedic injuries, COPD) on occupational performance.

ASSESSMENT METHODS AND TOOLS

A comprehensive top-down assessment of occupational performance begins with an overview and identification of a client's occupational needs, is followed by evaluation of one's engagement and competence in life roles and tasks, and continues with an assessment of the abilities or performance skills (e.g., coordination, strength, organization, etc.) needed to accomplish valued activities. See Assessment Table 4-1 for descriptions, reliability and validity data, and strengths/weaknesses of the evaluations discussed in this chapter. Resources 4-1 has contact information regarding purchase of these assessments.

Identification of Occupational Performance Needs

A client-centered occupational therapy assessment recognizes that engagement in life roles and occupations of one's choice is a personal issue and that the client's perception is an important force that drives the occupational therapy process (Law et al., 1994). Information about a person's occupational roles and tasks, developmental stage, and the environment in which he or she lives is best obtained through interview. This can be done through informal narrative interviews or through more structured interview-based assessments. Specific information about occupational performance can be further obtained via evaluations that involve direct observation.

Neistadt (1994) discussed the weaknesses of basing occupational therapy goals on informal client interviews. Her research indicated that this unstructured process often leads to goals that are vague and not specifically related to occupation. The occupational therapist is advised to select a range of standardized assessments that incorporate semi-structured interviews to identify occupational need areas, as well as direct measures of abilities and skills during observation of task performance.

Semi-Structured Interview Assessments

A semi-structured interview assessment that is widely used to evaluate a client's perception of his/her occupational performance is the *Canadian Occupational Performance Measure (COPM)* (Law et al., 1998). The *COPM* helps clients to identify concerns with occupational performance, assists in goal setting, and measures changes in client

Assessment Table 4-1

Summary of Assessments

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Occupational Performance						
<i>Canadian Occupational Performance Measure (COPM)</i> (Law et al., 1998)	Semi-structured interview with ordinal scale to measure changes in client self-perception of performance in self-care, productivity, and leisure occupations.	20–40 minutes.	Numerous studies support <i>COPM</i> as a valid measure of occupational performance. Combined <i>COPM</i> and <i>FIM</i> scores were 65% accurate in predicting discharge status (Simmons, Crepeau, & White, 2000).	Test-retest intraclass correlation coefficients in rehabilitation setting: 0.80 for performance scores; 0.89 for satisfaction scores (Bosch, 1995).	Carswell et al. (2004) report <i>COPM</i> is more sensitive to perceived changes in client status than other disability measures, including <i>SF-36</i> and <i>FIM</i> .	Strengths: Psychometrics studied in wide range of diagnoses (Carswell et al., 2004); translated into 20 languages and used in more than 35 countries around the world.
<i>Occupational Performance History Interview-II (OPHI-II)</i> (Kielhofner et al., 1998)	Semi-structured interview intended to give a broad and detailed appreciation of a person's life history, the impact of disability, and the direction in which the person would like to take his or her life. Specific criteria are provided to rate performance on 3 scales: occupational competence, identity, and behavior.	45–60 minutes.	Validity for all 3 scales is excellent. More than 90% of subjects tested (with varied ages, nationalities, and diagnoses) were validly measured, and over 90% of raters used scales validly, with approximately same degree of severity or leniency (Kielhofner et al., 2001).	Refer to test manual.	Adequate. Person separation statistic showed that the scale can distinguish meaningful differences among persons of approximately 3 different levels of competence, identity, and environmental support (Kielhofner et al., 2001).	Strengths: Specific criteria assist with rating. Rasch analysis has been used to calibrate and convert ordinal scores to interval data. Weakness: Evidence of rater reliability not well reported in research literature.
Roles and Community Integration						
<i>Role Checklist</i> (Oakley et al., 1986)	Written inventory/checklist that provides data on client perceptions of role participation and values throughout the lifespan.	15 minutes.	Content validity of role taxonomy is based on literature review and expert opinion (AOTA, 1996)	Test-retest reliability median is $r = 0.82$ within a 2-week period.	Not established.	Strengths: Appropriate across age groups. Translated into 10 languages. Can be adapted for verbal administration by therapist.

<p><i>Craig Handicap Assessment and Reporting Technique (CHART)</i> (Whiteneck et al., 1992)</p>	<p>Interview administered in person or by phone to assess WHO dimensions of handicap. Each dimension (orientation, physical independence, mobility, occupation, social integration, and economic self-sufficiency) is scored on 100-point scale. These dimensions indicate level of participation in life situations.</p> <p><i>CHART-SF</i> (short form) closely approximates scores on original <i>CHART</i> in less time.</p>	<p>Long form can take 45 minutes to administer and score.</p>	<p><i>CHART</i> scores correlate significantly with therapist ratings of level of handicap. Rasch analysis supports construct validity of the <i>CHART</i>.</p>	<p>Inter-rater reliability is 0.69–0.84 between patient and family member ratings. Test-retest reliability is 0.80–0.95.</p>	<p>Not established.</p>	<p>Strengths: Allows level of handicap comparisons among and between diagnostic groups.</p> <p>Weaknesses: Structure doesn't allow client to specify which test items are most valued and in need of intervention.</p> <p>Dimension scores can only be calculated if all questions are answered.</p>
<p><i>Reintegration to Normal Living Index (RNLI)</i> (Wood-Dauphinee et al., 1988)</p>	<p>Eleven declarative statements re: how well clients return to normal living after a disabling event (e.g., "I am comfortable with how my self-care needs are met.") are rated by either a visual analog scale (VAS) or 3–4 point categorical scale. Index can be therapist administered, by self-report, or proxy. VAS scores are converted to 100-point scale for easy interpretation.</p>	<p>Less than 10 minutes.</p>	<p>Construct validity reported by significant correlations with <i>Quality of Life Index</i> and <i>Affect Balance Scale</i> (Law, Baum, & Dunn, 2001).</p>	<p>Test-retest reliability: $r = 0.83$ for community-dwelling elderly. Internal consistency determined by Cronbach's alpha for client, proxy, and health professional scores ranged between 0.90 and 0.95.</p>	<p>Not established.</p>	<p>Strengths: Emphasis placed on client's perceptions of autonomy in life situations.</p> <p>Weaknesses: Problems in <i>RNL</i> domains were more likely reported by proxy than client scores. These differed significantly at discharge and follow-up, reinforcing importance of self-report.</p>

continued

Assessment Table 4-1

Summary of Assessments (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Community Integration Measure (CIM)</i> (McColl et al., 2001)</p> <p>Primary author M. A. McColl may be contacted at: mcollm@post.queensu.ca</p>	<p>10-item, qualitative measure based on client-centered model of community integration. Client agreement with test statements is measured by 5-point scale. Sample items include: “I feel like part of this community, like I belong here” and “I know the rules in this community and I can fit with them.”</p>	<p>Approximately 5 minutes.</p>	<p>Criterion validity supported by comparisons with <i>Community Integration Questionnaire</i> and <i>Satisfaction with Life Scale</i> (Reistetter et al., 2005). Discriminant validity supported by the ability of CIM to differentiate persons with brain injury from neurologically intact controls.</p>	<p>Cronbach’s alpha for internal consistency reliability is 0.87.</p>	<p>Not established.</p>	<p>Strengths: Quick and easy to administer and score and readily understood by clients and families.</p> <p>Weaknesses: Psychometrics to date have only been examined with clients diagnosed with TBI, potentially limiting generalizability of this tool to other disability groups. Specific instructions to help OT relate test results with treatment planning are not provided.</p>
Activities of Daily Living (ADL)						
<p><i>Barthel Index</i> (Mahoney & Barthel, 1965)</p> <p>Information available online at www.strokecenter.org/trials/scales/barthel.pdf</p>	<p>Self-report and direct observation used to evaluate 10 activities: feeding, bathing, grooming, dressing, bowel and bladder control, toilet use, transfers between chair and bed, mobility, and stair climbing. The total score ranges from 0 (total dependence) to 100 (total independence).</p>	<p>5–10 minutes if self-report; 20–60 minutes for direct observation.</p>	<p>Adequately classified stroke survivors as dependent or independent. Kappa = 0.77 compared to Katz Index. Spearman rho = 0.73 (K = 0.42) compared to <i>Kenny Self-Care Evaluation</i>. (Granget, Albrecht, & Hamilton, 1979; Gresham, Phillips, & Labi, 1980).</p>	<p>Studies indicate excellent reliability (Fricke & Unsworth, 1996). Interrater reliability $r = 0.99$ with mixed diagnoses (Loewen & Anderson, 1988). Test-retest reliability Kappa = 0.98 in clients with stroke (Wolfe et al., 1991).</p>	<p>Lacks sensitivity to amount of assistance needed. Initially high-functioning clients can reach “ceiling” score and show no further improvement (Shah, Vanclay, & Cooper, 1989).</p>	<p>Strengths: Excellent reliability and validity. Widely used. Time to administer.</p> <p>Weaknesses: “Ceiling” effect for higher-level clients. Only fair sensitivity to change.</p>

<p><i>Functional Independence Measure (FIM)</i> (Granger et al., 1993; Keith et al., 1987)</p>	<p>18 items (13 motor, 5 cognition) in the areas of self-care, sphincter control, transfers, locomotion, communication, and social cognition. A 7-point ordinal scale rates level of independence in ADL (independent without equipment = 7). Scores are based on clinical observation. Follow-up data can be gathered from phone interviews.</p>	<p>Approximately 45 minutes, depending on client abilities.</p>	<p>Excellent validity reported. Motor <i>FIM</i> able to predict level of assistance required in 83% of TBI clients tested; cognitive <i>FIM</i> predicted 77% of patients requiring supervision (Corrigan, Smith-Knapp, & Granger, 1997).</p>	<p>Numerous studies have reported excellent reliability in wide range of diagnostic groups. Chau et al. (1994) reported inter-rater ICC at 0.94, test-retest ICC at 0.93.</p>	<p>Greater sensitivity to change reported in motor than cognitive scales in persons with stroke (van der Putten et al., 1999) and multiple sclerosis (Sharrack et al., 1999).</p>	<p>Strengths: Extensive validation; widely recognized and used. Excellent reliability and validity in measuring disability. Weakness: <i>FIM</i> scores do not provide information re: factors (e.g., body functions, environmental support) that influence occupational performance.</p>
<p><i>Katz Index of Independence in Activities of Daily Living</i> (Katz, 1963)</p>	<p>Six ADL functions are assessed through interview and observation. Test items include: bathing, dressing, toileting, transferring, continence, and feeding. Performance is rated on dichotomous scale (independent, dependent).</p>	<p>5–10 minutes; longer if performed.</p>	<p>Face, construct, and concurrent validity have been reported. Predictive validity demonstrates 0.50 correlation with mobility and 0.38 with house confinement (AOTA, 1996).</p>	<p>Inter-rater reliability is reported to be low (Brorsson & Asberg, 1984). No report of test-retest reliability.</p>	<p>Although sensitive to changes in declining health status, its responsiveness to small increments of change during rehabilitation is limited.</p>	<p>Strength: Quick and easy to administer. Weakness: Results are too general to be useful in treatment planning.</p>
<p><i>Klein-Bell Activities of Daily Living Scale</i> (Klein & Bell, 1982)</p>	<p>Behavior rating scale consists of 170 specific items to rate performance in 6 ADL areas: dressing, elimination, mobility, bathing/hygiene, eating, and emergency phone communication. Performance is observed and scored as either able or unable; scores are also weighted from 1–3 points based on item difficulty.</p>	<p>30 minutes depending on client's level of ability and fatigue.</p>	<p>Validity was established on 14 patients by comparing the total score at discharge against the hours of assistance required. A correlation of -0.86 ($p < 0.01$) was obtained, indicating that the amount of assistance decreases as the <i>Klein-Bell</i> score increases.</p>	<p>Inter-rater agreement = 0.92 even without extensive training (Klein & Bell, 1982).</p>	<p>Specificity of test items makes this test highly responsive to changes in client status.</p>	<p>Strengths: Highly responsive. Excellent reliability and validity. Appropriate for clinical purposes and research. Weakness: Higher level subjects may reach test "ceiling."</p>

continued

Assessment Table 4-1

Summary of Assessments (continued)

Instrument and Reference	Instrument and Reference	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Instrumental Activities of Daily Living (IADL)						
<i>The Assessment of Motor and Process Skills (AMPS)</i> (Fisher, 1993, 1995)	The AMPS is an observational assessment that evaluates motor and process skills that directly impact occupational performance. Client chooses 2–3 IADL tasks for assessment from a list of more than 50. Computerized scoring and Rasch methods are used to generate adjusted IADL ability measures. These take into account the severity of the rater who scored performance and the relative challenge of tasks performed.	30–60 minutes for administration and scoring.	Many published studies have demonstrated the validity of the AMPS. Validity as a cross-cultural measure has been reported.	Intra-rater reliability is excellent ($r = 0.93$). Test-retest reliability reported to be $r = 0.88$ for motor skills and $r = 0.86$ for process skills (Fisher, 1995).	Excellent responsiveness to client change has been reported.	Strengths: Excellent reliability and validity. Evaluation tasks are chosen by client and are meaningful and relevant to his daily life situation. Appropriate for use across ages (3 years to adult) and diagnostic groups. Weaknesses: Training requirements are extensive, and this has limited its clinical utility.
<i>The Kohlman Evaluation of Living Skills (KELS)</i> (Kohlman Thomson, 1993)	Self-report and observation assessment of 17 IADL tasks in 5 areas: self-care, safety and health, money management, transportation and telephone, and work and leisure. Items such as “use of money to purchase items” or “use of phone book and telephone” are scored as 0 (independent) or 1 (needs assistance). A score of 5% or less indicates that client is able to live independently.	30–45 minutes.	Concurrent validity studies that compared KELS with <i>Global Assessment Scale</i> (0.78–0.89) and <i>BaFPE</i> (–0.84) indicate high agreement.	Inter-rater reliability in multiple studies is reported to be high ($r = 0.84$ –1.00) (Kohlman Thomson, 1993).	Not established.	Strengths: Easy to administer. Few materials are required. Can be used in many settings and with many diagnostic groups. Weaknesses: Tasks provide good screening of basic abilities, but higher level clients may reach test “ceiling.”

<p><i>Safety Assessment of Function and the Environment for Rehabilitation (SAFER)</i> (Oliver et al., 1993)</p>	<p>The SAFER tool consists of an easy-to-use checklist of 97 items grouped into 14 areas of concern: living situation, mobility, kitchen, fire hazards, eating, household, dressing, grooming, bathroom, medication, communication, wandering, memory aids, and general issues. A combination of observation, interview, and task performance is used to rate each item.</p>	<p>Approximately 1–1.5 hours, depending on administration method, client’s functioning level, and home environment.</p>	<p>Excellent content validity based on OT judgments and statistical methods. Construct validity has been supported in relation to cognitive impairment, but further research is needed.</p>	<p>Internal consistency is excellent with Kuder-Richardson coefficient of 0.83. Inter-rater and test–retest reliability demonstrated via kappa (w) or % agreement was acceptable to excellent.</p>	<p>Poor. The SAFER tool was not designed to measure changes post intervention. A revised 93-item scale, the SAFER-HOME v.2, is being developed (Chiu & Oliver, unpublished manuscript).</p>	<p>Strengths: Clear assessment guidelines and recommendations. Weaknesses: The original SAFER tool was a binary scale that only noted the presence or absence of a safety problem. This has been expanded into a 4-point scale on the SAFER-HOME v.2 to increase its sensitivity to detect change. Reliability testing of the revised scale is ongoing.</p>
<p><i>The Kitchen Task Assessment (KTA)</i> (Baum & Edwards, 1993)</p>	<p>The KTA assesses 5 cognitive abilities during the task of making cooked pudding from a package: initiation, organization, safety and judgment, and task completion. The level of support provided by the therapist is scored from 0 (independent) to 3 (not capable). Unlike the AMPS, this measure does not evaluate motor skills during task performance. The KTA was developed for persons with dementia and Alzheimer’s disease.</p>	<p>Less than 30 minutes.</p>	<p>Construct validity was supported by highly significant correlations between KTA scores and other cognitive measures, including the <i>Token Test</i>, <i>Clinical Dementia Rating</i>, and <i>Blessed Dementia Scale</i>.</p>	<p>Internal consistency of the KTA ranges from 0.87–0.96, and inter-rater reliability for the total score is 0.85.</p>	<p>KTA scores significantly differentiated cognitive performance across all stages of dementia (Baum & Edwards, 1993). Sensitivity to client change over time has not been established.</p>	<p>Strengths: Good reliability and validity in lower functioning adults with dementia. Quick and easy to administer. Weaknesses: Little data to support KTA use with other rehabilitation populations (Duncombe, 2004). Higher functioning clients will easily reach test “ceiling.”</p>

Summary of Assessments (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Rabideau Kitchen Evaluation Revised</i> (Neistadt, 1992, 1994)</p>	<p>Direct observation of meal preparation tasks, such as preparing a hot beverage and cold sandwich. Each task is broken down into component steps that are rated on a 0 (no assistance needed) to 3 scale (unable and requires direct intervention) (Neistadt, 1994). Six levels of task difficulty help guide the grading of tasks, based on client abilities (highest level involves preparation of fruit salad or baking frozen pastries).</p>	<p>20–30 minutes depending on tasks performed.</p>	<p>Criterion validity reported with the WAIS-R block design test ($r = -0.60$, $p = 0.0002$), suggesting that both tests measure common skills. The correlation was negative because good performance is indicated by low scores on the Rabideau and high scores on WAIS-R.</p>	<p>Inter-rater reliability is $r = 0.86$. Test-retest reliability on a small sample yielded $r = 0.80$ (Neistadt, 1992).</p>	<p>Not established.</p>	<p>Strengths: Reliable kitchen assessment based on information-processing theory. Dynamic assessment approach indicates amount of cognitive support needed for task completion.</p> <p>Weaknesses: Primarily validated with persons with TBI, limiting generalizability to other diagnostic groups. Choice of tasks is limited by test design.</p>
<p>Work</p>	<p>Direct observation of work tasks selected to evaluate client's specific job requirements and needs. Work samples are keyed to worker traits, as listed in the <i>Dictionary of Occupational Titles</i> (DOT). Each work sample consists of a scoring manual and standardized equipment ranging from common items to large equipment. Examples of the dexterity module include small parts assembly, tool manipulation, and bimanual coordination.</p>	<p>Dependent on number of work samples tested. Samples range in time from 20–90 minutes.</p>	<p>The work samples have been criterion-referenced according to the Department of Labor's DOT, yielding good face and content validity (AOTA, 1996).</p>	<p>Test-retest reliability for work samples 1–16 of the original series ranged from 0.70–0.99 for work rate and accuracy scores over a 1-week interval (AOTA, 1996).</p>	<p>Measures are highly sensitive to detecting changes in client performance over time.</p>	<p>Strengths: High face validity and reliability. Normative tables provide error and time percentiles for each exercise.</p> <p>Weaknesses: High cost. Work samples emphasize physical components of work tasks and should be supplemented with assessments of worker interests, goals, and psychosocial/contextual factors influencing performance.</p>

<p><i>Worker Role Interview</i> (Veloza, Kielhofner, & Fisher, 1998; Biernacki, 1993)</p>	<p>A semi-structured interview that assesses psychosocial/ environmental factors of concern to the injured worker or client with a long-term disability and poor/limited work history. Complements observations made during other physical or behavioral work assessments; designed to identify specific variables influencing client's ability to return to work.</p>	<p>30–60 minutes and 15 minutes for scoring.</p>	<p>Content areas were based on a theoretical model, the <i>Model of Human Occupation (MOHO)</i>, and extensive literature review of factors that influence return to work.</p>	<p>Test–retest reliability for total score with a 6- to 12-day interval was 0.95. Inter-rater reliability was 0.81 with 3 raters (Biernacki, 1993).</p>	<p>Not established.</p>	<p>Strength: Test items reflect occupational therapists' interest in the meaning of work. Weakness: Time to administer can be lengthy.</p>
<p>Leisure</p>						
<p><i>Interest Checklist</i> (Matsutuyu, 1969; Rogers, Weinstein, & Figone, 1978)</p>	<p>Self-report questionnaire and 80-item interview checklist. Gathers data about a client's interest patterns over time (past, present, and future). Activities range from gardening and yard work, to bowling, watching television, and driving. Modified version with 68 items is recommended for use with <i>Model of Human Occupation (MOHO)</i>. The checklist can be used by adolescents or adults.</p>	<p>10–15 minutes.</p>	<p>Evident face validity. Rogers (1988) reports that <i>Interest Checklist</i> discriminates among diagnostic groups and normal control subjects.</p>	<p>Good test–retest reliability (0.92) within 3-week interval (Rogers, Weinstein, & Figone, 1978).</p>	<p>Not established.</p>	<p>Strengths: Quick to administer. Participation in wide range of activities can be assessed over time. Provides activity ideas for treatment planning (Klyczek, Bauer-Yox, & Fiedler, 1997). Weaknesses: Lack of strong validity and sensitivity data. Clients may misinterpret some items (e.g., level of participation is unclear: do clients perform vs. watch activities such as auto-racing, concerts?). Limited testing with clients who have physical vs. psychosocial disabilities.</p>

Assessment Table 4-1

Summary of Assessments (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Activity Index and Meaningfulness of Activity Scales</i> (Gregory, 1983)</p>	<p><i>Activity Index</i> is a self-report, ordinal measure of a client's interest and frequency of participation in a variety of leisure activities. <i>Meaningfulness of Activity Scale</i> provides additional information re: a client's autonomy, competency, and leisure enjoyment. Clients can rate up to 3 additional activities not included in the <i>Activity Index</i> list. Higher scores are moderately but significantly related to greater life satisfaction scores.</p>	<p>15–20 minutes.</p>	<p>Not established.</p>	<p>Test-retest reliability for the <i>Activity Index</i> was 0.70; for the <i>Meaningfulness of Activity Scales</i>, it was 0.87 (Gregory, 1983).</p>	<p>Not established.</p>	<p>Strengths: Acknowledges importance of leisure/occupational performance in retired persons. Test items are particularly relevant to elderly clients.</p> <p>Weaknesses: No published evidence of validity. Psychometrics only for older adults.</p>

<p><i>Leisure Diagnostic Battery</i> (Witt & Ellis, 1984)</p>	<p>Self-report/interview to assess a client's perceptions about his/her leisure experiences. The first 5 subscales are used to rate perceived competence and control in leisure activities, identify needs and depth of leisure involvement, and consider self-perceptions about playfulness. Test items are scored on a 1 (strongly agree) to 5 (strongly disagree) scale. Average scores from these subscales are summed to determine a perceived freedom in leisure score and identify problems for treatment planning.</p>	<p>30–40 minutes.</p>	<p>Content validity reported through factor analysis.</p>	<p>Cronbach's alpha was 0.96 for the total score, indicating excellent internal consistency (Peebles et al., 1999). Test-retest reliability: intraclass correlation coefficient of 0.72.</p>	<p>These scales appear to be responsive to changes in leisure performance after a recreation intervention.</p>	<p>Strength: Well-developed measure to assess client's perception of leisure involvement.</p> <p>Weakness: Further testing of validity is needed.</p>
-----------------------------------------------------------------------	--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----------------------	-----------------------------------------------------------	----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	----------------------------------------------------------------------------------------------------------------	-----------------------------------------------------------------------------------------------------------------------------------------------------------

perceptions of occupational performance over the course of therapy. The *COPM* is a generic measure that can be used with clients across all developmental stages who have a variety of disabilities. It is client centered and addresses roles, role expectations, and activity performance within the client's own environment.

The *COPM* is administered in a four-step process that includes problem definition, priority setting, scoring, and reassessment. During the initial *COPM* interview, clients or caregivers identify areas of ADL, work, and leisure that are important to them and are in need of occupational therapy intervention. For each occupational performance area, the therapist gives examples of typical activities, and the client indicates which of these he needs to, wants to, or is expected to perform. When a client identifies an activity he must do, current performance is explored. If the client is unable to perform the activity or is not satisfied with the way he completes it, that activity is listed as a problem for intervention. If a client does not report problems with activities in a given performance area, the next occupational performance area is explored. After all of the occupational performance problems are identified, clients score them in terms of importance, their perception of current performance, and satisfaction with that performance. It is important to recognize that a client with a new illness may not recognize or be ready to identify these issues. The therapist and the client may begin treatment by working on identified concerns and can return to this semi-structured interview process later to see if other issues emerge. Reassessment is completed at discharge or when the client and the therapist consider it necessary for further treatment planning (Fig. 4-1).

Another semi-structured interview assessment that is used to identify occupational performance needs is the *Occupational Performance History Interview-II (OPHI-II)* (Kielhofner et al., 1998). *OPHI-II* is an assessment of occupational life history in work, leisure, and daily activities that was developed using the Model of Human Occupation. The *OPHI-II* contains three valid scales that provide insight into the nature of occupational perform-

ance and adaptation. These scales measure occupational competence, occupational identity, and the settings or environments in which behaviors occur (Kielhofner et al., 2001). For example, test items explore a client's ability to organize time for responsibilities; identify interests, goals, and role expectations; recognize personal responsibilities and values; and participate in varied environments (e.g., leisure, home, and work settings). An accompanying Life History Narrative Form is used to document qualitative information from the interview. *OPHI-II* can be used with occupational therapy clients who are adolescents or older and who are seen in psychiatry, physical disability, or gerontology practices (Kielhofner et al., 1991).

Assessing Roles and Community Integration

Trombly (1995b) sorts life roles into three domains that correspond well to the Occupational Therapy Practice Framework (OTPF) (AOTA, 2002): self-maintenance, self-advancement, and self-enhancement (see Chapter 1). The most widely used role assessments in occupational therapy include the *OPHI-II*, which was already reviewed in this chapter, and the *Role Checklist* (Oakley et al., 1986). The *Role Checklist* is a two-part self-report assessment. Part I assesses participation in 10 major life roles: student, worker, volunteer, caregiver, home maintainer, friend, family member, religious participant, hobbyist/amateur, participant in organizations, and other. Test items address past, present, and future performance of these roles. Part II measures how valuable or important each role is to the client. This assessment has been used to evaluate the client's perceptions of role participation in persons with mental illness, mothers with young children, persons with physical disabilities, and adolescents.

Community integration refers to the ability of a person to live, work, and enjoy his or her free time within the community setting. A client's competence and ability to engage in community tasks and roles after a disabling event or illness is related to intrinsic abilities or performance skills as well as characteristics of the environment in which he/she lives. Although most of the following assessments emphasize the client's perception of his/her competence in community or societal integration, others, such as the *Craig Hospital Inventory of Environmental Factors (CHIEF)* (Whiteneck et al., 2004), focus on environmental factors that limit community integration. Knowledge of the content and focus of these assessments will help the occupational therapist choose tools that best measure and identify occupational performance areas and skills in need of intervention.

The *Craig Handicap Assessment and Reporting Technique (CHART)* (Whiteneck et al., 1992) was initially developed to evaluate the World Health Organization's (WHO) dimensions of handicap. Handicap, a term that reflects

Through an interview, clients identify occupational performance activities that are important to them and which they are having difficulties performing satisfactorily. These are scored on a 1–10 scale.

Activity Problems:	Importance	Performance	Satisfaction
Doing up fasteners	9	3	1
Washing face and hands	10	1	1
Preparing sandwich	5	1	4
Holding a book	7	3	5
Visiting friends	9	2	4

Figure 4-1 Example of the scores for the *Canadian Occupational Performance Measure*.

one's level of participation in life situations after a disabling event (WHO, 2001), describes the total effects of social, economic, cultural, and environmental consequences of disability at the societal level (Whiteneck et al., 1992). The *CHART* assesses a client's performance according to the six dimensions of handicap, or participation, outlined by the WHO: physical independence, cognitive independence, mobility, occupation, social integration, and economic self-sufficiency. Although the *CHART* was initially developed for persons with spinal cord injuries, long and short forms of this assessment have also been validated for persons with various diagnoses, including traumatic brain injury, stroke, burn, amputation, and multiple sclerosis.

The *Reintegration to Normal Living (RNL) Index* (Wood-Dauphinee et al., 1988) is an easy-to-use 11-item assessment of how well individuals return to normal living patterns following incapacitating disease or injury. Client perceptions of reintegration are measured along the following domains: indoor, community, and distance mobility; self-care; daily activity (e.g., paid and unpaid work, school); recreational and social activities; general coping skills; family roles; personal relationships; and presentation of self to others. A visual analog scale is used by the client to rate performance (Fig. 4-2). This assessment has been tested with a wide variety of diagnostic groups including patients with arthritis, fractures, amputations, stroke, spinal cord injury, traumatic brain injury, and hip fracture.

The *Community Integration Measure (CIM)* (McColl et al., 2001) uses 10 items to gather qualitative information about a person's experience of community integration and participation. It is based on a theoretical model that is client centered and differs from other community assess-

ments because it makes no assumptions about the relative importance of particular activities or relationships (McColl et al., 2001). For example, the *CIM* does not assume that independent participation is a better measure of community integration than supported or mutual participation with others. The client uses a 5-point Likert-type scale to rate his/her agreement with statements such as "I feel that I am accepted in this community" and "I know my way around this community." Although this easy-to-use measure was developed for and tested primarily with persons diagnosed with traumatic brain injury, it has been used in practice with clients who have a wide range of disabilities (McColl et al., 2001). The *CIM* is able to differentiate persons with and without disabilities and correlates significantly with other measures of community integration and life satisfaction.

Many assessments of health-related quality of life have been developed for use with persons with chronic illness. Examples of these assessments that have excellent reliability and validity include the *Sickness Impact Profile (SIP)* (Bergner et al., 1981) and the *Medical Outcomes Study (MOS) Short Form 36 (SF-36)* (Jenkinson, Wright, & Coulter, 1994).

Assessing Tasks and Activities

Occupational therapists use a variety of assessment tools to measure baseline and discharge performance in tasks and activities of importance to the client, including ADL, instrumental ADL, work, and leisure.

Activities of Daily Living (ADL)

ADL generally include mobility at home, feeding, dressing, bathing, grooming, toileting, basic communication, and personal hygiene (Trombly, 1995a). Direct observation of problem activities identified by the client should be done at the time of day when they are normally performed and, if possible, in the place where they usually occur. Remember that many people may have strong feelings of modesty regarding personal care, and those feelings should be respected. The client's endurance and safety should be closely monitored, and ADL performance can be evaluated over several therapy sessions if slow performance or fatigue occurs. Items that would be unsafe or obviously unsuccessful (such as tub transfers) are postponed until the patient's physical status improves. When the patient is not independent in a required task at the time of discharge, plans are developed to ensure that others can assist with this task and that additional therapy is received if warranted.

Most standardized ADL evaluations were designed for program evaluation to document the level of independence achieved by patients as the result of a particular program. Frequently cited ADL assessments used by occupational therapists are briefly described in the following paragraphs.

<p>I move around my living quarters as I feel necessary. (Wheelchairs, other equipment or resources may be used.)</p> <p>I am comfortable with how my self-care needs (dressing, feeding, toileting, bathing) are met. (Adaptive equipment, supervision, and/or assistance may be used.)</p> <p>I spend most of my days occupied in a work activity that is necessary or important to me. (Work activity could be paid employment, housework, volunteer work, school, etc. Adaptive equipment, supervision, and/or assistance may be used.)</p> <p>In general, I am comfortable with my personal relationships.</p> <p>I feel that I can deal with life events as they happen.</p> <hr/> <p>Each item is scored with a 10-cm visual analogue, with 10 as "fully describes my situation" and 1 as "does not describe my situation."</p>

Figure 4-2 Example of items on the *Reintegration to Normal Living Index*. (Reprinted with permission from Wood-Dauphinee, S., Opzomer, A., Williams, J. I., Marchand, B., & Spitzer, W. O. [1988]. Assessment of global function: The *Reintegration to Normal Living Index*. *Archives of Physical Medicine and Rehabilitation*, 69, 583–590.)

The *Barthel Index* (Mahoney & Barthel, 1965) evaluates 10 activities: feeding, bathing, grooming, dressing, bowel and bladder control, toilet use, transfers between chair and bed, mobility, and stair climbing. The total score for these 10 activities can range from 0 to 100 (total independence), and the score for each activity is weighted according to its importance for independent functioning (Gresham, Phillips, & Labi, 1980; Mahoney & Barthel, 1965). A score of 60 seems to be the transition point from dependency to assisted independence. A modified version of the *Barthel Index* has been found to be reliable and valid when administered during a telephone interview (Korner-Bitensky & Wood-Dauphinee, 1995).

The *Functional Independence Measure (FIM)* (Granger & Hamilton, 1992) uses a 7-point ordinal scale to evaluate occupational performance for 18 items (13 motor and five cognition items) in the areas of self-care, sphincter control, transfers, locomotion, communication, and social cognition (Granger et al., 1993; Keith et al., 1987). The *FIM* is a basic measure of the severity of disability, not impairment. The scale rates a client's performance by taking into account his/her need for assistance from another person or a device. The *FIM* instrument is intended to measure what the person with disability actually does, whatever the diagnosis or impairment, and is scored according to information gathered by members of the rehabilitation team during client observation. The *FIM* can be used during rehabilitation to track changes in activities of daily living and provide data for program evaluation. It has been shown to predict functional status at discharge and length of rehabilitation stay (Heinemann et al., 1994). The *FIM* is part of a uniform data system that collects information about rehabilitation outcomes and effectiveness and is an integral part of the *Inpatient Rehabilitation Facility—Patient Assessment Instrument (IRF-PAI)* (Fig. 4-3) (UB Foundation Activities, Inc., 2004).

The *Katz Index* (Katz et al., 1963) evaluates six activities of daily living: bathing, dressing, toileting, transferring, continence, and feeding. Scoring is based on ontogenetic development of self-care skills (Gresham, Phillips, & Labi, 1980; Katz et al., 1963), and a 3-point scale is used to rate performance (independent, requires assistance, dependent). The *Katz Index* has been found to predict length of hospital stay, living situation 1 year after discharge, and mortality (Brorsson & Asberg, 1984; Asberg & Nydevik, 1991). Although the *Katz Index* is sensitive to changes in declining health status, it is limited in its responsiveness to small increments of change during rehabilitation. The *Katz Index* is quick to use, but its clinical utility is somewhat limited because it does not provide detailed information for treatment planning.

The *Klein-Bell Activities of Daily Living Scale* (Klein & Bell, 1982) documents a client's ability to perform in six basic ADL: dressing, elimination, mobility, bathing and

hygiene, eating, and emergency telephone communications. These ADL are broken down into 170 simple behavioral items, each of which is scored separately (Fig. 4-4). The large number of items makes the *Klein-Bell* one of the most responsive ADL assessments. Each item is scored as achieved (no physical or verbal assistance) or unable (assistance needed), and raw scores are converted to percentage scores to make the communication of results easier to understand. If the person can perform the test item with adapted equipment during the discharge evaluation, he or she is given credit for accomplishing that activity.

Instrumental Activities of Daily Living (IADL)

Although many IADL assessments include a few self-care items, their focus is primarily home management tasks such as meal planning, preparation, service, and cleanup; laundry; shopping for food and clothing; and routine and seasonal care of the home. Yard work and other maintenance tasks also might have been the responsibility of the patient prior to therapy and may require assessment and intervention. Frequently cited standardized IADL assessments used by occupational therapists are described in the following paragraphs.

The *Assessment of Motor and Process Skills (AMPS)* (Fisher, 1993, 1995) is an innovative observational assessment that was developed to reveal the relationship between an individual's performance of IADL tasks and the underlying process and motor skills that contribute to that performance. During the *AMPS* evaluation, motor and process skills are assessed concurrently with observation of functional performance. The client chooses to perform two or three familiar tasks from more than 50 possibilities described in the *AMPS* manual. Tasks offered to clients present a challenge to them, are not overlearned, and are appropriate to the client's environment, age, and culture (Fisher, 1993).

The *AMPS* uses a 4-point scale to assess performance of each IADL task by rating 16 motor and 20 process skill items. The motor skills (e.g., stabilizes, reaches, transports, etc.) are the actions observed during task performance that are thought to be related to underlying abilities in postural control, mobility, coordination, or strength. Process skills (e.g., sequences, initiates, adjusts) are used to organize and adapt actions during actual performance and represent the underlying attentional, conceptual, organizational, and adaptive capacities of the client (Park, Fisher, & Velozo, 1994). It is important to note that the *AMPS* is a test of skill in occupational performance and is not designed to evaluate the presence of neuromuscular, biomechanical, or cognitive impairments (e.g., strength, range of motion, memory) or underlying capacities. Unlike impairments and underlying capacities that often are evaluated sepa-

Scoring - Points in parentheses next to each item (either 1 or 2) are given if person is able to complete the activity. Use of equipment is allowed. Total score equals the addition of points for each item. Item is marked N/A if clearly not applicable.	

Figure 4-4 Example of items and scoring information for the *Klein-Bell ADL Scale*. (Used with permission from the University of Washington, Health Sciences for Educational Resources.)

rately from task performance, the motor and process skills of the *AMPS* are goal-directed actions that occur in the context of occupation. As a result, the *AMPS* is used to assess activities and participation, not body function or contextual factors (WHO, 2001).

Occupational therapists must attend a training workshop and become calibrated as a reliable rater before using the *AMPS*. Once trained, scoring of the *AMPS* is done by computer. The *AMPS* has been shown to discriminate well between people without disabilities and those with cognitive or physical disabilities. A significant advantage of *AMPS* is its flexibility in allowing the client to choose which tasks are used for assessment.

The Kohlman Evaluation of Living Skills (KELS) assesses daily activities in self-care, safety and health, money management, transportation and telephone use, and work and leisure (Kohlman Thomson, 1993). The *KELS* is a short living skills assessment that is administered through interview and direct observation. Individual items are scored as independent, needs assistance, or not applicable. Although originally created for use in short-term psychiatric units, it is also a good measure of IADL performance in elderly clients. When combined with other assessments and client input, the *KELS* data can help determine the environment that will allow a person to live as independently as possible.

The *Safety Assessment of Function and the Environment for Rehabilitation (SAFER)* tool was developed to provide

occupational therapists with a comprehensive, consistent measure to simultaneously assess safety and occupational performance in the home (Oliver et al., 1993). The *SAFER* tool assesses safety in 15 categories, including living situation, mobility, kitchen, household management, self-care, and recreation. Items in each category assess both the environmental situation and functional ability of the client. For example, the living situation category addresses whether stairs are in good condition, the presence of scatter rugs and electric cords, and environmental clutter that might impact home safety. The instruction manual includes a list of recommendations to help the occupational therapist identify solutions to difficult problem areas.

Kitchen Tasks

Two assessments of performance during kitchen tasks have been developed for use in occupational therapy. *The Kitchen Task Assessment (KTA)* (Baum & Edwards, 1993) uses the task of making pudding to assess the cognitive support required by persons with Alzheimer's disease to complete a basic cooking task. Thus, the *KTA* provides information about performance as well as components of occupation, such as initiation, sequencing, organization, and problem solving. There is a significant relationship between scores on the *KTA* and other neuropsychological assessments but limited evidence of its use with clients who have physical versus psychosocial and cognitive disabilities.

The Rabideau Kitchen Evaluation Revised (RKE-R) (Neistadt, 1992, 1994) is an assessment of meal preparation that was primarily developed for adults with brain injury. It tests the ability to prepare a sandwich and a hot beverage. All task components are scored according to the number of verbal cues or amount of physical assistance required for safe completion. This quick assessment can help with discharge planning by providing information about a client's safety and independence during basic kitchen tasks.

Child Care

Childcare and parenting activities include but are not limited to the physical care and supervision of children and the use of age-appropriate activities, communication, and behaviors to facilitate child development (AOTA, 2002). Because no standard evaluations exist, the occupational therapist must work with the client to identify and assess performance needs during required and valued childcare tasks, while taking into account the ages and personalities of the children involved. The *Canadian Occupational Performance Measure (COPM)* can be used to assess childcare concerns and to determine what interventions and adaptations may be needed to

enhance a client's competence and satisfaction in this area.

Work

Work assessments are used to determine whether an individual has the ability to perform necessary job skills and is otherwise prepared for employment in terms of work habits, work quality, ability to learn or acquire new skills, and ability to work with others as a team member, supervisor, or supervisee. Velozo (1993) described two categories of work evaluations: (1) standardized commercial evaluations such as those used in vocational rehabilitation, and (2) highly technical evaluations of physical and work capacity. He questioned whether these work evaluations truly reflect occupational therapists' interest in the meaning of work and emphasized our unique role in linking work evaluations to the psychosocial and environmental factors that contribute to client performance.

Standardized vocational evaluation systems use job analysis or work samples to determine an individual's ability to perform tasks similar to those encountered at work. In the United States, the *Dictionary of Occupational Titles* (United States Department of Labor, 1991) provides a taxonomy for measurement of work performance that lists specific job requirements, including skills and equipment. One standardized work assessment system that is often used is the *VALPAR Component Work Samples* (see Resources 4-1). The *VALPAR* system consists of a wide range of work samples that evaluate specific occupational performance skills (e.g., range of motion, problem solving, physical capacities, and mobility) during simulated job tasks. Although evidence of the reliability and validity for this standardized evaluation system is extensive, a potential disadvantage of the *VALPAR Component Work Samples* is its expense.

Because a large proportion of work evaluations are administered to clients who have musculoskeletal or soft-tissue injuries, their primary focus is on the physical capacities required for work tasks. Standardized Functional Assessments (FA) and Functional Capacity Evaluations (FCE) measure physical capacity (e.g., strength, endurance, and freedom from pain) during work-related tasks, such as lifting, sitting, and standing. In addition to evaluating a client's physical performance, however, a comprehensive work assessment must also include contextual information regarding the client's work environment, his medical condition and contraindications, and the whole person context in which he lives (e.g., information about non-work occupational activities such as homemaker, caregiver, or recreational roles) (Strong et al., 2004). Semi-structured interviews, such as the *Worker Role Interview* (Velozo, Kielhofner, & Fisher, 1998), can complement Functional Capacity Evaluations

by providing important information regarding the psychosocial and environmental factors that influence return to work. This well-established tool can be used to assess other behaviors considered important for work, such as punctuality, communication ability, ability to work with others, and grooming. The *Feasibility Evaluation Checklist* (Matheson et al., 1985) assesses the feasibility of a client's return to competitive employment and his potential for improvement in 21 work behaviors, including attendance, timeliness, workplace safety, and ability to accept supervision. Although the feasibility of competitive employment is an integral component of Functional Capacity Evaluations, reliability and validity data for the *Feasibility Evaluation Checklist* is not readily available in the research literature. See Resources 4-1 for contact information.

Recently developed online services from the Office of Disability Employment Policy (ODEP) of the United States Department of Labor are good resources for clients and occupational therapists. A wide range of information is provided, including links to a Job Accommodation Network that gives specific accommodation suggestions for persons with various diagnoses (see Resources 4-1).

Leisure

Leisure involves engaging in self-chosen, motivating, and goal-directed activities for amusement, relaxation, spontaneous enjoyment, and/or self-expression. Hersch (1990) pointed out that "the concept of leisure encompasses a multitude of meanings: the leisure event itself, the amount and frequency of the activity, its meaningfulness to the participant, and the social context" in which it is performed (p. 55). In fact, Hersch (1990) and Bundy (1993) have suggested that leisure, or the playfulness of an activity, depends on the characteristics of the activity rather than the classification of an activity as leisure. Leisure serves many purposes in one's life by fulfilling physical, social, and intellectual needs, particularly for the older adult (Hersch, 1990). Participation in valued leisure pursuits has been closely related to life satisfaction. The purpose of some assessments is to identify leisure interests (Matsutsuyu, 1969; Rogers, Weinstein, & Figone, 1978; Witt & Ellis, 1984); others evaluate performance and satisfaction with leisure activities (Gregory, 1983; Kloseck, Crilly, & Hutchinson-Troyer, 2001).

The *Interest Checklist* (Matsutsuyu, 1969; Rogers, Weinstein, & Figone, 1978) gathers information about a client's level of interest and participation in 80 different activities. Activities, such as dancing, playing checkers/chess, or sewing/needlework, are rated on a 3-point scale ranging from no interest to strong interest. Interests identified by the client can be used by the occupational therapist in

CASE

EXAMPLE

Optimizing Functional Recovery After Stroke

Occupational Therapy Assessment Process

Patient Information

E.B. is a 53-year-old married woman who experienced a left ischemic cerebrovascular accident 1 month ago while at work. She received tPA, a thrombolytic medication, within the first 3 hours of her stroke and is reported to have made excellent progress during 3 weeks of inpatient rehabilitation. She has recently been discharged home and is now being referred to outpatient rehabilitation for continued occupational, physical, and speech therapy. The OT discharge summary reports continued limitations in IADL tasks, with mild to moderate right-sided paresis and mild aphasia.

E.B. lives with her husband and 15-year-old daughter; her 19-year-old son is a college freshman who lives 4 hours from home. E.B. is an elementary school teacher who also coaches her daughter’s skating team and volunteers at the town library. Her husband has a demanding full-time job and travels 1–2 weeks per month. The occupational therapist focuses the initial occupational assessment on E.B.’s ability to resume self-maintenance roles and to engage in valued life roles and tasks now that she is home.

Assessment Process

The therapist selected the following evaluation tools: *Canadian Occupational Performance Measure (COPM)* to obtain information about the client’s perceived problems and priorities and the *Assessment of Motor and Process Skills (AMPS)* to assess IADL motor and process skills.

Clinical Reasoning Process

Objectives

Examples of Therapist’s Internal Dialogue

Understand the patient’s diagnosis or condition

“E.B. had a pretty significant stroke and would likely have had greater limitations in motor abilities and language if she hadn’t received such good care from emergency services. She is probably having difficulty using her dominant hand for daily tasks, and I wonder how she’s getting around and managing at home when her husband is at work.”

Know the person

“It must have been terrible for her to have a stroke while she was at work; at least it happened during lunch and not while she was in the classroom with her students. It sounds like she was pretty busy managing multiple roles as mother, teacher, coach, and volunteer, in addition to taking care of home responsibilities. I wonder how she’s dealing with this sudden change in routine.”

Appreciate the context

“It must be difficult for her husband and daughter to take on more home management tasks while she’s recovering from her stroke. I wonder if they have friends or other family members who can help with shopping, driving, etc.”

Develop provisional hypotheses

“Given her diagnosis and good rate of recovery, I think she’ll do well in therapy. I expect that her motor impairments will be the biggest barrier to regaining independence in home and leisure tasks. Her mild aphasia will likely limit her return to teaching, at least in the short term.”

Consider evaluation approach and methods

“Because of her mild aphasia, it might be difficult and a bit frustrating for her to verbally describe her priorities for therapy on the *COPM*. I’ll talk with the speech therapist to see if she might benefit from using a written list of activities to report concerns during this evaluation. It might also be helpful to have her husband present during the *COPM* to help clarify issues, as needed. The *AMPS* will give me the chance to observe how her right-sided paresis affects IADL performance and whether other cognitive and process-related impairments are a concern.”

Assessment Results

During an interview using the *COPM*, E.B. reported that it was very important for her to resume responsibilities in managing household tasks and fulfilling her roles as wife and mother. Planning and preparing meals and grocery shopping were very important to her. She expressed frustration with the clumsiness in her dominant right hand and with her low endurance and fatigue when walking a distance with a cane. She was very concerned about returning to her job as a teacher because of her mild aphasia and expressed a strong desire to help prepare her daughter's skating team for the state finals in 2 months.

The *AMPS* revealed that process skills were mildly impaired in the sequencing and organizing of chosen tasks. Although she required additional cues/support to initiate tasks, she showed good pacing once engaged and was able to adjust and adapt her approach to tasks when difficulties arose. Motor skills were mildly to moderately impaired, as she had difficulty reaching for items at or above shoulder height, lifting a medium sized sauce pan from the stove to sink, and manipulating items with her right hand. However, she was able to use her paretic right hand to stabilize and transport items during bilateral tasks. Extra time was required for task completion because she needed frequent rest breaks when performing IADL from an ambulatory level.

Interpret observations

“E.B. seems to have good awareness of her impairments and needs for therapy and is generally able to make her needs known despite her mild aphasia and word finding problems.”

“I wonder whether the problems E.B. had with sequencing and organizing tasks during the *AMPS* are related to the fact that she performed these in the rehab clinic and not at home. As she begins to take on more challenging tasks, it will be important to see how she performs in familiar versus unfamiliar settings.”

“It seems like E.B.'s mild hemiparesis is having the greatest impact on her performance of IADL, and she shows great determination and desire to improve the functional use of her right arm and hand. I'll administer a couple of stroke-specific assessments to get a better handle on her motor strengths and weaknesses so we can decide on a therapy program to best address these concerns. She's a great candidate for outpatient therapy.”

Occupational Therapy Problem List

1. Decreased participation and independence in IADL.
2. Impaired endurance and functional mobility, contributing to decreased productivity during IADL.
3. Reduced organizing and sequencing skills during IADL in an unfamiliar environment.
4. Mild to moderate hemiparesis RUE, impeding functional use of the limb during occupational tasks.

Synthesize results

“E.B. has experienced significant changes in her daily routine and ability to engage in important life roles and tasks since her stroke. I'll talk more with her family to see how they think she's coping with these changes. Although fatigue is common during early recovery from stroke, depression might also be affecting her initiation and reports of fatigue during IADL.”

“It will be important to get a better handle on E.B.'s ability to return to her coaching and teaching roles, but this will be a longer term process. First, I'll use the Interest Checklist to help identify meaningful activities to use in therapy so we can begin to work on problem areas and help her to feel more productive as she continues to recover from her stroke.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of the Environment on Cognitive Function

During the initial OT assessment, E.B. demonstrated some difficulty with initiating, sequencing, and organizing tasks during the *AMPS* and expressed concerns about returning to community and work roles.

How might the occupational therapist gain a better understanding of E.B.'s cognitive abilities during therapy? What task and environmental factors might exaggerate or minimize these problems? What other assessments might best help with clarifying occupational performance needs and planning OT treatment?

treatment planning and to determine changes in activity performance over time. The *Interest Checklist* can be used for clients throughout the lifespan, from adolescence through old age.

The revised *Activity Index* (Gregory, 1983) is a self-report assessment that determines a person's interest and frequency of participation in a variety of activities, ranging from card games and theater to quiet hobbies at home. When used in conjunction with the *Meaningfulness of Activity Scale*, it can be used to indicate a client's autonomy, competency, and enjoyment derived from leisure activities (Gregory, 1983). Scores on these combined scales were found to significantly correlate with life satisfaction in elderly persons (Gregory, 1983).

The *Leisure Diagnostic Battery* (Witt & Ellis, 1984) was designed to assess a client's perceptions about his/her leisure experiences. The first five subscales are used by the client to rate his/her perceived competence and control in leisure activities, identify needs and depth of leisure involvement, and consider self-perceptions about playfulness. Scores from these subscales are summed to determine a perceived freedom in leisure score, and identified problems are used for treatment planning. These scales appear to be responsive to changes in leisure performance after a recreation intervention. The *Leisure Diagnostic Battery* effectively discriminates adults who have chronic pain and physical injuries from persons without evidence of neurologic or physical dysfunction (Peebles et al., 1999).

Other assessment batteries are used primarily by recreational therapists to evaluate leisure interests and competence of clients receiving rehabilitation services. The *Leisure Competence Measure* is one example of assessments that are gaining evidence of reliability and validity (Kloseck, Crilly, & Hutchinson-Troyer, 2001). Please refer to Resources 4-1 for more information.

SUMMARY REVIEW QUESTIONS

1. Define self-report and direct observation methods of assessment. What are the advantages and disadvantages of these methods when evaluating a client's occupational performance?
2. Distinguish between IADL and basic ADL, and describe one standardized assessment for each.
3. What are three measurement concepts or psychometric properties of standardized evaluation instruments? Define each, and provide an example of how these properties might affect the results of occupational therapy assessments administered in the clinic.
4. What is the relationship between the assessment of occupational performance and development of the occupational therapy treatment plan?
5. Compare two different IADL measures. Describe the assessment and its psychometric properties, strengths, and weaknesses. Based on this information, which measure would you choose to evaluate a client recently admitted for outpatient rehabilitation services? Why?
6. A client-centered approach has been emphasized when assessing occupational roles and competence. List three ways in which this approach might influence occupational therapy intervention.

ACKNOWLEDGMENT

I thank Mary Law for her thoughtful work in developing and writing the previous edition of this chapter.

CHAPTER 5

LEARNING OBJECTIVES

After studying this chapter and practicing the skills described here, the reader will be able to do the following:

1. Evaluate range of motion of the upper extremity using a goniometer.
2. Use two different methods to determine the amount of edema of the hand.
3. Perform a manual muscle test to evaluate strength of the upper extremity.
4. Determine the functional strength of selected lower extremity musculature.
5. Determine functional endurance level.
6. Use a Visual Analog Scale to determine pain level.
7. Interpret the findings of the evaluations in this chapter.

Assessing Abilities and Capacities: Range of Motion, Strength, and Endurance

Nancy A. Flinn, Catherine A. Trombly Latham, and Carolyn Robinson Podolski

Glossary

Glossary

Active range of motion (AROM)—The amount of movement possible at a joint when the patient voluntarily moves the limb by muscle contraction.

Anatomical position—Standing straight with feet together and flat on the floor, with arms by the sides and hands facing forward. The zero position for ROM measurement.

Calibrate—To set an instrument at a known value according to a standard.

Contracture—Inability to move a body part because of soft tissue shortening or bony ankylosis.

Limits of motion—The beginning and ending positions of movement at a joint.

Maximum heart rate reserve (MHRR)—The difference between resting and peak exercise heart rates; measured in beats per minute (Whaley et al., 1997).

Maximum voluntary contraction—The greatest amount of tension a muscle can generate and hold only for a moment, such as in muscle testing.

Mechanical advantage—The position in which the muscle is able to generate greatest tension, that is, when it is longer than the resting length of the muscle. In this position, the passive tension generated by the viscoelastic properties of the muscle and its tendon combine with the active tension generated by the contraction of the muscle fibers to produce a maximum voluntary contraction. When the muscle is fully lengthened or shortened, the viscoelastic, or passive, tension is reduced.

Passive range of motion (PROM)—The amount of movement possible at a joint when an outside force moves the limb.

Reliability—Characteristic of a measuring instrument, indicating the stability of the instrument's findings over time between testers when properly administered under similar

circumstances (Portney & Watkins, 2000). Reliability is usually defined by a correlation coefficient (r) or an interclass correlation coefficient (ICC). An r or ICC of 1 indicates a perfect linear relationship between one variable (e.g., rater A's scores) and another variable (e.g., rater B's scores). An r of 0.85 or ICC of 0.75 is considered acceptable for measuring instruments. Reliability can be increased by controlling all variables that affect the scores other than the one being measured (e.g., change in ROM). Control is gained by keeping everything the same or by deleting some variables.

Standard deviation (SD)—A measure of dispersion indicating the variability within a set of scores. Low variability within the scores of a set of therapists indicates that the therapists are following the same protocol and the phenomenon being measured is unchanging; high variability indicates that the phenomenon being measured is unstable or that the therapists should control their test administration better.

To interpret a score, the therapist often compares it with norms (averages and SDs). The SD tells you where your patient's score falls in relation to the norm because you can relate it to the normal curve. In the bell-shaped normal curve, 1 SD is equal to approximately 68% of the area under the curve (34% on each side of the mean); 2 SD is equal to approximately 95% of the area under the curve; and 3 SD is equal to approximately 99% of the area under the curve. A score of 2 to 3 SD below the mean normative score indicates a limitation in need of treatment.

Tenodesis—The mechanical effect caused by the length of extrinsic finger flexors and extensors. When the wrist is flexed, the fingers tend to extend because the extensors are too short to allow full finger flexion and wrist flexion at the same time. Similarly, when the wrist is extended, the fingers tend to flex.

The assessments presented in this chapter are appropriate for patients who are unable to do or are restricted in doing the occupational tasks and activities important to them because of impairments in range of joint motion, strength, or endurance. Being able to move (mobility, or range of motion) and use extremities against resistance (strength) for an extended period (endurance) is essential for the completion of most occupational tasks. For example, a person who cannot fully flex the elbow, is too weak to lift a spoon to the mouth, or is too fatigued to lift the utensil repeatedly cannot eat a meal independently. Since deficits in abilities and capacities may lead to impaired occupational functioning, it is within the realm of occupational therapy to assess them. Keep in mind that occupational therapy assessments of mobility, strength, endurance, and pain focus on occupational functioning, and not on these abilities and capacities per se.

Furthermore, besides an individual's abilities and capacities, many variables, including environmental and contextual constraints, contribute to the ability to do an activity. Use of the assessments described in this chapter allows establishment of a baseline of the patient's abilities. Reassessment produces documentation of progress. With the demands for efficiency in health care delivery, it is essential that occupational therapists be skilled in their evaluations of patients.

MEASUREMENT OF RANGE OF MOTION

Normally, each joint can move in certain directions and to certain **limits of motion** determined by its structure and the integrity of surrounding tissues. Trauma or disease

that affects joint structures or the surrounding tissues can decrease the amount of motion at the joint and limit occupational functioning.

Measurement of joint range may be done actively or passively. **Passive range of motion** (PROM) is the amount of motion at a given joint when the joint is moved by an outside force. **Active range of motion** (AROM) is the amount of motion at a given joint achieved by the patient using his or her own strength. If AROM is less than PROM, there is a problem of muscle weakness (or tendon integrity in hands). AROM measurement, which is used as a supplement to the measurement of the strength of muscles graded poor minus (2-) or fair minus (3-), indicates small gains that would otherwise not be noted by the muscle test.

Evaluation of ROM should start with a quick functional AROM scan (Procedures for Practice 5-1). If no limitations in ROM that would interfere with occupational functioning are found during the functional AROM scan, record the range as within normal limits; no further testing is required.

If limitations are observed, the therapist attempts to move the joint through its full ROM. If the joint is free to move to the end range, the problem is with active motion. The limited active range is measured and recorded. If the

end range cannot be attained when the therapist moves the limb, the problem is with passive motion, and the limitation is measured and recorded.

A goniometer is used for measuring joint motion. Every goniometer has a protractor, an axis, and two arms. The stationary arm extends from the protractor, on which the degrees are marked. The movable arm has a center line or pointer to indicate angle measurement. The axis is the point at which these two arms are riveted together. A full-circle goniometer, which measures 0–180° in each direction, permits measurement of motion in both directions, such as flexion and extension, without repositioning the tool. When using a half-circle goniometer, it is necessary to position the protractor opposite to the direction of motion so that the indicator remains on the face of the protractor. A finger goniometer is designed with a shorter movable arm and flat surfaces to fit comfortably over the finger joints. Figure 5-1 shows each of these types of goniometers.

The therapist must place the axis and arms appropriately to ensure accuracy and **reliability** (Procedures for Practice 5-2). The specific placement of the goniometer for each joint is described and demonstrated in this chapter.

PROCEDURES FOR PRACTICE 5-1

Functional Active Range of Motion Scan

- The patient should be seated if possible.
- The patient should perform the motions bilaterally if possible. If not, the more normal side should move first to set a baseline for normal for this person.
- Observe for complete movements, symmetry of movements, and timing of movements.
- Demonstrate the movements if the patient has a language barrier or cognitive deficits.
- To estimate the amount of active movement in the following motions, give instructions such as these to the patient:

Motion	Examples of Instruction
Shoulder flexion (sagittal plane)	Lift your arms straight up in front and reach toward the ceiling.
Shoulder abduction (frontal plane)	Move your arms out to the side. Now reach over your head.
Shoulder horizontal abduction and adduction (horizontal plane)	Raise your arms forward to shoulder height. Move each arm out to the side, then back again.
External rotation	Touch the back of your head with your hand.
Internal rotation	Touch the small of your back with your hand.
Elbow flexion and extension	Start with your arms straight down by your sides. Now bend your elbows so your hands touch your shoulders.
Forearm supination and pronation	With your arms at your side and your elbows flexed to 90°, rotate your forearms so the palms of your hands face the floor and then the ceiling.
Wrist flexion and extension	Move one of your wrists up and down. Now, move the other one.
Finger flexion and extension	Make a fist, then spread your fingers out.
Finger opposition	Touch your thumb to the tip of each finger one at a time.

Figure 5-1 Three types of goniometers. The large full-circle goniometer (*top*) is used to measure large joints. The small finger goniometer (*bottom left*) has flat arms that fit over the fingers. The small half-circle goniometer (*bottom right*) is used to measure small joints, such as the wrist.

In addition to goniometer placement, multiple patient-related and environmental factors can affect accuracy and reliability of ROM measurements. Patient-related factors include pain, fear of pain, fatigue, and feelings of stress or tension. For the most accurate and reliable results, every effort should be made to make the patient physically and

emotionally comfortable, including talking to the patient and describing the procedure that is to follow. Environmental factors include time of day, temperature of the room, type of goniometer used, and training and experience of the tester. For the most reliable pre-test–post-test information, the same tester should use the same goniometer at the same time of day.

Reliability

Intra-rater reliability is consistently higher than inter-rater reliability for ROM testing using a universal goniometer. In one study of internal and external rotation measured in the supine position, intra-rater reliability was good ($r = 0.58\text{--}0.71$), and inter-rater reliability was fair to good ($r = 0.41\text{--}0.66$) (Awan, Smith, & Boon, 2002). In a second study, it was found that combined finger flexion measured with a ruler was a reliable measure when taken by different therapists but that goniometric measures of the finger joints were more reliable when a single therapist was involved (Ellis & Bruton, 2002).

Active motion measurements are more reliable than passive ones. In one study by Sabari et al. (1998), 30 adults were measured for both active and passive ROM for shoulder flexion and abduction in two positions, sitting and supine. The AROM measurements were more reliable than the PROM measurements for both positions (Sabari et al., 1998). Furthermore, the researchers found only a moderate range of agreement ($r = 0.64\text{--}0.81$) between goniometric measurements of shoulder movements with the patient sitting and supine. The authors concluded that the position of the patient can affect the ROM. Therefore, therapists should record the testing position, and the same position should be used each time the patient is retested. This chapter demonstrates measurement of shoulder ROM in a sitting patient because it measures shoulder mobility in the position more frequently used for functional task performance.

A multicenter study looked at the reliability of three goniometric techniques for measuring passive wrist flexion and extension: radial, ulnar, and volar-dorsal approaches. The study found the volar-dorsal approach to be slightly more reliable. The interclass correlation coefficient (ICC) was 0.93 for flexion and 0.84 for extension with the volar-dorsal approach, whereas the corresponding values were 0.88 and 0.80 for the radial approach and 0.89 and 0.80 for the ulnar approach (LaStayo & Wheeler, 1994). All three approaches are reliable, but they are not interchangeable. The therapist must be sure to document which approach is being used and use the same approach consistently to document progress.

It is commonly believed that experience plays a major role in the reliability of ROM measurements. A study of experience of the therapist and how it influences reliabil-

PROCEDURES FOR PRACTICE 5-2

Principles of Goniometer Placement

- Place the axis of the goniometer over the axis of motion. The axis of motion for some joints coincides with bony landmarks, but for others, it must be found by observing movement and finding the point around which the movement occurs. In that case, the axis of motion can change position during movement, so it is acceptable for the goniometer to be repositioned at the end of range. When the two arms of the goniometer are placed correctly, they intersect at the axis of motion (Triffitt, Wildon, & Hajioff, 1999), so it is more important to have the arms line up correctly. The axis placement then automatically falls in line.
- Position the stationary arm parallel to the longitudinal axis of the body segment proximal to the joint being measured, although there are some exceptions.
- Position the movable arm parallel to the longitudinal axis of the body segment distal to the joint being measured, with some exceptions.

ity of goniometric measurements found no dramatic difference in reliability between experienced and inexperienced therapists who were measuring foot position. All of the inexperienced therapists were uniformly trained on specific testing procedures (Somers et al., 1997). It may be inferred from this study that inter-rater reliability may be more dependent on training than experience.

Recording Range of Motion

Each measurement is accurately recorded on a ROM form, which the therapist signs and dates because a medical record is a legal document. Notation is made whether scores represent AROM or PROM. A sample form is provided in Figure 5-2. Any form should allow for recording the starting and ending positions (limits of motion) for each movement. When reading the goniometer, always state your results as a range using two numbers. The first number is the starting position of the extremity, and the second number is the limit of motion at end range. Two columns can be used for recording of initial and retest information. Both columns should be dated to allow for tracking and easy analysis of the patient's progress.

The most common method of determining ROM is the Neutral Zero Method recommended by the Committee on Joint Motion of the American Academy of Orthopaedic Surgeons (Greene & Heckman, 1994). In this method, the **anatomical position** is considered to be 0, or if a given starting position is different from anatomical position, it is defined as 0. Measurement is taken from the stated starting position to the stated end position. If the patient cannot achieve the stated starting and end positions, the actual starting and end positions are recorded to indicate limitations in movement. An example of this, using elbow flexion, is as follows:

0 to 150°: No limitation

20 to 150°: A limitation in extension (problem with the start position)

0 to 120°: A limitation in flexion (problem with end position)

20 to 120°: Limitations in flexion and extension (problems with start and end positions)

To record hyperextension of a joint, which may be occasionally seen in metacarpophalangeal or elbow joints, the American Academy of Orthopaedic Surgeons recom-

mends a separate measurement to describe the available ROM without confusion. For example, if 20° of elbow hyperextension (an unnatural movement) is noted, it should be recorded as follows:

0 to 150° of flexion

150 to 0° of extension

0 to 20° of hyperextension

If a joint is fused, the starting and end positions are the same, with no ROM. This is recorded as fused at X°. If a joint that normally moves in two directions cannot move in one direction, the ROM-limited motion is recorded as none. For example, if wrist flexion is 15–80° with a 15° flexion **contracture**, the wrist cannot be positioned at 0 or be moved into extension; therefore, wrist extension is recorded as none.

Because there are various systems of notations, each having its own meaning, it is important to clarify the intended meaning to ensure consistency among therapists and physicians within the same facility.

MEASUREMENT OF RANGE OF MOTION OF THE UPPER EXTREMITY

This chapter addresses ROM of the upper extremity, as most functional activities require upper extremity use and manipulation skills. Lower extremity ROM is typically measured by physical therapists who are interested in the ability to walk. References listed at the end of the chapter are good sources of information concerning measurement of lower extremity ROM.

For the measurements given here, unless otherwise noted, the patient is seated with trunk erect against the back of an armless straight chair, although the measurements can be taken with the patient standing or supine, if necessary. This procedure can be done actively or passively. For active movement, take special care to ensure that there are no substitutions of movement. For PROM, the tester supports both the body part and the goniometer proximal and distal to the joint, leaving the joint free to move. Practice is required for comfortable handling of the goniometer together with the movable body segment.

On the pages that follow, the reader will find narrative and pictorial descriptions to help in understanding and practicing measurement of range of motion of the upper extremity.

Patient's Name _____

Type of motion: AROM _____

PROM _____

Therapist's signature: _____

Figure 5-2 Sample range of motion recording form.

Shoulder Flexion

Movement of the humerus anteriorly in the sagittal plane (0–180°, which represents both glenohumeral and acromioclavicular motion) (Figs. 5-3 and 5-4).

Goniometer Placement

Axis

A point around which motion occurs through the lateral aspect of the glenohumeral joint; at the start of motion, it lies approximately 1 inch below the acromion process. At the end position, the axis has moved, and the goniometer must be repositioned.

Stationary Arm

Parallel to the lateral midline of the trunk.

Movable Arm

Parallel to the longitudinal axis of the humerus on the lateral aspect.

Possible Substitutions

Trunk extension, shoulder abduction.

Figure 5-3 Shoulder flexion, start position.

Figure 5-4 Shoulder flexion, end position.

Shoulder Extension

Movement of the humerus posteriorly in a sagittal plane (0–60°) (Figs. 5-5 and 5-6).

Goniometer Placement

Axis

A point around which motion occurs; it lies approximately 1 inch below the acromion process through the lateral aspect of the glenohumeral joint.

Stationary Arm

Parallel to the lateral midline of the trunk.

Movable Arm

Parallel to the longitudinal axis of the humerus on the lateral aspect.

Possible Substitutions

Trunk flexion, scapular elevation, and downward rotation, shoulder abduction.

Figure 5-5 Shoulder extension, start position.

Figure 5-6 Shoulder extension, end position.

Shoulder Abduction

Movement of the humerus laterally in a frontal plane (0–180°, which represents both glenohumeral and axioscapular motion) (Figs. 5-7 and 5-8).

Goniometer Placement

Axis

A point through the anterior or posterior aspect of the glenohumeral joint. Some people consider measurement from the anterior aspect safer because the patient's back can be supported against the chair, but it is preferable to measure women from the posterior aspect.

Stationary Arm

Laterally along the trunk, parallel to the spine.

Movable Arm

Parallel to the longitudinal axis of the humerus.

Possible Substitutions

Lateral flexion of trunk, scapular elevation, shoulder flexion or extension.

Figure 5-7 Shoulder abduction, start position.

Figure 5-8 Shoulder abduction, end position.

Horizontal Abduction

Movement of the humerus on a horizontal plane from 90° of shoulder flexion to 90° of shoulder abduction and beyond to the limit of motion (0–90°) (Figs. 5-9 and 5-10).

Goniometer Placement

Axis

On top of the acromion process.

Stationary Arm

To start, the arm is parallel to the longitudinal axis of the humerus on the superior aspect and remains in that posi-

tion, perpendicular to the body, although the humerus moves away. An alternative position of the stationary arm is across the shoulder, anterior to the neck and in line with the opposite acromion process. In this alternative position, the goniometer reads 90° at the start, and this must be considered when recording.

Movable Arm

Parallel to the longitudinal axis of the humerus on the superior aspect.

Possible Substitutions

Trunk rotation or trunk flexion.

Figure 5-9 Shoulder horizontal abduction, start position.

Figure 5-10 Shoulder horizontal abduction, end position.

Horizontal Adduction

Movement of the humerus on a horizontal plane from 90° of shoulder abduction through 90° of shoulder flexion, across the trunk to the limit of motion. The 90° of return motion from horizontal abduction is not measured. The motion is measured from 90° shoulder flexion across the trunk (0–45°) (Figs. 5-11 and 5-12).

Goniometer Placement

Axis

On top of the acromion process.

Stationary Arm

Parallel to the longitudinal axis on the superior aspect of the humerus in the starting position, it remains perpendi-

cular to the body, although the humerus moves away. The alternative placement given for horizontal abduction also applies in this case.

Movable Arm

Parallel to the longitudinal axis of the humerus on the superior aspect.

Possible Substitution

Trunk rotation.

Figure 5-11 Shoulder horizontal adduction, start position.

Figure 5-12 Shoulder horizontal adduction, end position.

Internal Rotation

Movement of the humerus medially around the longitudinal axis of the humerus (0–70°) (Figs. 5-13 and 5-14).

Goniometer Placement

Axis

Olecranon process of the ulna.

Stationary Arm

Perpendicular to the floor, which will be parallel to the lateral trunk if the patient is sitting up straight with hips at 90°. The goniometer reads 90° at the start, and this score

must be deducted from the final score when recording ROM. *NOTE:* If the patient is supine with the shoulder abducted to 90° and the elbow flexed to 90°, the stationary arm is perpendicular to the floor, with the movable arm along the ulna. The goniometer reads 0° at the start (Boone & Smith, 2000).

Movable Arm

Parallel to the longitudinal axis of the ulna.

Possible Substitutions

Scapular elevation and downward rotation, trunk flexion, elbow extension.

Figure 5-13 Shoulder internal rotation, start position.

Figure 5-14 Shoulder internal rotation, end position.

External Rotation

Movement of the humerus laterally around the longitudinal axis of the humerus (0–90°) (Figs. 5-15 and 5-16).

Goniometer Placement

Axis

Olecranon process of the ulna.

Stationary Arm

Perpendicular to the floor. The goniometer will read 90° at the start, and this must be considered when recording the ROM score.

Movable Arm

Parallel to the longitudinal axis of the ulna.

Possible Substitutions

Scapular depression and upward rotation, trunk extension, elbow extension.

Figure 5-15 Shoulder external rotation, start position.

Figure 5-16 Shoulder external rotation, end position.

Internal and External Rotation: Alternative Method

If shoulder limitation prevents positioning for the previously described method, the patient may be seated with humerus adducted to the side and elbow

flexed to 90° (Figs. 5-17 and 5-18). This method is inaccurate in internal rotation if the patient has a large abdomen. (Internal rotation, 0–80°; external rotation, 0–60°.)

Figure 5-17 Shoulder internal and external rotation, alternative method, start position.

Figure 5-18 Shoulder external rotation, alternative method, end position.

Elbow Flexion–Extension

Movement of the supinated forearm anteriorly in the sagittal plane (0–150°) (Figs. 5-19 and 5-20).

Goniometer Placement

Axis

Lateral epicondyle of the humerus.

Stationary Arm

Parallel to the longitudinal axis of the humerus on the lateral aspect.

Movable Arm

Parallel to the longitudinal axis of the radius.

Figure 5-19 Elbow flexion, start position (elbow extension).

Figure 5-20 Elbow flexion, end position.

Forearm Supination

Rotation of the forearm laterally around its longitudinal axis from midposition so that the palm of the hand faces up (0–80°) (Figs. 5-21 and 5-22).

Goniometer Placement

Axis

Longitudinal axis of the forearm displaced toward the ulnar side.

Stationary Arm

Perpendicular to the floor.

Movable Arm

Across the distal radius and ulna on the volar surface.

Possible Substitutions

Adduction and external rotation of the shoulder.

Figure 5-21 Supination, start position.

Figure 5-22 Supination, end position.

Forearm Pronation

Rotation of the forearm medially around its longitudinal axis from midposition so that the palm of the hand faces down (0–80°) (Figs. 5-23 and 5-24).

Goniometer Placement

Axis

Longitudinal axis of forearm displaced toward the ulnar side.

Stationary Arm

Perpendicular to the floor.

Movable Arm

Across the distal radius and ulna on the dorsal surface.

Possible Substitutions

Abduction and internal rotation of the shoulder.

Figure 5-23 Pronation, start position.

Figure 5-24 Pronation, end position.

Wrist Flexion (Volar Flexion)

Movement of the hand volarly in the sagittal plane (0–80°) (Figs. 5-25 and 5-26).

Goniometer Placement

Axis

On the dorsal aspect of the wrist joint in line with the base of the third metacarpal.

Stationary Arm

Along the midline of the dorsal surface of the forearm.

Movable Arm

Parallel to the longitudinal axis of the third metacarpal.

Figure 5-25 Wrist flexion, start position.

Figure 5-26 Wrist flexion, end position.

Wrist Extension (Dorsiflexion)

Movement of the hand dorsally in the sagittal plane (0–70°) (Figs. 5-27 and 5-28).

Goniometer Placement

Axis

On the volar surface of the wrist in line with the insertion of the tendon of the palmaris longus.

Stationary Arm

Along the midline of the volar surface of the forearm.

Movable Arm

Parallel to the longitudinal axis of the third metacarpal.

Figure 5-27 Wrist extension, start position.

Figure 5-28 Wrist extension, end position.

Wrist Ulnar Deviation

Movement of the hand toward the ulnar side in a frontal plane (0–30°) (Figs. 5-29 and 5-30).

Goniometer Placement

Axis

On the dorsal aspect of the wrist joint in line with the base of the third metacarpal.

One Arm

Along the midline of the forearm on the dorsal surface.

Other Arm

Along the midline of the third metacarpal.

Possible Substitutions

Wrist extension, wrist flexion.

Figure 5-29 Wrist ulnar deviation, start position.

Figure 5-30 Wrist ulnar deviation, end position.

Wrist Radial Deviation

Movement of the hand toward the radial side in a frontal plane (0–20°) (Figs. 5-31 and 5-32).

Goniometer Placement

Axis

On the dorsal aspect of the wrist joint in line with the base of the third metacarpal.

Stationary Arm

Along the midline of the forearm on the dorsal surface.

Movable Arm

Along the midline of the third metacarpal.

Possible Substitution

Wrist extension.

Figure 5-31 Wrist radial deviation, start position.

Figure 5-32 Wrist radial deviation, end position.

Thumb Carpometacarpal Flexion

Movement of the thumb across the palm in the frontal plane (0–15°) (Figs. 5-33 and 5-34).

Goniometer Placement

Axis

On the radial side of the wrist at the junction of the base of the first metacarpal and the trapezium.

Stationary Arm

Parallel to the longitudinal axis of the radius.

Movable Arm

Parallel to the longitudinal axis of the first metacarpal. For accuracy, the arms of the goniometer must remain in full contact with skin surface over the bones, but *excessive pressure with the edge of a half-circle goniometer must be avoided*. These statements apply to all flexion–extension measurements of the thumb and fingers.

Figure 5-33 Thumb carpometacarpal flexion, start position.

Figure 5-34 Thumb carpometacarpal flexion, end position.

Thumb Carpometacarpal Extension

Movement of the thumb away from the palm in the frontal plane (0–20°) (Figs. 5-35 and 5-36).

Goniometer Placement

Axis

On the volar side of the wrist at the junction of the base of the first metacarpal and the trapezium.

One Arm

Parallel to the longitudinal axis of the radius.

Other Arm

Parallel to the longitudinal axis of the first metacarpal.

Figure 5-35 Thumb carpometacarpal extension, start position.

Figure 5-36 Thumb carpometacarpal extension, end position.

Thumb Metacarpophalangeal (MP) Flexion–Extension

Movement of the thumb across the palm in the frontal plane (0–50°) (Figs. 5-37 and 5-38).

Goniometer Placement

Axis

On the dorsal aspect of the MP joint.

Stationary Arm

On the dorsal surface along the midline of the first metacarpal.

Movable Arm

On the dorsal surface along the midline of the proximal phalanx of the thumb.

Figure 5-37 Thumb metacarpophalangeal flexion and extension start position.

Figure 5-38 Thumb metacarpophalangeal flexion and extension, end position.

Thumb Interphalangeal (IP) Flexion–Extension

Movement of the distal phalanx of the thumb toward the volar surface of the proximal phalanx of the thumb (0–80°) (Figs. 5-39 and 5-40).

Goniometer Placement

Axis

On the dorsal aspect of the IP joint.

Stationary Arm

On the dorsal surface along the proximal phalanx.

Movable Arm

On the dorsal surface along the distal phalanx. *NOTE:* If the thumbnail prevents full goniometer contact, shift the movable arm laterally to increase accuracy. Also, thumb MP and IP flexion and extension can be measured on the lateral aspect of the thumb using lateral aspects of the same landmarks.

Figure 5-39 Thumb interphalangeal flexion, start position (extension).

Figure 5-40 Thumb interphalangeal flexion, end position.

Thumb Abduction and Opposition: Ruler Measurements

Abduction

Take the measurement from the midpoint of the head of the first metacarpal to the midpoint of the head of the second metacarpal while the thumb is in full abduction (Fig. 5-41).

Figure 5-41 Measurement of thumb abduction using a centimeter ruler.

Opposition

The pad of the thumb rotates to meet the pad of each finger. The little finger rotates to better meet the pad of the thumb. As a summary measure of opposition, record the distance from the tip of the thumb (not the thumbnail) to the tip end of the little finger (Fig. 5-42).

Figure 5-42 Measurement of opposition to the little finger using a centimeter ruler.

Finger Metacarpophalangeal Flexion–Extension

Movement of the finger at the MP joint in a sagittal plane (0–90°) (Figs. 5-43 and 5-44).

Goniometer Placement

Axis

On the dorsal aspect of the MP joint of the finger being measured.

Stationary Arm

On the dorsal surface along the midline of the metacarpal of the finger being measured.

Movable Arm

On the dorsal surface along the midline of the proximal phalanx of the finger being measured.

Figure 5-43 Finger metacarpophalangeal flexion, start position (extension).

Figure 5-44 Finger metacarpophalangeal flexion, end position.

Finger Proximal Interphalangeal (PIP) Flexion–Extension

Movement of the middle phalanx toward the volar surface of the proximal phalanx in the sagittal plane (0–100°) (Figs. 5-45 and 5-46).

Goniometer Placement

Axis

On the dorsal aspect of the PIP joint of the finger being measured.

Stationary Arm

On the dorsal surface along the midline of the proximal phalanx of the finger being measured.

Movable Arm

On the dorsal surface along the midline of the middle phalanx of the finger being measured.

Figure 5-45 Proximal interphalangeal flexion, start position (extension).

Figure 5-46 Proximal interphalangeal flexion, end position.

Finger Distal Interphalangeal (DIP) Flexion–Extension

Movement of the distal phalanx toward the volar surface of the middle phalanx in a sagittal plane (0–90°) (Figs. 5-47 and 5-48).

Goniometer Placement

Axis

On the dorsal aspect of the DIP joint of the finger being measured.

Stationary Arm

On the dorsal surface along the midline of the middle phalanx of the finger being measured.

Movable Arm

On the dorsal surface along the midline of the distal phalanx of the finger being measured. *NOTE:* If the fingernail prevents full goniometer contact, shift the movable arm laterally to increase accuracy. Also, finger PIP and DIP flexion and extension can be measured from the lateral aspect of each finger using the lateral aspect of the same landmarks. This method may be more accurate when joints are enlarged.

Figure 5-47 Distal interphalangeal flexion, start position (extension).

Figure 5-48 Distal interphalangeal flexion, end position.

Composite Measurement and Recording of Total Finger Flexion

A method of recording composite digital motion used by hand therapists is to sum the values for the degrees of flexion motion of the MP, PIP, and DIP joints, taking into consideration extension deficits (Ellis & Bruton, 2002). Total active motion (TAM) or total passive motion

(TPM) can then be expressed by a single number. The formula for calculating these values is as follows: (MP + PIP + DIP flexion) – (MP + PIP + DIP extension deficits) = TAM or TPM.

Another method for measuring combined flexion of the PIP and DIP joints (Fig. 5-49) or combined flexion of the MP, PIP, and DIP joints (Fig. 5-50), using a centimeter ruler, is illustrated in the figures.

Figure 5-49 PIP and DIP combined finger flexion; ruler measurement.

Figure 5-50 MP, PIP, and DIP combined finger flexion; ruler measurement.

Finger Abduction

Movement of the index, ring, and little fingers away from the midline of the hand in a frontal plane. The middle finger, which is the midline of the hand, abducts in both radial and ulnar directions (Figs. 5-51 and 5-52).

Goniometer Placement

Axis

On the dorsal aspect of the MP joint of the finger being measured.

Stationary Arm

Along the dorsal surface of the metacarpal of the finger being measured.

Movable Arm

Along the dorsal surface of the proximal phalanx of the finger being measured.

Figure 5-51 Finger abduction, start position.

Figure 5-52 Finger abduction, end position.

Finger Adduction

Movement of the index, ring, and little fingers toward the midline of the hand in a frontal plane (Figs. 5-53 and 5-54).

Goniometer Placement

Axis

On the dorsal aspect of the MP joint of the finger being measured.

One Arm

Along the dorsal surface of the metacarpal of the finger being measured. The middle finger is not measured.

Other Arm

Along the dorsal surface of the proximal phalanx of the finger being measured.

Figure 5-53 Finger adduction, start position.

Figure 5-54 Finger adduction, end position.

MP Deviation Correction Measurement

When there is ulnar deviation deformity of the metacarpophalangeal joints, often seen in rheumatoid arthritis, this additional measurement is taken (Figs. 5-55 and 5-56).

The active range is compared with the passive range to determine whether muscle weakness is present. PROM is compared with the norm of 0° deviation to determine whether a fixed deformity exists.

Figure 5-55 Metacarpophalangeal deviation correction, start position.

Goniometer Placement

Axis

Over the MP joint of the finger being measured.

One Arm

Placed along the dorsal midline of the metacarpal.

Other Arm

Placed along the dorsal midline of the proximal phalanx.

Figure 5-56 Metacarpophalangeal deviation correction, end position.

Interpreting the Results

The initial evaluation is interpreted by reviewing the recording form to identify which joints have significant limitation. A significant limitation is one that decreases occupational functioning or may lead to deformity. The therapist notes whether the limitation is the result of tissue changes ($PROM < \text{norms}$) or muscle weakness ($AROM < PROM$).

Limits of motion scores can be used in several ways. First, the therapist can compare the scores of the involved to the uninvolved extremity. A study of more than 1000 healthy male subjects, however, found a significant difference in ROM between the dominant and nondominant sides. The nondominant side had greater range in many of the upper extremity joints tested (Gunal et al., 1996). This information should be kept in mind when comparing the two sides. The patient's scores can be compared with the average limits (norms) expected for each motion. The average limits stated by the Committee on Joint Motion of the American Academy of Orthopaedic Surgeons (Greene & Heckman, 1994) are commonly used and are included here. However, patients may be functional with less ROM than is noted in the norms for particular joints. The emphasis in occupational therapy is to enable occupational functioning.

With the significant limitations and probable cause in mind, treatment goals that reflect the identified problem can be developed. For example, if skin, joint, and/or muscle tissues have shortened as a result of immobilization, the goal is to increase range by stretching these tissues. If the limitation is caused by edema, pain, spasticity, or muscle weakness, the primary goal is to reduce or correct the underlying problem, and the secondary goal is to prevent loss of ROM caused by the immobility imposed by the primary condition. If the cause is bony ankylosis or long-standing contracture, the goal is to teach the patient methods of compensation, as these conditions do not respond to nonsurgical treatment.

It is important to compare initial evaluation scores to mid- and post-treatment scores to assess the outcome and redirect treatment if necessary. Interpretation of a reevaluation that shows improvement following treatment must be tempered, however, with the realization that changes may occur simply as a result of remeasurement. For measurements of ROM to be considered to reflect actual change, the amount of change must exceed measurement error, which was found to be 5° for both the upper and lower extremities (Aalto et al., 2005; Groth et al., 2001). For example, if in a reevaluation the patient has shown an increase of 10° in shoulder flexion, it is considered a minimal improvement, as 5° may be accounted for by measurement error.

EDEMA

Edema, one cause of limited ROM, is quantified using circumferential or volumetric measurements. A millimeter tape is used to measure the circumference of a body part not easily submerged. It is essential to measure at exactly the same place from test to test.

Volumetric measures document changes in the mass of a body part by use of water displacement. It is most often used to measure hand edema. A water vessel that is large enough to allow submersion of the whole hand is used (Fig. 5-57). It has a spillover spout near the top of the water level. When the hand is placed in the vessel, water is displaced and spills out into a graduated beaker. An edematous hand displaces more water than an unswollen hand, so that a lower reading is considered an improvement. Dodds et al. (2004) examined the ability of therapists to orient the extremity consistently within the volumeter and to measure the displaced water accurately. In this protocol, the measurement was done with the participant standing; trunk support was provided by a therapist to maintain a stable position; and a micropipette was used to measure the water. There was high reliability over

Figure 5-57 Measuring edema of the hand using a volumeter. Note the water being displaced into the graduated beaker as the hand is submerged.

Figure 5-58 Measuring edema of the hand using a tape measure.

two repeated tests on 50 hands, showing a inter-rater reliability of 0.99 (Dodds et al., 2004). To interpret findings, compare the measurement of the affected part with that of its contralateral counterpart. If edema is present, the short-term goal of treatment may be, for example, to decrease edema more than 10 mL, which is slightly more than the identified within-patient variance of 3 mL (Dodds et al., 2004), or to reduce measurement by X mL.

A second method of measuring edema of the whole hand is the figure-of-eight technique (Pellecchia, 2004). Using a ¼-inch wide fiberglass tape measure and the wrist in neutral and fingers adducted, the tape is started at the medial aspect of the wrist just distal to the ulnar styloid. The tape is then run across the ventral surface of the wrist to the most distal point of the radial styloid, then run diagonally across the dorsum of the hand to the fifth metacarpophalangeal joint. The tape is then run across the heads of the metacarpals to the second metacarpophalangeal joint, and then back across the dorsum of the hand to the starting point. The measurement recorded is the distance measured by the tape (Fig. 5-58). The inter-tester and the intra-tester reliabilities for this method were high ($r = 0.98-0.99$) (Pellecchia, 2004;

Leard et al., 2004). When the figure-of-eight measurement was compared to the submersion method, the two methods were highly correlated ($r = 0.94-0.95$) (Maihafer et al., 2004). The figure-of-eight measurement technique may be especially appropriate in cases of open wounds or skin conditions but would not be appropriate if the edema was localized to a single finger.

PAIN

Pain is another possible cause of ROM limitations. Pain or fear of pain may affect a person's willingness to move. The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage" (Merskey & Bogduk, 1994). Because pain is subjective, self-report measures provide the most valid measure of the experience (Katz & Melzack, 1999). The several self-report measures include the *Visual Analog Scale (VAS)*, *Faces Test*, *Color Scale*, and the *Adjective Test* (Gordon et al., 1998). The most frequently used method to measure the intensity of pain is the VAS (Gordon et al., 1998; Katz & Melzack, 1999). It is quick and simple to use. It consists of a 10-cm line, with 0 and 10 noted at each end of the line. The zero end is designated as "no pain at all"; the other end is designated as "the worst pain I ever felt" (Fig. 5-59). The patient marks on the line the point that represents the intensity of the pain he or she feels. The score is obtained by measuring the line from the zero point to the patient's mark in cm. For example, if the mark is made at 4.6 cm on the 10-cm line, the score could be 4 or the more exact 4.6, depending on the practice at the facility. There are no norms for this scale, and it cannot be used to compare different patients, but it is useful in monitoring the progress of the same patient over time (Wittink & Michel, 1997).

MUSCLE STRENGTH

The Quick Reference Dictionary for Occupational Therapy defines strength as "demonstrating a degree of muscle power when movement is resisted, as with objects or gravity" (Jacobs & Jacobs, 2004, p. 225). Weakness is a lack or reduction of the power of a muscle or muscle group. When weakness limits or impairs the individual's occupational

Figure 5-59 A Visual Analog Scale used to quantify the phenomenological experience of pain.

functioning, it is necessary to determine the degree and distribution of weakness to establish an appropriate intervention plan. Treatment can be focused on remediating the weakness, or it can focus on alternative ways of accomplishing the task. Weakness can be manifested in several forms. It can be general, such as with Guillain-Barré syndrome, or it can be local, such as with a peripheral nerve lesion. In the former case, muscles throughout the body are assessed; in the latter case, just the muscles innervated by the involved nerve are tested. In both cases, the muscles to be tested are the ones contributing to the functional limitations on which treatment will focus.

A **maximum voluntary contraction (MVC)**, the maximum amount of tension that can be produced under voluntary control, is commonly used to measure strength (Wilmore & Costill, 1999). Because muscle testing is a measurement of voluntary contraction of an isolated muscle or muscle group, strength testing is inappropriate for patients who lack the ability to contract a single muscle or a muscle group in isolation, such as patients who exhibit patterned movement.

In this chapter, a technique called the break test is used. In the break test, the muscle to be tested is positioned at its greatest **mechanical advantage**. Once the extremity is positioned, the patient is asked to hold the position as the tester imparts an external force to overcome the contractile force of the muscle or muscle group using his or her hand. In other words, the therapist tries to break the patient's isometric contraction (Bohannon, 1988).

Another method of strength measurement is the make test, and it is the preferred method when using a hand-held dynamometer (Andrews, Thomas, & Bohannon, 1996). The joint is placed in a gravity-eliminated position, and the hand-held dynamometer is placed perpendicular to the limb segment. The patient is asked to build a maximum contraction against the dynamometer for a 1- to 2-second period and then to hold that contraction against the dynamometer for 4–5 seconds. The recorded measure is the maximum isometric value that was achieved by the patient. This type of measurement is particularly helpful for quantifying anti-gravity strength (grades 3+ to 5) (Hayes et al., 2002).

The term mechanical advantage refers to the length-tension relationship of a muscle. Total tension of a muscle is the sum of the passive tension exerted by the elastic components in the lengthened muscle and surrounding tissue and the active tension generated by the contractile elements of the contracting muscle (Hall & Brody, 1999). A muscle is able to generate its greatest total tension or sustain the heaviest load when positioned at a length that gives it optimal mechanical advantage. This is usually slightly (10%) longer than resting length. Developed (active) tension, which is total tension minus the elastic contribution, is greatest at resting length but decreases as the muscle shortens or lengthens. The length-tension principle is used to elicit the best response from prime movers during muscle testing. Furthermore, this principle is used to reduce the contribution of

synergist muscles when testing the prime mover. Synergist muscles are placed at a mechanical disadvantage (either lengthened or shortened) while the prime mover is asked to resist the applied force (Hall & Brody, 1999).

For muscles or muscle groups too weak to resist an external force, muscle strength is evaluated by isotonic contraction, in which the muscle is required to move the mass of the body part against gravity without applied resistance or with the effect of gravity decreased (Hislop & Montgomery, 1995; Kendall et al., 2005).

Gravity as resistance is considered an important variable and is used to test all motions when practical. Standard procedures for evaluation against gravity and with gravity eliminated are described in this chapter. Tests of the upper and lower extremities described here for the most part are motion tests for the purpose of evaluating strength in terms of ability to perform functionally. Tests of individual muscles in the wrist and hand are included because of the responsibility of the occupational therapist in rehabilitation of hand injuries.

The movements of the face, head, neck, and trunk, although important in the assessment of some patients, have not been included in the interest of conserving space; however, this information can be found in references listed at the end of this chapter.

Prior to the start of manual muscle testing (MMT), a passive ROM scan should be done to determine what ROM is available at each joint. Although the available range is considered to be full ROM for the purposes of muscle testing, a notation should be made of any limitation. The muscle or muscle group is assigned a grade, according to the amount of resistance it can take. Two grading systems are presented here; Table 5-1 equates the Medical Research Council (1976) Oxford system to the descriptive grading system (Clarkson, 2000).

Procedures for Practice 5-3 shows the sequence of steps for testing every muscle or muscle group to ensure reliability and accuracy. There are additional considerations when performing a manual muscle test. First, although fatigue differs for each person and each muscle, a rest of 2 minutes between maximum effort of the same muscle is considered adequate (Milner-Brown, Mellenthin, & Miller, 1986). Second, for the comfort and convenience of the patient, all testing in one position is done before the patient changes to another position. Also, position of head, neck, and proximal parts are usually kept the same from test to test, although preliminary study results indicated that this does not affect tension development (Anderson & Bohannon, 1991; Bohannon, Warren, & Cogman, 1991).

Reliability

Reliability is essential for meaningful evaluation. Most important to the reliability of the scores of repeated tests is strict adherence to the exact procedures of testing. In

Table 5-1. Muscle Testing Grading System

Grade	Definition	Description
5	Normal	The part moves through full ROM against gravity and takes maximal resistance.
4	Good	The part moves through full ROM against gravity and takes moderate resistance.
4–	Good minus	The part moves through full ROM against gravity and takes less than moderate resistance.
3+	Fair plus	The part moves through full ROM against gravity and takes minimal resistance before it breaks.
3	Fair	The part moves through full ROM against gravity and is unable to take any added resistance.
3–	Fair minus	The part moves less than full range of motion against gravity.
2+	Poor plus	The part moves through full ROM in a gravity-eliminated plane and takes minimal resistance, then breaks.
2	Poor	The part moves through full ROM in a gravity-eliminated plane with no added resistance.
2–	Poor minus	The part moves less than full ROM in a gravity-eliminated plane.
1	Trace	Tension is palpated in the muscle or tendon, but no motion occurs at the joint.
0	Zero	No tension is palpated in the muscle or tendon.

PROCEDURES FOR PRACTICE 5-3

Muscle Testing Procedures

1. Explain the procedure and demonstrate the desired movement.
2. Position the patient so the direction of movement will be against gravity.
3. Stabilize proximal to the joint that will move to prevent substitutions.
4. Instruct the patient to move actively to the end position. If the patient cannot move actively against gravity, place the patient in a gravity-eliminated position and ask the patient to move actively in this position.
5. If the patient can move actively against gravity, tell the patient to hold the contraction at the end position.
6. Apply resistance:
 - to the distal end of the segment into which the muscle inserts
 - in the direction the movement came from
 - by starting with light resistance and increase to maximal resistance over a 2- to 3-second period
7. Palpate over the prime mover to determine whether the muscle is contracting or whether gravity and/or synergistic muscles are substituting.
8. Record the appropriate grade according to the resistance tolerated before the muscle broke or by the amount of movement achieved without resistance in an against-gravity or gravity-eliminated position.

addition, reliability of muscle testing scores is affected by the interest and cooperation of the patient and by the experience and tone of voice of the tester (Johannson, Kent, & Shepard, 1983). The most suitable environment is free of distractions, is at a comfortable temperature, and has proper lighting. Other factors known to affect outcome are posture, fatigue, the patient's ability to understand directions, the therapist's operational definitions of various grades, and test positions (Kendall et al., 2005). For reliability, these variables must be controlled from test to test and among therapists at the same facility. It is necessary for the inexperienced therapist to develop a kinesthetic sense of minimal, moderate, and maximal resistances by working with experienced therapists, each testing the same patient and discussing the grade to be assigned.

Manual muscle testing (MMT) is a valid and reliable procedure to measure muscle strength (Herbison et al., 1996; Marx, Bombardier, & Wright, 1999; Schwartz et al., 1992). A study of reliability for testing intrinsic hand muscles found the correlation for intra-rater reliability to range from .71 to .96, and from .72 to .93 for inter-rater reliability (Brandsma et al., 1995). Florence et al. (1992) performed MMT on patients with Duchenne's muscular dystrophy. Using a standard method of testing and the modified Medical Research Council grading scale (Table 5-1), reliability for muscle grades 0 to 5 ranged from .80 to .99. The most reliable graders were 3 and below, with the least reliable grades being 3+ (.80), 4- (.83), and 5- (.83), those that involve a developed kinesthetic sense of minimal, moderate, and maximal resistance.

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Planning a Muscle Testing Strategy

Testing of shoulder, elbow, and lower extremity musculature may require the patient to lie prone or supine or to sit up, depending on whether you are testing in an antigravity or gravity-eliminated position. It would be too tiring for the patient to keep switching postures between lying and sitting during a muscle test as presented in this chapter. Devise a practical strategy you will use in muscle testing that will be least fatiguing for a patient. The strategy will list the order of muscles to be tested and for what grade, according to position.

Recording Muscle Strength Scores

The grade is accurately recorded in the appropriate place on a form that has columns to record grades for both the right and left sides of the body. The therapist must sign and date each test; if a test continues over several days, the form should reflect that. A sample form is presented in Figure 5-60. On that form, the peripheral nerve and spinal segmental levels are listed beside each muscle to assist the therapist in interpreting the results of the muscle test.

On the pages that follow, the reader will find narrative and pictorial descriptions to help in understanding and practicing measurement of upper extremity strength.

Patient's Name: _____ Age: _____

Figure 5-60 (continued)

MEASUREMENT OF THE PROXIMAL UPPER EXTREMITY

Scapular Elevation

Prime Movers

Upper trapezius
Levator scapulae

Against-Gravity Position (Fig. 5-61)

Start Position

Patient sitting erect with arms at side.

Stabilize

Trunk is stabilized against the plinth or chair back.

Figure 5-61 Scapular elevation against gravity.

Instruction

“Lift your shoulders toward your ears. Don’t let me push them down.”

Resistance

The therapist places his or her hands over each acromion and pushes down toward scapular depression. A normal trapezius of an adult cannot be broken.

Substitution

A substitution is the use of an alternate muscle or position a patient may use to complete a motion. In this case, it could appear that the patient’s shoulders elevated if he or she pushed on the knees with his or her hands.

Gravity-Eliminated Position (Fig. 5-62)

Start Position

Prone with arms at side and therapist supporting under the shoulder.

Stabilize

The trunk is stabilized against the mat.

Instruction

“Lift your shoulder toward your ear.”

Palpation

The upper trapezius is palpated on the shoulder at the curve of the neck. The levator scapulae is palpated posterior to the sternocleidomastoideus on the lateral side of the neck.

Figure 5-62 Scapular elevation, gravity eliminated.

Scapular Depression

Prime Movers

Lower trapezius
Latissimus dorsi

Resistance Test (Fig. 5-63)

Start Position

This movement is tested in a gravity-eliminated position as the patient cannot be positioned to move against gravity. The patient lies prone with arms by the sides.

Stabilize

The trunk is stabilized by the mat.

Instruction

“Reach your hand down toward your feet.”

Resistance

The therapist’s hand cups the inferior angle of the scapula; the therapist pushes up toward scapular elevation. When the inferior angle is not easily accessible because of tissue bulk, apply resistance at the distal humerus if the shoulder joint is stable and pain free.

Palpation

Palpate the lower trapezius lateral to the vertebral column as it passes diagonally from the lower thoracic vertebrae to the spine of the scapula. Palpate the latissimus dorsi along the posterior rib cage or in the posterior axilla as it attaches to the humerus.

Figure 5-63 Scapular depression.

Scapular Adduction: Retraction

Prime Movers

Middle trapezius
Rhomboids

Against-Gravity Position for the Middle Trapezius (Fig. 5-64)

Start Position

Prone on a mat with the shoulder abducted to 90° and the elbow flexed to 90°.

Stabilize

The trunk is stabilized against the mat. Additional stabilization over the contralateral scapula provides counterpressure during action and resistance.

Instruction

“Raise your elbow toward the ceiling. Don’t let me push it down.”

Resistance

Apply resistance laterally at the vertebral border of the scapula or, if the shoulder is stable and pain free, downward at the distal humerus.

Figure 5-64 Scapular adduction, test for middle trapezius.

Palpation

With your hand over the vertebral border of the scapula, feel to see whether the scapula stays adducted during resistance. Palpate the middle trapezius between the vertebral column and vertebral border of the scapula at the level of the spine of the scapula.

Against-Gravity Position for the Rhomboids (Fig. 5-65)

Start Position

Prone on the mat with the shoulder internally rotated and with the back of the hand resting on the lumbar region.

Stabilize

The trunk is stabilized against the mat. Additional stabilization over the contralateral scapula will provide counterpressure during action and resistance.

Instruction

“Lift your hand off of your back. Don’t let me push it down.”

Resistance

Apply downward resistance against the distal humerus or, if the shoulder is unstable or painful, against the vertebral border of the scapula in the direction of scapular abduction.

Palpation

Palpate the rhomboids along the vertebral border of the scapula near the inferior angle.

Figure 5-65 Scapular adduction, test for rhomboids.

Gravity-Eliminated Position for the Middle Trapezius and Rhomboids (Fig. 5-66)

Start Position

Sitting erect with the humerus abducted to 90° and supported.

Stabilize

The trunk is stabilized by the chair.

Instruction

“Try to move your arm backward.”

Grading

If the scapula moves toward the spine, give a grade of 2. If no movement is noted, palpate the scapular adductors.

Palpation

Same as previously described.

Figure 5-66 Scapular adduction, gravity eliminated. The therapist is pointing to the middle trapezius.

Scapular Abduction: Protraction

Prime Mover

Serratus anterior

Against-Gravity Position (Fig. 5-67)

Start Position

Supine with the humerus flexed to 90°. The elbow may be flexed or extended.

Stabilize

The trunk is stabilized on the mat.

Instruction

“Reach your arm toward the ceiling.”

Resistance

According to the rule, resistance should be applied along the axillary border of the scapula. Because it is difficult to apply resistance there, therapists often resist this motion either by grasping the distal humerus or by cupping the hand over the patient’s elbow and pushing down or back toward scapular adduction. *Of course, this method is not used if the glenohumeral joint is unstable or painful.*

Figure 5-67 Scapular abduction against gravity.

Gravity-Eliminated Position (Fig. 5-68)

Start Position

Sitting erect with the humerus flexed to 90° and supported.

Stabilize

The trunk is stabilized against the chair.

Instruction

“Try to reach your arm forward.”

Grading

Movement of the scapula into abduction receives a grade of 2. If no movement occurs, palpate the serratus anterior.

Palpation

Palpate the serratus anterior on the lateral ribs just lateral to the inferior angle of the scapula.

Substitution

In the gravity-eliminated position, this motion can be achieved by inching the arm forward on a supportive surface using the finger flexors.

Figure 5-68 Scapular abduction, gravity eliminated.

Shoulder Flexion

Prime Movers

Anterior deltoid
Coracobrachialis
Pectoralis major, clavicular head
Biceps, both heads

Against-Gravity Position (Fig. 5-69)

Start Position

Sitting in a chair with the arm down at the side in mid-position.

Stabilize

Over the clavicle and the scapula.

Instruction

“Lift your arm in front of you to shoulder height. Don’t let me push it down.”

Resistance

The therapist’s hand, placed over the distal end of the humerus, pushes down toward extension. Movement above 90° involves scapular rotation; these motions are

separated for muscle testing, although they are not separated for ROM measurement.

Substitutions

Shoulder abductors, scapular elevation, or trunk extension.

Gravity-Eliminated Position (Fig. 5-70)

Start Position

Side-lying with the arm along the side of the body in midposition; therapist supports the arm under the elbow.

Instruction

“Try to move your arm so your hand is at the level of your shoulder.”

Palpation

Palpate the anterior deltoid immediately anterior to the glenohumeral joint. Coracobrachialis may be palpated medially to the tendon of the long head of the biceps, which is palpated on the anterior aspect of the humerus. The clavicular head of the pectoralis major may be palpated below the clavicle on its way to insert on the humerus below the anterior deltoid.

Figure 5-69 Shoulder flexion against gravity.

Figure 5-70 Shoulder flexion, gravity eliminated.

Shoulder Extension

Prime Movers

Latissimus dorsi
Teres major
Posterior deltoid
Triceps, long head

Against-Gravity Position (Fig. 5-71)

Start Position

Sitting with the arm by the side and the humerus internally rotated.

Stabilize

Over the clavicle and scapula; make sure the patient remains upright.

Instruction

“Move your arm straight back as far as it will go. Keep your palm facing the back wall.”

Figure 5-71 Shoulder extension against gravity.

Resistance

The therapist's hand, placed over the distal end of the humerus, pushes forward toward flexion.

Substitutions

Shoulder abductors, tipping the shoulder forward, bending the trunk forward.

Gravity-Eliminated Position (Fig. 5-72)

Start Position

Side-lying with the arm along the side of the body and in internal rotation. Therapist supports the elbow during the motion.

Instruction

“Try to move your arm backward.”

Palpation

The latissimus dorsi and teres major form the posterior border of the axilla. The latissimus dorsi is inferior to the teres major. The posterior deltoid is immediately posterior to the glenohumeral joint. The triceps are palpated on the posterior aspect of the humerus.

Figure 5-72 Shoulder extension, gravity eliminated.

Shoulder Abduction

Prime Movers

Supraspinatus
Middle deltoid

Against-Gravity Position (Fig. 5-73)

Start Position

Sitting erect with the arm down at the side and in midposition.

Stabilize

Over the clavicle and the scapula.

Instruction

“Raise your arm out to the side to shoulder level. Don’t let me push it down.”

Resistance

The therapist’s hand, placed over the distal end of the humerus, pushes the humerus down toward the body.

Movement above 90° involves scapular rotation and is not measured.

Substitutions

The long head of the biceps can substitute if the humerus is allowed to move into external rotation; trunk lateral flexion.

Gravity-Eliminated Position (Fig. 5-74)

Start Position

Supine with the arm supported at the side in midposition. The therapist supports the elbow during the motion.

Instruction

“Try to move your arm out to the side.”

Palpation

The supraspinatus lies too deep for easy palpation. Palpate the middle deltoid below the acromion and lateral to the glenohumeral joint.

Figure 5-73 Shoulder abduction against gravity.

Figure 5-74 Shoulder abduction, gravity eliminated.

Shoulder Adduction

Prime Movers

Pectoralis major
Teres major
Latissimus dorsi

Gravity-Eliminated Position (Fig. 5-75)

The patient cannot be positioned for this motion against gravity.

Start Position

Supine with the humerus abducted to 90° and the forearm in midposition.

Stabilize

The trunk is stabilized by the mat.

Instruction

“Bring your arm down to your side, and don’t let me pull it away.”

Resistance

The therapist’s hand, placed on the medial side of the distal end of the humerus, attempts to pull the humerus away from the patient’s body.

Palpation

The pectoralis major forms the anterior border of the axilla, where it may be easily palpated. Palpation of the teres major and the latissimus dorsi is described earlier in the chapter.

Grading

Antigravity grades can only be estimated; a question mark should be entered beside the grade on the form. With experience, the therapist develops the skill to estimate reliably.

Substitutions

On a supporting surface, the arm can be inched down using the finger flexors.

Figure 5-75 Shoulder adduction.

Shoulder Horizontal Abduction

Prime Mover

Posterior deltoid

Against-Gravity Position (Fig. 5-76)

Start Position

Prone with the arm over the edge of the plinth. The shoulder is abducted to 90°, and the elbow is flexed to 90°.

Stabilize

The scapula and trunk are stabilized by the mat. Counterpressure over the contralateral scapula is helpful during action and resistance.

Instruction

“Raise your elbow toward the ceiling.”

Resistance

The therapist’s hand, placed on the posterior surface of the distal end of the humerus, pushes the arm down toward horizontal adduction.

Figure 5-76 Shoulder horizontal abduction against gravity.

Gravity-Eliminated Position (Fig. 5-77)

Start Position

Sitting in a chair with the humerus supported in 90° of flexion and the elbow straight. The therapist supports the elbow.

Stabilize

The trunk is stabilized against the back of the chair.

Instruction

“Try to move your arm out to the side.”

Palpation

Palpate the posterior deltoid immediately posterior to the glenohumeral joint.

Substitution

Trunk rotation.

Figure 5-77 Shoulder horizontal abduction, gravity eliminated.

Shoulder Horizontal Adduction

Prime Movers

Pectoralis major
Anterior deltoid

Against-Gravity Position (Fig. 5-78)

Start Position

Supine with the humerus abducted to 90° in neutral rotation and the elbow extended.

Stabilize

The table stabilizes the scapula and trunk. If the elbow extensors are weak, be sure to support the distal end of the forearm so the hand doesn't fall into the patient's face during horizontal adduction.

Instruction

“Move your arm in front of you and across your chest.”

Resistance

The therapist's hand, placed on the anterior surface of the distal end of the humerus, pulls the arm out toward horizontal abduction.

Figure 5-78 Shoulder horizontal adduction against gravity.

Gravity-Eliminated Position (Fig. 5-79)

Start Position

Sitting in a chair with the arm abducted to 90°.

Stabilize

The trunk is stabilized against the back of the chair. The therapist supports the arm under the elbow.

Instruction

“Try to bring your arm across your chest.”

Palpation

Palpate the pectoralis major along the anterior border of the axilla. The anterior deltoid is immediately anterior to the glenohumeral joint below the acromion process and superior to the pectoralis major.

Substitutions

Trunk rotation can substitute. The arm can be inched across a supporting surface using the finger flexors.

Figure 5-79 Shoulder horizontal adduction, gravity eliminated.

Shoulder External Rotation

Prime Movers

Infraspinatus
Teres minor
Posterior deltoid

Against-Gravity Position (Fig. 5-80)

Start Position

Prone with the humerus abducted to 90° and supported by the mat. The elbow is flexed to 90° and is hanging over the edge of the table.

Stabilize

The humerus is held just proximal to the elbow to allow only rotation.

Instruction

“Lift the back of your hand toward the ceiling.”

Resistance

The therapist’s hand, placed on the dorsal surface of the forearm, pushes toward the floor. The therapist’s other hand keeps the patient’s elbow supported and flexed to 90° to prevent supination.

Substitutions

Scapula adduction combined with downward rotation can substitute. The triceps may substitute when resistance is applied.

Figure 5-80 Shoulder external rotation against gravity.

Gravity-Eliminated Position (Fig. 5-81)

Start Position

Prone with the entire arm hanging over the edge of the mat. The arm is in internal rotation.

Stabilize

The trunk and scapula are stabilized on the plinth.

Instruction

“Try to turn your palm outward.”

Palpation

Palpate the infraspinatus inferior to the spine of the scapula. Palpate the teres minor between the posterior deltoid and the axillary border of the scapula; it is superior to the teres major. Palpation of the posterior deltoid was described earlier.

Substitution

Supination may be mistaken for external rotation in a gravity-eliminated position.

Figure 5-81 Shoulder external rotation, gravity eliminated.

Alternative Gravity-Eliminated Position (Fig. 5-82)*Start Position*

Sitting in a chair with the humerus adducted to the side and the elbow flexed to 90°.

Stabilize

The distal end of the humerus is held against the body to allow only rotation.

Instruction

“Try to move the back of your hand out to the side.”

Palpation

Same as previously described.

Figure 5-82 Shoulder external rotation, alternative position with gravity eliminated.

Shoulder Internal Rotation

Prime Movers

Subscapularis
Teres major
Latissimus dorsi
Pectoralis major
Anterior deltoid

Against-Gravity Position (Fig. 5-83)

Start Position

Prone with the humerus abducted to 90° and supported by the mat. The elbow is flexed to 90° and hangs over the edge of the mat.

Stabilize

The humerus is held just proximal to the elbow to allow only rotation.

Instruction

“Lift the palm of your hand toward the ceiling.”

Resistance

The therapist’s hand, placed on the volar surface of the distal end of the forearm, pushes toward the floor. The therapist’s other hand keeps the patient’s elbow supported and flexed to 90° to prevent supination.

Figure 5-83 Shoulder internal rotation against gravity.

Substitutions

Scapular abduction combined with upward rotation can substitute. The triceps can substitute as in external rotation.

Gravity-Eliminated Position (Fig. 5-84)

Start Position

Prone with the entire arm hanging over the edge of the mat. The arm is in external rotation.

Stabilize

The trunk and scapula are stabilized by the mat.

Instruction

“Try to turn your palm inward.”

Palpation

The subscapularis is not easily palpated but may be found in the posterior axilla. Palpate the teres major, latissimus dorsi, pectoralis major, and anterior deltoid as previously described.

Figure 5-84 Shoulder internal rotation, gravity eliminated.

Substitutions

Scapular abduction combined with upward rotation can substitute. Pronation may be mistaken for internal rotation in a gravity-eliminated position.

Alternative Gravity-Eliminated Position (Fig. 5-85)*Start Position*

Sitting in a chair with the humerus adducted to the side and the elbow flexed to 90°.

Stabilize

The distal end of the humerus is held against the body to allow only rotation.

Instruction

“Try to move the palm of your hand in toward your stomach.”

Palpation

Same as previously described.

Figure 5-85 Shoulder internal rotation, alternative position with gravity eliminated.

Elbow Flexion

Prime Movers

Biceps
Brachialis
Brachioradialis

Against-Gravity Position (Fig. 5-86)

Start Position

Sitting in a chair with the arm at the side. The position of the forearm determines which muscle is working primarily: forearm in supination, biceps brachii; forearm in pronation, brachialis; forearm in midposition, brachioradialis.

Stabilize

Stabilize the distal end of the humerus during the action. While applying resistance, provide counterpressure at the front of the shoulder.

Figure 5-86 Elbow flexion against gravity.

Instruction

While the patient is in each of the three forearm positions, say, “Bend your elbow to touch your shoulder and don’t let me pull it back down.”

Resistance

For each of the three positions, the therapist’s hand is placed on the distal end of the forearm and pulls out toward extension.

Gravity-Eliminated Position (Fig. 5-87)

Start Position

Sitting with the arm supported by the therapist in 90° of abduction and elbow extension. The position of the forearm determines which muscle is working, as described earlier.

Stabilize

Distal humerus.

Instruction

“Try to move your hand toward your shoulder.”

Palpation

The biceps is easily palpated on the anterior surface of the humerus. With the biceps relaxed and the forearm pronated, palpate the brachialis just medial to the distal biceps tendon. With the forearm in midposition, palpate the brachioradialis along the radial side of the proximal forearm.

Substitution

In a gravity-eliminated plane, the wrist flexors may substitute.

Figure 5-87 Elbow flexion, gravity eliminated.

Elbow Extension

Prime Mover

Triceps

Against-Gravity Position (Fig. 5-88)

Start Position

Prone with humerus abducted to 90° and supported on the table. The elbow is flexed, and the forearm is hanging over the edge of the table.

Stabilize

Support the arm under the anterior surface of the distal humerus.

Instruction

“Straighten your arm, and don’t let me push it back down.”

Figure 5-88 Elbow extension against gravity.

Resistance

Apply resistance with the elbow at 10–15° less than full extension so that the elbow does not lock into position, which may indicate greater strength than the patient actually has. The therapist’s hand, placed on the dorsal surface of the patient’s forearm, pushes toward flexion.

Gravity-Eliminated Position (Fig. 5-89)

Start Position

Sitting, with the humerus supported by the therapist in 90° of abduction. The elbow is fully flexed.

Stabilize

The humerus is supported and stabilized.

Instruction

“Try to straighten your elbow.”

Palpation

The triceps are easily palpated on the posterior surface of the humerus.

Substitutions

In the gravity-eliminated position, no external rotation of the shoulder is permitted, so as to avoid letting the assistance of gravity produce extension. On a supporting surface, finger flexion may be used to inch the forearm across the surface.

Figure 5-89 Elbow extension, gravity eliminated.

Pronation

Prime Movers

Pronator teres
Pronator quadratus

Against-Gravity Position (Fig. 5-90)

Start Position

Sitting with the humerus adducted, elbow flexed to 90°, and forearm supinated. The wrist and fingers are relaxed.

Stabilize

The distal humerus is stabilized to keep it adducted to the body.

Instruction

“Turn your palm to the floor, and don’t let me turn it back over.”

Resistance

The therapist’s hand encircles the patient’s volar wrist with the therapist’s index finger extended along the forearm. The therapist applies resistance in the direction of supination.

Figure 5-90 Pronation against gravity.

Substitutions

Shoulder abduction or wrist and finger flexion may substitute.

Gravity-Eliminated Position (Fig. 5-91)

Start Position

Sitting with the humerus flexed to 90° and supported. The elbow is flexed to 90° and the forearm is in full supination. The wrist and fingers are relaxed.

Stabilize

The humerus is stabilized.

Instruction

“Try to turn your palm away from your face.”

Palpation

The pronator teres is palpated medial to the distal attachment of the biceps tendon on the volar surface of the proximal forearm. Pronator quadratus is too deep to palpate.

Figure 5-91 Pronation, gravity eliminated.

Supination

Prime Movers

Supinator
Biceps

Against-Gravity Position (Fig. 5-92)

Start Position

Sitting, with the humerus adducted, elbow flexed to 90°, and forearm pronated. The wrist and fingers are relaxed. To differentiate the supinator from the supination function of the biceps, isolate the supinator by extending the elbow. The biceps does not supinate the extended arm unless resisted (Kendall et al., 2005).

Stabilize

The distal humerus is stabilized.

Instruction

“Turn your palm up toward the ceiling, and don’t let me turn it back over.”

Resistance

Same as for pronation except that resistance is in the direction of pronation.

Figure 5-92 Supination against gravity.

Substitutions

The wrist and finger extensors may substitute.

Gravity-Eliminated Position (Fig. 5-93)

Start Position

Sitting with the humerus flexed to 90° and supported. The elbow is flexed to 90°, and the forearm is in full pronation. The wrist and fingers are relaxed.

Stabilize

The humerus is stabilized and supported.

Instruction

“Try to turn your palm toward your face.”

Palpation

The supinator is palpated on the dorsal surface of the proximal forearm just distal to the head of the radius. Palpation of the biceps was described earlier.

Figure 5-93 Supination, gravity eliminated.

MEASUREMENT OF THE WRIST AND HAND

Many tendons of the wrist and hand cross more than one joint. For this reason, test positions for individual muscles must include ways to minimize the effect of other muscles crossing the joint. As a general rule, to minimize the effect of a muscle, place it opposite the prime action. For example, to minimize the effect of the extensor pollicis longus on extension of the proximal joint of the thumb, flex the distal joint.

Wrist Extension

Prime Movers

Extensor carpi radialis longus (ECRL)

Extensor carpi radialis brevis (ECRB)

Extensor carpi ulnaris (ECU)

Against-Gravity Position (Figs. 5-94 and 5-95)

Start Position

The forearm is supported on a table in full pronation with fingers and thumb relaxed or slightly flexed.

Stabilize

The forearm is stabilized on the table.

Instruction

“Lift your wrist as far as you can, and don’t let me push it down.”

Figure 5-94 Wrist extension. Resistance is being given to the extensor carpi radialis.

Resistance

To test the ECRL, which extends and radially deviates, apply resistance to the dorsum of the hand on the radial side in the direction of flexion and ulnar deviation (Fig. 5-94). To test the ECRB, apply resistance on the dorsum of the hand and push into flexion. To test the ECU, which extends and ulnarly deviates, apply resistance to the dorsum of the hand on the ulnar side and push in the direction of flexion and radial deviation (Fig. 5-95).

Substitutions

Extensor pollicis longus, extensor digitorum.

Gravity-Eliminated Position

Start Position

The forearm is supported on the table in midposition with the wrist in a slightly flexed position.

Instruction

“Try to bend your wrist backward.”

Palpation

Palpate the tendon of the ECRL on the dorsal surface of the wrist at the base of the second metacarpal. The muscle belly is on the dorsal proximal forearm adjacent to the brachioradialis. Palpate the tendon of the ECRB on the dorsal surface of the wrist at the base of the third metacarpal adjacent to the ECRL. The muscle belly of the ECRB is distal to the belly of the ECRL on the dorsal surface of the proximal forearm. Palpate the ECU on the dorsal surface of the wrist between the head of the ulna and the base of the fifth metacarpal. The muscle belly is approximately 2 inches distal to the lateral epicondyle of the humerus (Rybski, 2004).

Figure 5-95 Wrist extension. Resistance is being given to the ECU.

Wrist Flexion

Prime Movers

Flexor carpi radialis (FCR)

Palmaris longus

Flexor carpi ulnaris (FCU)

Against-Gravity Position (Figs. 5-96 and 5-97)

Start Position

The forearm is supinated, the wrist is extended, and fingers and thumb are relaxed.

Stabilize

The forearm is stabilized on the table with the back of the hand raised off the table to allow the wrist to go into slight extension.

Instruction

“Bend your wrist all the way forward, and don’t let me push it back.”

Resistance

To test the FCR and palmaris longus, the therapist applies resistance over the heads of the metacarpals on the volar surface of the hand toward extension. To test for the FCU, the therapist applies resistance over the head of the fifth metacarpal on the volar surface of the hand toward wrist extension and radial deviation.

Substitutions

Abductor pollicis longus, flexor pollicis longus, flexor digitorum superficialis, and flexor digitorum profundus.

Gravity-Eliminated Position

Start Position

Forearm in midposition, wrist extended, and fingers and thumb relaxed.

Figure 5-96 Wrist flexion. The therapist is pointing to the flexor carpi radialis longus tendon as she gives resistance.

Figure 5-97 Wrist flexion. The therapist is pointing to the FCU tendon as she gives resistance.

Stabilize

The forearm rests on the table.

Instruction

“Try to bend your wrist forward.”

Palpation

Palpate the FCR on the volar surface of the wrist in line with the second metacarpal and radial to the palmaris longus (if present) (Fig. 5-96). Palpate the FCU on the volar surface of the wrist just proximal to the pisiform bone (Fig. 5-97). The palmaris longus is a weak wrist flexor. The tendon crosses the center of the volar surface of the wrist (Fig. 5-98). It is not tested for strength and may not even be present; if it is present, it will stand out prominently in the middle of the wrist when wrist flexion is resisted or the palm is cupped.

Figure 5-98 The therapist is pointing to the tendon of the palmaris longus as the patient cups his hand in an effort to make his tendon stand out.

Finger MP Extension

Prime Movers

Extensor digitorum (ED)
Extensor indicis proprius
Extensor digiti minimi

Against-Gravity Position (Fig. 5-99)

Start Position

The forearm is pronated and supported on the table. The wrist is supported in neutral position, and the finger MP and IP joints are in a relaxed flexed posture.

Stabilize

Wrist and metacarpals.

Instruction

“Lift this knuckle straight as far as it will go [touch the finger that is to be tested]. Keep the rest of your fingers bent. Don’t let me push your knuckle down.” (Be sure to demonstrate this action.)

Resistance

Using one finger, the therapist pushes the head of each proximal phalanx toward flexion, one at a time.

Substitution

Apparent extension of the fingers can result from the rebound effect of relaxation following finger flexion.

Flexion of the wrist can cause finger extension through **tenodesis** action.

Gravity-Eliminated Position

Start Position

Forearm supported in midposition, wrist in neutral position, and fingers flexed.

Stabilize

Wrist and metacarpals.

Instruction

“Try to move your knuckles back as far as they will go, one at a time. Keep the rest of your fingers bent.”

Palpation

Palpate the muscle belly of the ED on the dorsal-ulnar surface of the proximal forearm. Often the separate muscle bellies can be discerned. The tendons of this muscle are readily seen and palpated on the dorsum of the hand. The extensor indicis proprius tendon is ulnar to the extensor digitorum tendon. Palpate the belly of this muscle on the mid to distal dorsal forearm between the radius and ulna. Palpate the extensor digiti minimi tendon ulnar to the ED. Actually, it is the tendon that looks as if it were the ED tendon to the little finger because the ED to the little finger is only a slip from the ED tendon to the ring finger.

Figure 5-99 Finger metacarpophalangeal extension. The tendons of the extensor digitorum can be seen on the back of the patient’s hand.

Finger Interphalangeal Extension

Prime Movers

Lumbricales
 Interossei
 Extensor digitorum
 Extensor indicis proprius
 Extensor digiti minimi

According to electromyographic evidence, the intrinsics, especially the lumbricales, are the primary extensors of the interphalangeal joints (Long, 1968; Long & Brown, 1962). Except for the lumbricales and interossei, the other muscles have been discussed. The interossei are discussed under their alternative action of finger abduction and adduction. The lumbricales, arising as they do from the flexor profundus and inserting on the extensor digitorum, have a unique action in regard to finger extension. Contracting against the noncontracting flexor profundus, the lumbricales pull the tendons of the profundus toward the fingertips. This slackens the profundus tendons distal to the insertion of the lumbricales, allowing the extensor digitorum to extend the interphalangeal joints fully, regardless of the position of the MP joints (Landsmeer & Long, 1965; Long, 1968). The interossei flex the MP joints while extending the interphalangeal joints and, in fact, operate to extend only when the MP joints are flexed or flexing (Long, 1968).

Against-Gravity Position for the Lumbricales

There is no reliably good test for lumbrical function. Test 1 is traditional. Test 2 is suggested in accordance with electromyographic evidence.

Start Position

The forearm is supinated and supported. The wrist is in neutral position. Test 1: MPs are extended with the IPs flexed. Test 2: MPs are flexed with the IPs extended.

Stabilize

Metacarpals and wrist.

Instruction

Test 1: “Bend your knuckles and straighten your fingers at the same time.” (Be sure to demonstrate this movement.)
 Test 2: “Straighten your knuckles and keep your fingers straight at the same time.”

Resistance

Test 1: The therapist holds the tip of the finger being tested and pushes it toward the starting position. Test 2: The therapist places one finger on the patient’s fingernail and pushes toward flexion (Fig. 5-100).

Substitution

Nothing substitutes for DIP extension in the event of the loss of lumbrical function when the MP joint is extended. Other muscles of the dorsal expansion can substitute for DIP extension when the MP joint is flexed.

Palpation

Lumbricales lie too deep to be palpated.

Figure 5-100 Finger interphalangeal extension. Resistance is given to the lumbricales as described for test 2.

Finger DIP Flexion

Prime Mover

Flexor digitorum profundus (FDP)

Against-Gravity Position (Fig. 5-101)

Start Position

Forearm supinated and supported on a table; wrist and interphalangeal joints relaxed.

Stabilize

Firmly support the middle phalanx of each finger as it is tested to prevent flexion of the proximal interphalangeal joint; wrist should remain in neutral position.

Instruction

“Bend the last joint on your finger as far as you can.”

Resistance

The therapist places one finger on the pad of the patient’s finger and applies resistance toward extension.

Substitutions

Rebound effect of apparent flexion following contraction of extensors. Wrist extension causes tenodesis action.

Gravity-Eliminated Position

Start Position

The forearm is in midposition, resting on the ulnar border on a table. The wrist and interphalangeal joints are relaxed in neutral position.

Stabilize

Same as previously described.

Instruction

Same as previously described.

Palpation

Palpate the belly of the FDP just volar to the ulna in the proximal third of the forearm. The tendons are sometimes palpable on the volar surface of the middle phalanges.

Figure 5-101 Finger distal interphalangeal flexion. The other joints of the finger are prevented from flexing.

Finger PIP Flexion

Prime Movers

Flexor digitorum superficialis (FDS)

Flexor digitorum profundus

Against-Gravity Position for the Flexor Digitorum Superficialis (Fig. 5-102)

Start Position

Forearm supinated and supported on the table; wrist and metacarpophalangeal joints relaxed and in zero position. To rule out the influence of the profundus when testing

Figure 5-102 Finger proximal interphalangeal flexion. The flexor profundus is prevented from substituting because the therapist is holding in extension all fingers not being tested.

the superficialis, hold all interphalangeal joints of the fingers not being tested in full extension. Because the profundus is essentially one muscle with four tendons, preventing its action in three of the four fingers prevents it from working in the tested finger. In fact, the patient cannot flex the distal joint of the tested finger at all. In some people, the profundus slip to the index finger is such that this method cannot rule out its influence on the PIP joint of the index finger. This should be noted on the test form.

Stabilize

All IP joints of the other digits of the hand.

Instruction

Point to the PIP joint and say, “Bend just this joint.”

Resistance

Using one finger, the therapist applies resistance to the head of the middle phalanx toward extension.

Substitutions

Flexor digitorum profundus. Wrist extension causes tenodesis action.

Gravity-Eliminated Position

Start Position

Forearm supported in midposition, with the wrist and MP joints relaxed in neutral position. Again, rule out the influence of the FDP by holding all the joints of the untested fingers in extension.

Stabilize

Proximal phalanx of the finger being tested as well as all IP joints of the other digits of the hand.

Instruction

Point to the PIP joint and say, “Try to bend just this joint.”

Palpation

Palpate the superficialis on the volar surface of the proximal forearm toward the ulnar side. Palpate the tendons at the wrist between the palmaris longus and the flexor carpi ulnaris.

Finger MP Flexion

Prime Movers

Flexor digitorum profundus
Flexor digitorum superficialis
Dorsal interossei
Volar (palmar) interossei
Flexor digiti minimi

The tests for the first four muscles are discussed under their alternative actions. The flexor of the little finger has no other action and is described here.

Against-Gravity Position for the Flexor Digiti Minimi (Fig. 5-103)

Start Position

Forearm supported in supination.

Stabilize

Other fingers in extension.

Instruction

“Bend the knuckle of your little finger toward your palm while you keep the rest of the finger straight.”

Resistance

Using one finger, the therapist pushes the head of the proximal phalanx toward extension. The therapist must be sure the interphalangeal joints remain extended.

Substitutions

The flexor digitorum profundus, flexor digitorum superficialis, or third volar interosseus may substitute.

Gravity-Eliminated Position

Start Position

Forearm supported in midposition.

Stabilize

Other fingers in extension.

Instruction

“Try to bend the knuckle of your little finger toward your palm while you keep the rest of the finger straight.”

Palpation

The flexor digiti minimi is found on the volar surface of the hypothenar eminence.

Figure 5-103 Flexor digiti minimi. The therapist is pointing to the muscle belly.

Finger Abduction

Prime Movers

Dorsal interossei (4)
Abductor digiti minimi

Gravity-Eliminated Position (Fig. 5-104)

Start Position

The pronated forearm is supported with the wrist neutral. The fingers are extended and adducted. Be sure the MP joints are in neutral or slight flexion.

Stabilize

The wrist and metacarpals are gently supported.

Instruction

“Spread your fingers apart, and don’t let me push them back together.”

Action

Because the midline of the hand is the third finger and abduction is movement away from midline, the action of each finger is different. It is important to know which dorsal interossei (DAB) you are testing. The first dorsal interosseus (DAB 1) abducts the index finger toward the thumb. The DAB 2 abducts the middle finger toward the thumb. The DAB 3 abducts the middle finger toward the little finger. The DAB 4 abducts the ring finger toward the little finger. The abductor digiti minimi abducts the little finger ulnarly.

Resistance

Using the thumb and index finger to form a pincer, the therapist applies resistance at the radial or ulnar side of the head of the proximal phalanx in an attempt to push the finger toward midline. Applying resistance to the radial side of the heads of the index and middle fingers tests DABs 1 and 2. Applying resistance to the ulnar side of the middle, ring, and little fingers tests DABs 3 and 4 and the abductor digiti minimi.

Substitutions

Extensor digitorum.

Grading

Normal finger abductors do not tolerate much resistance. If the fingers give way to resistance but spring back when the resistance is removed, the grade is 5. The grade is 4 if the muscle takes some resistance. The grade is 3 when there is full AROM. The grade is 2 if there is partial AROM. The grade is 1 when contraction is felt with palpation. The grade is 0 when no contractile activity is palpable.

Palpation

DAB 1 fills the dorsal web space and is easy to palpate there. Palpate the abductor digiti minimi on the ulnar border of the fifth metacarpal. The other interossei lie between the metacarpals on the dorsal aspect of the hand, where they may be palpated; on some people, the tendons can be palpated as they enter the dorsal expansion near the heads of the metacarpals. When the DABs are atrophied, the spaces between the metacarpals on the dorsal surface appear sunken.

Figure 5-104 Finger abduction.

Finger Adduction

Prime Movers

Volar (palmar) interossei (3)

Gravity-Eliminated Position (Fig. 5-105)

Start Position

The forearm is pronated, and the MPs are abducted and in extension.

Stabilize

Both of the therapist's hands are needed for resistance. The forearm and wrist can be supported on a table.

Instruction

"Bring your fingers together and hold them. Don't let me pull them apart."

Action

Because the midline of the hand is the third finger and adduction is movement toward midline, the action of each finger is different. Palmar interosseus (PAD) 1 adducts the

index finger toward the middle finger. PAD 2 adducts the ring finger toward the middle finger. PAD 3 adducts the little finger toward the middle finger.

Resistance

The therapist holds the heads of the proximal phalanx of two adjoining fingers and applies resistance in the direction of abduction to pull the fingers apart. For the index and middle finger pair, PAD 1 is tested. For the middle and ring finger pair, PAD 2 is tested. For the ring and little finger pair, PAD 3 is tested.

Substitutions

Extrinsic finger flexors.

Grading

Same as with the finger abductors.

Palpation

The palmar interossei are usually too deep to palpate with certainty. When these muscles are atrophied, the areas between the metacarpals on the volar surface appear sunken.

Figure 5-105 Finger adduction.

Thumb IP Extension

Prime Mover

Extensor pollicis longus (EPL)

Against-Gravity Position (Fig. 5-106)

Start Position

Forearm supported in midposition, wrist flexion of 10–20°, and thumb MP and IP flexion.

Instruction

“Straighten the end of your thumb.”

Stabilize

Proximal phalanx into MP flexion.

Resistance

The therapist places one finger over the dorsum of the distal phalanx (thumb nail) and pushes only the DIP toward flexion.

Substitutions

Relaxation of the flexor pollicis longus produces apparent extensor movement as a result of rebound effect. Because the

abductor pollicis brevis, adductor pollicis, and flexor pollicis brevis insert into the lateral aspects of the dorsal expansion, they may produce thumb IP extension when the extensor pollicis longus is paralyzed. To prevent this, the position of maximal flexion of the carpometacarpal and MP joints, wrist flexion of 10–20°, and full forearm supination are used to put these synergists in a shortened, disadvantaged position while testing the EPL (Howell et al., 1989).

Gravity-Eliminated Position

Start Position

Forearm supinated, thumb flexed.

Instruction

“Try to straighten the end of your thumb.”

Palpation

The tendon of the EPL may be palpated on the ulnar border of the anatomical snuffbox and on the dorsal surface of the proximal phalanx of the thumb.

Figure 5-106 The therapist is resisting the extensor pollicis longus, whose tendon is prominent.

Thumb MP Extension

Prime Movers

Extensor pollicis brevis (EPB)
Extensor pollicis longus

Against-Gravity Position for the Extensor Pollicis Brevis (Fig. 5-107)

Start Position

Forearm supported in midposition, MP and IP joints flexed.

Stabilize

Firmly support the first metacarpal in abduction.

Instruction

“Straighten the knuckle of your thumb while keeping the end joint bent.” You may have to move the thumb passively a few times for the patient to get the kinesthetic input regarding the movement.

Resistance

The therapist’s index finger, placed on the dorsal surface of the head of the proximal phalanx, pushes toward flexion.

Substitution

Extensor pollicis longus.

Gravity-Eliminated Position

Start Position

Forearm supinated, MP and IP joints flexed.

Stabilize

First metacarpal in abduction.

Instruction

“Try to straighten the knuckle of your thumb while keeping the end joint bent.”

Palpation

Palpate the tendon of the EPB on the radial border of the anatomical snuffbox medial to the tendon of the abductor pollicis longus. The EPB may not be present.

Figure 5-107 The therapist is resisting the extensor pollicis brevis, whose tendon can be seen.

Thumb Abduction

Prime Movers

Abductor pollicis longus
Abductor pollicis brevis

Against-Gravity Position for the Abductor Pollicis Longus (Fig. 5-108)

Start Position

Forearm supinated, wrist in neutral position, thumb adducted.

Stabilize

Support the wrist on the ulnar side and hold it in neutral position.

Instruction

“Bring your thumb away from your palm. Don’t let me push it back in.”

Action

Patient abducts the thumb halfway between thumb extension and palmar abduction. The therapist may have to demonstrate this action while giving the instructions.

Resistance

The therapist’s finger presses the head of the first metacarpal toward adduction.

Substitutions

Abductor pollicis brevis, extensor pollicis brevis.

Gravity-Eliminated Position

Start Position

Forearm in midposition, wrist in neutral position, thumb adducted.

Stabilize

Support the wrist on the ulnar side and hold it in neutral position.

Instruction

“Try to bring your thumb away from your palm.”

Palpation

Palpate the tendon of the abductor pollicis longus at the wrist joint just distal to the radial styloid and lateral to the EPB.

Figure 5-108 The therapist is resisting the abductor pollicis longus, which moves the thumb away from the palm halfway between extension and palmar abduction.

Against-Gravity Position for the Abductor Pollicis Brevis (Fig. 5-109)

Start Position

Forearm is supported in supination, wrist in neutral position, and thumb adducted.

Stabilize

Support the wrist in neutral position by holding it on the dorsal and ulnar side.

Instruction

“Lift your thumb directly out of the palm of the hand. Don’t let me push it back in.”

Resistance

The therapist’s finger presses the head of the first metacarpal toward adduction.

Substitution

Abductor pollicis longus.

Gravity-Eliminated Position

Start Position

Forearm is supported in midposition, wrist in neutral position, thumb adducted.

Stabilize

Support the wrist in neutral position by holding it on the dorsal and ulnar side.

Instruction

“Try to move your thumb away from the palm of your hand.”

Palpation

Palpate the abductor pollicis brevis over the center of the thenar eminence.

Figure 5-109 The therapist is resisting the abductor pollicis brevis, which moves the thumb directly up from the palm of the hand (palmar abduction).

Thumb IP Flexion

Prime Mover

Flexor pollicis longus

Against-Gravity Position (Fig. 5-110)

Start Position

Elbow flexed and supported on a table. Forearm supinated so that the palmar surface of the thumb faces the ceiling; thumb extended at the MP and IP joints.

Stabilize

Proximal phalanx, holding MP joint in extension.

Instruction

“Bend the tip of your thumb as far as you can, and don’t let me straighten it.”

Resistance

The therapist’s finger pushes the head of the distal phalanx toward extension.

Substitution

Relaxation of the extensor pollicis longus causes apparent rebound movement.

Gravity-Eliminated Position

Start Position

Forearm supinated to 90° so that the thumb can flex across the palm.

Stabilize

Proximal phalanx, holding MP joint in extension.

Instruction

“Try to bend the tip of your thumb as far as you can.”

Palpation

Palpate the flexor pollicis longus on the palmar surface of the proximal phalanx.

Figure 5-110 The therapist is resisting the flexor pollicis longus.

Thumb MP Flexion

Prime Movers

Flexor pollicis brevis
Flexor pollicis longus

Against-Gravity Position for the Flexor Pollicis Brevis (Fig. 5-111)

Start Position

Elbow flexed and supported on the table. Forearm supinated so that the palmar surface of the thumb faces the ceiling; thumb is extended at both the MP and IP joints.

Stabilize

Firmly support the first metacarpal.

Instruction

“Bend your thumb across your palm, keeping the end joint of your thumb straight. Don’t let me pull it back out.”

Resistance

The therapist’s finger pushes the head of the proximal phalanx toward extension.

Substitution

Flexor pollicis longus; the abductor pollicis brevis and the adductor pollicis through insertion into the extensor hood. To rule out the effect of the flexor pollicis longus when testing the flexor pollicis brevis, a test position of maximal elbow flexion, maximal pronation, and maximal wrist flexion has been recommended (Howell et al., 1989).

Gravity-Eliminated Position

Start Position

Forearm supinated to 90° so that the thumb can flex across the palm.

Stabilize

First metacarpal.

Figure 5-111 The therapist is resisting the flexor pollicis brevis.

Instruction

“Try to bend your thumb into your palm, keeping the end joint of your thumb straight.”

Palpation

Palpate the flexor pollicis brevis on the thenar eminence just proximal to the MP joint and medial to the abductor pollicis brevis.

Thumb Adduction

Prime Mover

Adductor pollicis

Against-Gravity Position (Fig. 5-112)

Start Position

Forearm pronated, wrist and fingers in neutral position, thumb abducted, and MP and IP joints of the thumb in extension.

Stabilize

Metacarpals of fingers, keeping the MP joints in neutral.

Instruction

“Lift your thumb into the palm of your hand, and don’t let me pull it out.”

Resistance

The therapist grasps the head of the proximal phalanx and tries to pull it away from the palm toward abduction.

Substitutions

The extensor pollicis longus, flexor pollicis longus, or flexor pollicis brevis may substitute.

Gravity-Eliminated Position

Start Position

Same except forearm is in midposition.

Stabilize

Metacarpals of fingers, keeping the MP joints in neutral.

Instruction

“Try to bring your thumb into the palm of your hand.”

Palpation

Palpate the adductor pollicis on the palmar surface of the thumb web space.

Figure 5-112 The therapist is resisting the adductor pollicis.

Opposition

Prime Movers

Opponens pollicis
Opponens digiti minimi

Against-Gravity Position (Fig. 5-113)

Start Position

Forearm supinated and supported, wrist in neutral position, thumb adducted and extended.

Stabilize

Hold the wrist in a neutral position.

Instruction

“Touch the pad of your thumb to the pad of your little finger. Don’t let me pull them apart.”

Resistance

The therapist holds along the first metacarpal and derotates the thumb or holds along the fifth metacarpal and derotates the little finger. These can be resisted simultaneously using both hands.

Substitutions

The abductor pollicis brevis, flexor pollicis brevis, or flexor pollicis longus may substitute.

Gravity-Eliminated Position

Start Position

Elbow resting on the table with forearm perpendicular to the table, wrist in neutral position, thumb adducted and extended.

Stabilize

Hold the wrist in a neutral position.

Instruction

“Try to touch the pad of your thumb to the pad of your little finger.”

Palpation

Place fingertips along the lateral side of the shaft of the first metacarpal where the opponens pollicis may be palpated before it becomes deep to the abductor pollicis brevis. The opponens digiti minimi can be palpated volarly along the shaft of the fifth metacarpal.

Figure 5-113 The therapist is resisting both the opponens pollicis and the opponens digiti minimi.

MEASUREMENT OF SELECTED LOWER EXTREMITY MUSCLE GROUPS

Muscle testing of the flexors and extensors of the three major joints of the lower extremity is described here because of their importance to functions required for completion of certain activities of daily living, such as climbing stairs and curbs, dressing, bathing, sitting, standing, and transferring. Only against-gravity testing is described. Muscles weaker than 3 (fair) are too weak for functional activities in occupational therapy, and in these cases, adaptive methods of doing activities of daily living are the most efficient therapeutic intervention.

Hip Flexion

Prime Movers

Iliopsoas
Iliacus
Psoas major

Against-Gravity Start Position

Sitting on the plinth with lower leg hanging down.

Stabilize

The pelvis is stabilized on the plinth.

Instruction

“Lift your knee toward the ceiling, keeping your knee bent. Don’t let me push your leg back down.”

Resistance

The therapist presses the distal anterior thigh down toward extension (Fig. 5-114).

Palpation

The iliacus is too deep to be palpated. With the patient sitting, the psoas major can be palpated if the patient bends forward and relaxes the abdominal muscles. The therapist’s fingers lie at the waist between the ribs and the iliac crest, and the therapist applies pressure posteriorly to feel the contraction of the psoas major as the hip flexes (Smith, Weiss, & Lehmkuhl, 1996).

Figure 5-114 The therapist is attempting to palpate the psoas major while resisting hip flexion.

Hip Extension

Prime Movers

Gluteus maximus
Biceps femoris

Against-Gravity Start Position for the Gluteus Maximus

The patient lies prone with the knee flexed to 90° or more (Kendall et al., 2005).

Stabilize

The pelvis and lumbar spine are stabilized on the plinth.

Instruction

“Lift your leg off the table as high as you can. Keep your knee bent.”

Resistance

The therapist presses the distal posterior thigh down toward flexion (Fig. 5-115).

Palpation

The gluteus maximus, the large muscle of the buttocks, can be easily palpated.

Substitutions

Extension of the lumbar spine. The other hamstrings, the semimembranosus and the semitendinosus, assist resisted hip extension if the hip is internally rotated (Kendall et al., 2005).

Figure 5-115 The therapist is resisting hip extension with the knee flexed to test the gluteus maximus.

Start Position for Combined Gluteus Maximus and Biceps Femoris Action

The patient lies supine with the leg to be tested in full extension and holds the other leg in flexion at the hip and knee (Diekmeyer, 1978).

Stabilize

The pelvis and lumbar spine are stabilized by the plinth.

Instruction

“Do not let me lift your leg off the plinth.”

Resistance

The therapist holds the thigh just above the knee and attempts to raise the leg off the plinth (Fig. 5-116).

Grading

Hip extension is graded as 5 (normal) if the trunk rather than the leg comes up off the plinth and as 3 (fair) if the hip gives as the trunk begins to come up off the table.

Palpation

Palpate the biceps femoris on the posterior aspect of the thigh; its tendon bounds the popliteal fossa laterally (Kendall et al., 2005).

Figure 5-116 During testing of the gluteus maximus and the biceps femoris together, the patient lies supine and holds the hip and knee of the untested leg flexed. The therapist tries to lift the extended leg off of the plinth.

Knee Flexion

Prime Movers

Hamstrings
Semimembranosus
Semitendinosus
Biceps femoris

Against-Gravity Start Position

The patient lies prone, with both hips and knees extended.

Stabilize

The thigh is stabilized against the plinth.

Instruction

“Bend your knee. Hold it. Don’t let me push it back to the plinth.”

Resistance

The therapist’s hand, placed on the distal end of the posterior surface of the tibia, pushes toward extension. If resistance is applied to one side, medially or laterally, either the lateral or medial hamstrings will contract more strongly (Fig. 5-117).

Grading

In deciding between a 3– and 3 grade, the therapist must make an educated guess unless the patient can stand up and demonstrate knee flexion to 120°, that is, full flexion, against gravity.

Palpation

Palpate these three muscles on the posterior surface of the thigh. Palpate the tendon of the biceps femoris on the lateral side of the popliteal space and the tendon of the semitendinosus on the medial side of the popliteal space. Both tendons become prominent when resistance is applied. Isolate the biceps femoris from the other muscles by rotating the lower leg externally with respect to the femur. The semitendinosus contracts more prominently if the lower leg is rotated internally with respect to the femur. The semimembranosus lies deep to the semitendinosus, but its lower portion is palpable on both sides of the semitendinosus (Kendall et al., 2005).

Substitutions

When the patient is prone, gravity assists flexion beyond 90°. When the patient is sitting, gravity can flex the knee.

Figure 5-117 Knee flexion against gravity.

Knee Extension

Prime Movers

Quadriceps
 Rectus femoris
 Vastus medialis
 Vastus intermedius
 Vastus lateralis

Against-Gravity Start Position

The patient sits on the plinth with the knee flexed and lower leg hanging down.

Stabilize

The thigh is stabilized on the plinth.

Instruction

“Straighten your knee. Don’t let me bend it.”

Resistance

After the patient achieves full extension, the knee is flexed approximately 10–15° before resistance is applied. The therapist’s hand is placed at the distal end of the anterior surface of the tibia (Fig. 5-118). Resistance is applied slowly to build up to the patient’s maximum to avoid injury to the knee. *Applying sudden or excessive resistance can injure the knee.* It is almost impossible to break a normal quadriceps (Hines, 1965).

Palpation

Palpate the tendon of the quadriceps as it approaches the patella. Except for the vastus intermedius, the muscle bellies can be palpated on the anterior surface of the thigh. The rectus femoris is in the center and lies over the vastus intermedius. Palpate the other vasti medially and laterally to the rectus femoris.

Substitutions

None.

Figure 5-118 Knee extension against gravity.

Ankle Dorsiflexion

Prime Movers

Tibialis anterior
Extensor hallucis longus
Extensor digitorum longus

Against-Gravity Start Position

The patient sits on the plinth with the lower leg hanging down. The foot is perpendicular to the lower leg.

Stabilize

Lower leg just proximal to the ankle.

Instruction

“Lift your foot up so your toes point to the ceiling.”

Resistance

The therapist’s hand lies on the forefoot and pushes toward plantar flexion without allowing the foot to invert or evert (Fig. 5-119).

Palpation

Palpate the belly of the tibialis anterior immediately lateral to the shaft of the tibia. Palpate its large tendon on the anterior surface of the ankle, medial to the tendon of the extensor hallucis longus. Palpate the latter in the middle of the anterior surface of the ankle. The extensor digitorum longus tendon is prominent on the lateral side of the anterior aspect of the ankle. The tendons of the extensor hallucis longus and extensor digitorum longus can be traced to their insertions on the toes.

Substitutions

None.

Figure 5-119 Ankle dorsiflexion against gravity.

Ankle Plantar Flexion

Prime Movers

Gastrocnemius
Soleus

Against-Gravity Start Position

There are two ways to test plantar flexion: (1) The patient stands. (2) The patient who cannot stand lies prone on the plinth with the foot off the end of the plinth.

Stabilize

In the standing test, the patient may have to hold onto something for balance. In the prone test, stabilize the lower leg just above the ankle.

Instruction

(1) “Stand on your tiptoes. Do it 20 times.” (2) “Press down with your foot as if you were pressing on the gas pedal of a car. Don’t let me push it back.”

Resistance

In the standing test, the full body weight resists these muscles (Fig. 5-120). In the prone test, the therapist applies

Figure 5-120 Ability to stand on tiptoe indicated grade 5 ankle plantar flexion.

manual resistance against the distal portion of the foot and pushes the foot toward dorsiflexion (Fig. 5-121).

Grading

According to Hislop and Montgomery (1995), the grade is 5 (normal) if the patient completes 20 heel raises through full ROM without rest or fatigue. Other therapists grade 5 if the person can go up on tiptoes and maintain the position longer than momentarily. Hislop and Montgomery give a grade of 4 (good) if the patient completes 10 to 19 heel raises through full ROM without rest or fatigue. The grade is 3 (fair) if 1 to 9 heel raises are completed correctly without rest or fatigue. If the patient is unable to complete full ROM in any one repetition, the grade drops automatically to the next lower level. If the patient cannot complete one heel raise, the grade must be less than 3, and the patient is tested prone. In the prone test, the grade is 2+ (poor plus) if the patient can complete full range and hold against maximal resistance. If the patient completes full range but cannot take any resistance, the grade is 2 (poor).

Palpation

The soleus is palpable at the distal portion of the lower leg. The gastrocnemius is the superficial muscle of the calf; the two heads can be palpated at their origin on either side of the posterior femur. The Achilles tendon is the insertion of both the soleus and gastrocnemius and is readily palpable at the back of the ankle. To minimize the influence of the gastrocnemius when testing for the soleus, the patient lies prone with the knee flexed. Slight resistance is applied to plantar flexion (Kendall et al., 2005).

Substitutions

Gravity substitutes when the person is lying supine or is sitting with feet off the supporting surface. The extrinsic toe flexors substitute weakly.

Figure 5-121 Ankle plantarflexion against gravity.

Interpreting the Muscle Test

After recording all muscle test scores, the therapist reviews the scores and looks for the weak muscles and the distribution and significance of the weakness. Any muscle that grades good minus (4−) or below is considered weak. Good plus (4+) muscles are functional and usually require no therapy. Good (4) muscles may or may not be functionally adequate for the patient, depending on his or her occupational task requirements. The pattern of muscle weakness is important. The pattern may indicate general weakness caused by disuse secondary to immobilization, or it may reflect the level of spinal innervation in a patient after spinal cord injury or the distribution of a peripheral nerve in the case of peripheral nerve injury. A pattern of imbalance of forces in agonist and antagonist muscles may be deforming; therefore, counterpositioning or splinting should be considered along with strengthening of the weak muscles.

The pattern of significant strengths is also important. For example, a muscle test of a patient with injured spinal cord that indicates some strength in a muscle innervated by a segment below the diagnosed level of injury is hopeful for more recovery. Or, because muscles are reinnervated proximally to distally after peripheral nerve injury, findings showing beginning return of strength in particular muscles help to track the progress of nerve regeneration.

Short-term goals move the patient from the level of strength determined by testing to the next higher level; for example, if a muscle grades 3, the short-term goal is to improve strength to 3+; if it grades 3+, the goal is to increase strength to 4−, and so on. The required strength for occupational functioning must always be kept in mind when establishing goals.

If the muscle test is a reevaluation, the scores are compared with those of the previous test. The frequency of reevaluation depends on the nature of expected recovery. Expected rapid recovery requires frequent reevaluation. If

the repeated muscle test shows that the patient is making gains, the program is considered beneficial and its demands are upgraded. If repeated muscle tests show no gains despite program adaptations, the patient is considered to have reached a plateau and to no longer benefit from remedial therapy. In that case, the focus of treatment shifts to teaching the patient compensatory strategies to enable participation in desired tasks and activities.

Patients with degenerative diseases are expected to get weaker; therefore, therapy is aimed at maintaining their strength and function for as long as possible. Repeated muscle tests confirm that effect of therapy. A plateau for these patients is desirable; it indicates that the therapy is effective for maintaining strength and should be continued.

MEASUREMENT OF GRASP AND PINCH STRENGTH

Therapists supplement manual strength testing with dynamometric evaluations of grip and pinch strength that are valid and reliable (Bellace et al., 2000; Peolsson, Hedlund, & Öberg, 2001) and for which norms have been established (Mathiowetz et al., 1985). Abbreviated versions of the norms are listed in Tables 5-2 and 5-3. Although these norms were originally established using a specific version of the Jamar dynamometer, it has now been established that the Jamar (Blair, 1989), Rolyan (Mathiowetz, 2002), Dexter (Bellace et al., 2000), BTE-Primus (Schechtman et al., 2003), or Baseline (Mathiowetz, Vizenor, & Melander, 2000) models can be used with these grip strength norms. Because variations in measurement between models have been reported (Schechtman, Gestewitz, & Kimble, 2005), therapists are cautioned to use the same dynamometer consistently with any specific patient. The pinch norms can be used with the B & L, JTech, and NK pinch meters because they have been

found to be interchangeably reliable: for symptomatic subjects ($r < 0.90$) and for non-symptomatic subjects ($r > 0.80$) (MacDermid, Evenhuis, & Louzon, 2001).

As with any tool of measurement, the instrument must be **calibrated** and set at 0 to start. Dynamometers and pinch meters can be calibrated by placing known weights on or suspending them from the compression part of the meter (Fess, 1987). With this procedure, the Jamar dynamometer was found to be accurate to within $\pm 7\%$ (Schechtman, Gestewitz, & Kimble, 2005), and the B & L pinch meter was found to be accurate to within $\pm 1\%$ (Mathiowetz, Vizenor, & Melander, 2000).

The standard method of measurement used in the study from which the norms were established reflects the recommendations of the American Society of Hand Therapists (Fess, 1992). Test–retest (1 week) reliability of this method using the Jamar hydraulic dynamometer was found to be 0.88; inter-rater reliability (two raters, same time) was 0.99. Inter-rater (two raters, same time) reliability of averaged B & L pinch meter scores was 0.98, and test–retest (1 week) reliability was 0.81 (Mathiowetz et al., 1984).

A vigorimeter is an acceptable alternative hand strength-measuring device for patients whose diagnoses contraindicate stress on joints and/or skin. It requires the patient to squeeze a rubber bulb rather than a steel handle. The vigorimeter is a commercially available instrument for which norms have been published (Fike & Rousseau, 1982).

Another adapted sphygmomanometer for measuring grip strength of patients with rheumatoid arthritis was found to have a strong linear relationship ($r = 0.83$ for the

right hand; $r = 0.84$ for the left hand) to the Jamar when tested on 88 patients. Agnew and Maas (1991) used linear regression equations to develop conversion tables to relate scores of the Jamar to the sphygmomanometer.

Position can be a factor in the results of a grip strength test. Su et al (1994) examined the effects of different positions of the elbow and shoulder on grip strength using the Jamar dynamometer. The researchers found significant differences in the highest mean grip strength recorded in various positions. This study demonstrates the importance of consistency in the position used for grip testing. If the shoulder or elbow is positioned differently from test to test, the scores will not be reliable, and if the patient is not positioned as in the study that established the norms, the norms are unusable.

Lamoreaux and Hoffer (1995) looked at wrist deviation and its effects on grip and pinch strength. They found no statistical difference in pinch strength when the wrist was deviated, but wrist radial and ulnar deviation significantly decreased grip strength. This research is clinically relevant because certain patients in occupational therapy practice, such as those with Colles' fractures and rheumatoid arthritis, are prone to develop wrist deviations.

A study by Nitschke et al. (1999) addressed how much change in a grip score is necessary to result in a functional change. The study consisted of 42 female participants; 32 were healthy, and 10 had nonspecific regional pain. The authors concluded that at least a 13-pound change in grip strength was necessary to be sure the improvement was not a chance occurrence.

With occupational therapy practice moving into the community and home, the need for valid tools that are quick, portable, and easy to use is increasing. Bohannon (1998) examined the validity of using the Jamar dynamometer to assess upper extremity strength as compared to manual muscle testing in adult home care patients. There were significant correlations between grip dynamometry and manual muscle testing, with the highest correlation between the dynamometer and manual tests of grip for the left hand ($r = 0.80$) and for the right hand ($r = 0.78$). Therefore, the handgrip dynamometer was found to be a good predictor of overall strength.

Grasp (Fig. 5-122; Table 5-2)

The patient should be seated with his or her shoulder adducted and neutrally rotated, the elbow flexed at 90° , and the forearm and wrist in neutral position. Grip strength varies with elbow position, so a standardized position is necessary (Su et al., 1994). The handle of the dynamometer is set at the second position (Mathiowetz et al., 1984, 1985). The task is demonstrated to the patient. After the dynamometer is positioned in the patient's hand, the therapist says, "Ready? Squeeze as hard as you can," and urges the patient on throughout the attempt. The patient squeezes the dynamometer with as much force as he or she can three times, with a 2- to 3-minute rest between trials. The score is the average of the three trials.

Pinch

Three types of pinch are typically evaluated because they are involved in accomplishing occupational tasks and activities efficiently.

Figure 5-122 Measuring grasp using a dynamometer. The patient's upper arm is close to his body, and the elbow is flexed to 90° .

Figure 5-123 Measuring tip pinch with a pinch meter.

Tip Pinch (Fig. 5-123; Table 5-3)

The patient pinches the ends of the pinch meter between the tips of the thumb and index finger (Mathiowetz et al., 1985) or between the thumb and the index and middle fingers (MacDermid, Evenhuis, & Louzon, 2001). The test is administered by first giving the patient instructions and a demonstration. Then the therapist says, "Ready? Pinch as hard as you can." The patient is urged on as he or she attempts to pinch. Three trials, with a rest between each trial, are completed. The average of three trials is recorded.

Lateral Pinch (Fig. 5-124; Table 5-3)

The patient pinches the meter between the pad of the thumb and the lateral surface of the index finger. The instructions and procedure are the same as for tip pinch.

Palmar Pinch: Three-Jaw Chuck (Fig. 5-125; Table 5-3)

The patient pinches the meter between the pad of the thumb and the pads of the index and middle fingers. The instructions and procedure are the same as for tip pinch.

Interpretation of Grasp and Pinch Scores

Scores are compared with those of the other hand or to norms to ascertain whether the patient has a significant

Figure 5-124 Measuring lateral pinch.

Figure 5-125 Measuring palmar pinch or three-jaw chuck pinch.

limitation. The accuracy of the Jamar dynamometer was found to be $\pm 7\%$, which means that, if the patient scored 50 pounds, the actual strength may range from 46.5 to 53.5 pounds (Schechtman, Gestewitz, & Kimble, 2005). Grasp and pinch scores are considered abnormal if they are associated with a functional limitation and/or if they are ± 3 **standard deviations** (SD) from the mean. For example, suppose a 40-year-old man had a grasp score of 50 pounds when you averaged the three trials for his dominant right hand. Table 5-2 shows that the average score for his age group is 117 pounds, so the patient's grasp score was 67 pounds less than the mean normal score on the table. When you divide the difference in his score (67) by the SD given in the table (21), you find that he is 3.2 SD below the mean. This is more than 3 SD below the mean, so he has a significant limitation. Grasp and pinch measurements can be quickly and easily reevaluated over time to monitor the progress of the patient and the effectiveness of the treatment plan.

MEASUREMENT OF ENDURANCE

Endurance is the ability to sustain effort and to resist fatigue (Wilmore & Costill, 1999). It is related to cardiopulmonary and muscular function. The better cardiopulmonary and muscular function a person has, the better the endurance. Many of the patients seen in occupational therapy have endurance limitations. A variety of conditions, including cardiac or pulmonary impairments, a major trauma or illness requiring bed rest, loss of significant muscle function, or the need to use prostheses or adapted equipment, can affect one's endurance.

Cardiopulmonary Aspects of Endurance

Cardiopulmonary endurance is the ability of the whole body to sustain prolonged rhythmical activity (Wilmore & Costill, 1999). Muscular work creates a demand for

oxygen. As an immediate effect of activity, the heart rate and stroke volume increase. Heart rate increases to deliver the required amount of oxygenated blood to the active muscles. Stroke volume, or amount of blood pumped per heartbeat, increases because of increased venous flow into the heart during diastole (the period of relaxation when the chambers fill) (American College of Sports Medicine, 2000). As the intensity of muscular work increases, more oxygen is required. There is, however, a maximal amount of oxygen that a person can take in and dispense to muscles during exercise. Termed maximal oxygen uptake, it is abbreviated $\dot{V}O_{2\max}$. $\dot{V}O_{2\max}$ is a standard measure of cardiovascular fitness (American College of Sports Medicine, 2001). It increases with physical training and decreases with bed rest and age. With physical training, the heart rate becomes lower for the same level of work, which is referred to as the training effect. The training effect indicates improvement in efficiency of the circulatory system (American College of Sports Medicine, 2000).

There is a linear relationship between oxygen uptake and heart rate for various intensities of light to moderately heavy exercise. Therefore, heart rate can be used to estimate $\dot{V}O_2$. However, the heart rate of those who are physically unfit increases faster for a given level of oxygen uptake; therefore, the relationship is individual (American College of Sports Medicine, 2001).

Muscular Aspects of Endurance

Endurance of a muscle or muscle group is its ability to sustain intensive activity (Wilmore & Costill, 1999); endurance may be decreased because of local trauma or reduction of innervation. In normal muscle contraction against low resistance, only a few of the available motor units are needed at any one time. The active and resting units take turns. Fatigue rarely occurs in conditions required for activities of daily life. If the person sustains a contraction that exceeds 15–20% MVC for the muscle group involved, however, blood flow to the working muscle decreases, causing a shift to anaerobic metabolism, which limits duration of contraction. The limitation is signaled by symptoms of muscle fatigue (cramping, burning, and tremor, which are secondary to the accumulation of lactic acid) and slowed nerve conduction velocity to the muscle fibers, which reduce tension and eventually result in inability to hold the contraction (American College of Sports Medicine, 2001). Strength and endurance are closely related. As a muscle gains strength, its endurance for a given level of work also increases.

For neurologically disadvantaged muscle, such as after a spinal cord injury, peripheral nerve injury, or stroke, fewer motor units or muscle fibers may be available than are required for daily activity. Such muscles work at as much as 50–75% MVC to do otherwise low-intensity work (Trombly & Quintana, 1985).

The Evaluation

Endurance can be measured dynamically or statically. Dynamic assessments include the number of repetitions per unit of time or the percentage of maximal heart rate generated by an aerobic activity or exercise or metabolic equivalent (MET) level. Static assessment is the amount of time a contraction can be held (American College of Sports Medicine, 2000; Fletcher et al., 2001).

Intensity, duration, and frequency of the activity are considerations in evaluation of endurance. Intensity is related to both resistance and speed. The heavier the resistance or the faster the pace is, the higher the intensity. The intensity of the test activity must be kept constant from test to test to gauge improvement.

Intensity of an activity is estimated in terms of light, moderate, or heavy work or number of METs. One MET equals basal metabolic rate (American College of Sports Medicine, 2001). Basal metabolic rate is the amount of oxygen consumption necessary to maintain the metabolic processes (e.g., respiration, circulation, peristalsis, temper-

ature regulation, glandular function) of the body at rest and is quantified as 3.5 mL of oxygen per kilogram of body weight per minute. The energy cost of activities or exercise can be rated using multiples of METs. An exercise that is rated 4 METs requires 4 times the amount of oxygen per kilogram of body weight per minute than the basal rate. The oxygen consumption of daily living, recreational, and vocational tasks has been measured for normal subjects, and the METs required for each task have been calculated (Table 5-4). These costs are estimates that vary with environmental conditions, such as humidity and temperature, and personal conditions, such as anger.

Heart rate is a simple means to quantify the physiological demand of a dynamic activity for a particular person (Hall & Brody, 1999). Because heart rate relates linearly to $\dot{V}O_{2\max}$ except at the upper limits (80–90%) of maximal capacity, if a person's heart rate is 70% of maximal heart rate (HR_{\max}), he or she is using approximately 70% of $\dot{V}O_{2\max}$. HR_{\max} is estimated by subtracting the person's age from 220. The pulse taken immediately after aerobic large-muscle exercise is then related to the person's HR_{\max} as percent-

Table 5-4. Metabolic Equivalents

Energy Level	Activities of Daily Living	Occupational Activities	Recreational Activities
1–2 MET	Eating Dressing and undressing Washing hands and face Sweeping the floor	Desk and phone work Keyboard operation Riding in a car Watch repair	Standing Walking (strolling 1 mile/hr) Playing cards and board games Painting
2.5–3.5 MET	Showering Food preparation Making beds Ironing Cleaning windows	Welding Small-parts assembly Bricklaying and plastering Playing a musical instrument	Walking (2 miles/hr) Cycling (5.5 miles/hr) Horseback riding (walk) Billiards Bowling Golf (pulling bag cart)
4–5 MET	Raking leaves Hoeing Walking downstairs Beating carpets	Heavy assembly work Painting Light carpentry Paperhanging	Walking (3 miles/hr) Cycling (9 miles/hr) Golf (carrying clubs) Ballroom dancing Table tennis
5.5–6.5 MET	Walking with braces and crutches Mowing lawn by hand mower	Carpentry Chopping wood	Walking (4 miles/hr) Tennis Horseback riding (trot) Folk dancing Ice or roller skating
7–8 MET		Shoveling (22 pounds for 10 minutes) Digging	Jogging (5 miles/hr) Skiing (vigorous) Horseback riding (gallop)
8.5–9.5 MET		Shoveling (31 pounds for 10 minutes)	Running (7.5 miles/hr) Squash Fencing Football Basketball

MET, metabolic equivalents.

age of maximum. A constant heart rate obtained during exercise indicates a steady state, that is, a balance of oxygen intake and consumption (Fletcher et al., 2001). Heart rate is measured by placing the index and middle fingers lightly but firmly over the radial artery at the wrist (lateral to the flexor carpi radialis) and counting the number of beats per minute (bpm). It is most accurate to count for a full minute, but an exercise heart rate can be counted for only 10 to 15 seconds, as the return to resting rate occurs quickly after stopping exercise. In that case, the obtained value is multiplied by 6 for 10 seconds or 4 for 15 seconds to arrive at the bpm (American College of Sports Medicine, 2001).

The relation between heart rate and oxygen uptake does not hold for patients with chronic obstructive pulmonary disease, who, because of reduced expiration and expulsion of carbon dioxide waste, have greater ventilatory requirements. These patients have limited exercise capacity (American College of Sports Medicine, 2001).

Whether to measure dynamically or statically depends on the functional goal of the patient and his or her cardiopulmonary status. If the patient's self-advancement and self-enhancement roles require mostly isotonic activity, endurance should be evaluated dynamically. To measure endurance in terms of number of repetitions, use a light repetitive activity such as the *Box and Block Test*, which is described in Chapter 42. It can be adapted to measure upper extremity endurance for light work by counting the number of blocks the patient can transfer before becoming fatigued.

If the patient expects to return to a job or hobby that requires maintained grasp or holding loads (isometric contractions), static endurance should be tested. To measure statically, the amount of time a person can hold an object or position requiring a certain level MVC is noted. Normally, a person can hold 25% MVC for 5 to 6 minutes, 50% MVC for 1 to 2 minutes, and 100% MVC only momentarily (Dehn & Mullins, 1977).

Isometric holding increases blood pressure and stresses the cardiopulmonary system (Pollock et al., 2000) (Safety Tip 5-1). This is true especially if the person holds his or her breath (Valsalva maneuver) while holding the contraction. Therefore, persons being tested should talk (e.g., count or sing) while doing an isometric contraction to preclude breath holding. Isometric testing can produce arrhythmias and, therefore, electrocardiogram and blood pressure should be monitored during isometric testing of patients with heart disease or abnormalities. The results of isometric testing cannot be extrapolated to gauge isotonic aerobic exercise capacity (Pollock et al., 2000).

Another way to assess dynamic endurance is to ascertain the individual's perception of how hard he or she is working. Scales of ratings of perceived exertion (RPE), such as the *Rating of Perceived Exertion* (Borg, 1985), are based on psychophysics or the relating of a physical property to a subjective property via scaling procedures (Russell, 1997). The *Borg (15-point) Scale of Perceived Exertion* ranges from 6 (no

SAFETY NOTE 5-1

Precautions for Isometric Testing

- If the patient exhibits dyspnea, weakness, changes in sensorium, angina, decreased heart rate (HR) for increased workload, increased ventricular arrhythmias, pallor, or cyanosis, his or her cardiopulmonary capacity has been exceeded (American College of Sports Medicine, 2001).
- Endurance testing in occupational therapy should not reach this level, but if any of these symptoms are observed or reported by the patient, the intensity of work should be immediately reduced to a comfortable level.

exertion at all) to 20 (maximal exertion) (Wilmore & Costill, 1999). This scale allows the person to assign one of a consecutive set of numbers with a corresponding descriptor of amount of exertion to the ongoing activity (e.g., 11, fairly light; or 17, very hard). The American Heart Association (2001) and the American College of Sports Medicine (2000) suggest that an RPE of 12–16 on the 15-point *Borg Scale* is associated with a physiological training effect (Whaley et al., 1997). Therapists should be aware, however, that perceived exertion for a given level of oxygen uptake is higher for arm work than leg work (Russell, 1997). For dynamic activities, the *Borg Scale* has been found over the years to correlate validly with heart rate and oxygen uptake (Finucane, Fiddler, & Lindfield, 2005). Lamb, Eston, and Corns (1999) looked at test–retest reliability and found it to differ by as much as 3 RPE when level of agreement between trials was examined and the scores of the two trials were not merely correlated. Whaley et al. (1997) tested the validity of the oxygen consumption associated with each score on the 15-point *Borg Scale*. They found interindividual differences that ranged from a rating of 6 to 20 for 60% **maximum heart rate reserve** (MHRR) and from 8 to 20 for 80% MHRR in both normal healthy adults and cardiac patients. Nevertheless, these scales provide a good estimate when used repeatedly for the same patient and, therefore, may be used clinically during ongoing continuous activity, such as walking, bicycling, scrubbing floors, painting a wall, mowing the lawn, raking leaves, and calisthenic exercises. These scales do not apply to activities composed of sporadic variable movements.

The therapist should orient the person to the scale using standardized instructions published by Borg (1985) prior to the start of the activity. The scale should be enlarged and posted so that it can be seen easily from where the person is exercising. At 1- or 2-minute intervals, the therapist prompts the patient to rate exertion at that moment. The decision to continue depends on the goal and precautions for the particular patient.

Assessment Table 5-1

Summary of Assessment of Abilities and Capacities

Instrument & Reference	Description	Time to Administer	Validity ^a	Reliability ^b	Sensitivity ^c	Strengths & Weaknesses
Measurement of Range of Motion	Interval scale, ranges vary with joint being measured.	Full evaluation of all joints in the upper extremity, 45 minutes to an hour.	Gold standard.	Intra-rater reliability for shoulder external rotation, ICC = 0.58–0.67; internal rotation ICC = 0.63–0.71. Inter-rater reliability for external rotation = 0.41–0.66, internal rotation ICC = 0.41–0.66 (Awan, Smith, & Boon, 2002).	In the upper and lower extremities, measurement error is estimated at 5° (Aalto et al., 2005; Groth et al., 2001).	Strengths: Relatively fast and inexpensive measure. Measurements are consistently more accurate when done by a single therapist, with the patient in the same position from test to test. Weaknesses: Inter-rater reliability is consistently lower than intra-rater reliability. Accuracy of measurement is dependent on the consistent placement of the goniometer.
Hand Volumetry (Dodds et al., 2004)	Interval scale because it is a direct measure of the volume of water displaced.	15–20 minutes.	Direct measurement of hand volume.	Test–retest reliability, $r = 0.99$ (Dodds et al., 2004).	Variation of measurement, 3–5 mL (Dodds et al., 2004).	Strength: Gold standard for edema measurement. Weaknesses: Hand must be immersed in water, so cannot be used with open wounds, skin conditions, etc. Takes considerable time.

continued

Assessment Table 5-1

Summary of Assessment of Abilities and Capacities (continued)

Instrument & Reference	Description	Time to Administer	Validity ^a	Reliability ^b	Sensitivity ^c	Strengths & Weaknesses
Figure-of-Eight Technique to Measure Hand Edema (Pellecchia, 2004)	Interval scale.	3–4 minutes.	Correlation coefficient between figure-of-eight technique and hand volumetry, ICC = 0.94–0.95 (Malhafer et al., 2004).	Intra-tester ICC for figure-of-eight ICC = 0.98–0.99; inter-tester reliability ICC = 0.99 (Leard et al., 2004).	Not established.	Strengths: Fast measurement; can be used with individuals with open wounds or skin conditions. Weakness: Sensitivity not established.
Visual Analog Scale for Pain Measurement	Interval scale with scores from 1–10.	1 minute.	Gold standard.	Not established.	Not established.	Strengths: Fast measurement and can be used to monitor changes in pain in a single patient. Weakness: Cannot be used to compare pain levels between patients.
Manual Muscle Testing	Ordinal scale from 0–5.	Depending on the number of muscles being tested, up to 1 hour.	Gold standard.	In a reliability test for intrinsic hand muscles, intra-rater $r = 0.71$ – 0.96 and inter-rater $r = 0.72$ – 0.93 (Brandsma et al., 1995). In an evaluation of reliability for the deltoid muscles, Pollard et al. (2005) found that two testers agreed exactly 82% of the time ($\kappa = 0.62$).	Not established.	Strength: No equipment needed. Weakness: Dependent on training and experience of the tester.

continued

Hand-Held Dynamometry	Interval scale, measurement is in kilograms.	Depending on the number of muscles being tested, up to 1 hour.	Direct measure of strength.	Inter-rater reliability ICC = 0.79–0.96; intra-rater reliability ICC = 0.87–0.98 (Ottenbacher, et al., 2002).	Norms established (Bohannon, 1998).	Strength: Reliable testing device. Weaknesses: Validity and sensitivity not established; expense of device.
Grip Strength Test	Interval scale, measures resistance in pounds or kilograms.	5 minutes.	Recommended by American Society of Hand Therapy as a valid measure of hand strength (Fess, 1992).	Test–retest reliability of Jamar dynamometer = 0.88; inter-rater reliability = 0.99 (Mathiowetz et al., 1984).	Norms established (Mathiowetz et al., 1985).	Strengths: Quick and easy measure; norms available. Weakness: Dynamometers need to be calibrated regularly to be accurate.
Pinch Test	Interval scale, measures resistance in pounds or kilograms	5 minutes.	Recommended by American Society of Hand Therapy as a valid measure of pinch strength (Fess, 1992).	Inter-rater reliability = 0.98; test–retest reliability = 0.81 (Mathiowetz et al., 1984).	Norms established (Mathiowetz, et al., 1985).	Strengths: Quick and easy measure; norms available. Weaknesses: Pinchmeters need to be calibrated regularly to be accurate.
Borg Rating of Perceived Exertion Scale	Ordinal scale, from 6–20.	1 minute.	Valid measure of exercise intensity (Chen, Fan, & Moe, 2002).	Not established.	Not established.	Strength: Good measure for individuals. Weakness: Not consistent between individuals.

^a Validity is the ability of an instrument to measure what it is intended and presumed to measure. Criterion validity is determined by comparing its results to an agreed-on gold standard (accepted test). Predictive validity is its ability to predict future outcomes.

^b Reliability is a measure of an instrument's stability. Inter-observer or inter-rater reliability refers to the ability of two different individuals to administer the instrument to a particular person and achieve similar results.

Test–retest reliability refers to the constancy of results over repeated use of the instrument in the absence of change in the patient.

^c Sensitivity to change is the ability of an instrument to detect clinically important change.

CASE

EXAMPLE

Occupational Therapy Assessment Process

Clinical Reasoning Process

Patient Information

Mrs. B. is a 58-year-old right-handed woman with a 5-year history of primary degenerative joint disease (DJD), or osteoarthritis. She complains of upper extremity weakness, stiffness, and Heberden's nodes over several DIP joints. She also complains of pain and fatigue that are increasingly limiting her self-maintenance, self advancement, and self-enhancement roles.

She is a divorced fifth-grade teacher who lives alone in a one-story house. She has two grown children and enjoys gardening, reading, and shopping for antiques. She has a referral for occupational therapy services because of the occupational dysfunction and has been approved for four outpatient visits.

Assessment Process

To determine Mrs. B.'s perception of her occupational dysfunction and her priorities, the therapist administered the Canadian Occupational Performance Measure (COPM). To determine to what extent strength and endurance problems affected Mrs. B.'s occupational functioning, a manual muscle test on selected muscle groups, grip and pinch strength assessment, visual analogue pain rating scale, and the Borg Perceived Exertion Scale for endurance during activities were administered.

Assessment Results

The results of the COPM are as follows:
 Difficulty writing on the chalk board, which she does 2 to 3 hours a day (performance 4, satisfaction 3)
 Difficulty with morning activities of daily living, including showering and dressing. She has problems reaching overhead, manipulating bottle caps, doing buttons and zippers, and putting on jewelry (performance 6, satisfaction 5)

Objectives

Understand the patient's diagnosis or condition

Know the person

Appreciate the context

Develop provisional hypotheses

Consider evaluation approach and methods

Interpret observations

Examples of Therapist's Internal Dialogue

"Mrs. B is very active, and the increasing problems she is having because of the progression of her DJD are probably very frustrating to her. I wonder how much she knows about DJD?"

"Mrs. B. lives alone and is used to taking care of herself. I wonder if she stops activities due to pain and fatigue, or works through it?"

"I bet teaching in a fifth grade classroom is a challenging environment, and I think it might be difficult to adapt the classroom to her limitations, for example, her need for rest, or stopping when she has pain. I wonder if she has any help with the heavy work around the house-heavy cleaning, lawn-mowing, snow shoveling, etc."

"She has had this diagnosis for 5 years, and it sounds like she is having increasing problems. I wonder if she is limiting her activities due to pain and fatigue, and therefore losing more strength and endurance?"

"I need to get a picture of what occupations are important to her. I also need to know exactly how her arms are functioning in terms of strength in her shoulders, elbows, and wrists, as well as her grip and pinch strength. I'd like to know how much pain she is having at rest and during activity, and what her endurance is for important activities."

"Mrs. B. is involved in lots of gross and fine motor activities during the day, and seems to be having problems with all of them."

Difficulty decorating her classroom bulletin boards and doing arts and crafts at school because of the cutting and stapling (performance 5, satisfaction 5)

Inability to do many meal preparation activities, including manipulating kitchen appliances, cutting vegetables, and carrying dishes (performance 4, satisfaction 4)
 Unable to garden as desired, specifically planting, digging with a trowel, and weeding (performance 3, satisfaction 2)

The results of Mrs. B.'s manual muscle test are displayed below. Grip strength using a Jamar dynamometer was 18 pounds on the right and 45 pounds on the left. Tip pinch strength was 3 pounds on the right, 9 pounds on the left. Lateral pinch was 5 pounds on the right, 12 pounds on the left. Palmar pinch was 4 pounds on the right, 13 pounds on the left.

Manual muscle strength	Right	Left
Shoulder flexion	3-	4-
Shoulder abduction	3-	4-
Shoulder external rotation	3-	4
Elbow flexion	4	4+
Elbow extension	3+	4
Forearm supination	3+	4+
Forearm pronation	4	4+
Wrist flexion	3+	4
Wrist extension	3+	4

Mrs. B. reported a 2 on the visual analog scale (VAS) for pain at rest but stated that pain in her hands and shoulders increases to 4 during morning activities of daily living, 5 during meal preparation, and 6 when she uses scissors or gardening tools.

Using the Borg Scale, Mrs. B. rated bathing and dressing this morning a 13; teaching an hour math lesson using the blackboard, a 14; and gardening for a half an hour, a 17.

“Mrs. B. is weak in all of the muscle groups of the right arm and proximally in her left arm. The weakness of her right shoulder would interfere with writing on the blackboard, and with washing and brushing her hair. The dynamometer test showed a significant decrease in grip strength for her right hand, which is her dominant hand, but was within normal limits for her left hand. Her right hand pinches were also significantly limited compared to the left or to the norms, while all three pinches of her left hand were within normal limits. The weakness in her right hand also contributes to her difficulty in many occupational tasks, such as using scissors or a stapler, opening jars, and manipulating garden tools.”

“Mrs. B.'s scores on the VAS indicate increased pain in her hands and shoulders during many functional activities, with decreased pain at rest. The results of the Borg Scale indicate low endurance, which contributes to her fatigue and decreased ability to perform a number of tasks, including standing while bathing, teaching, and gardening. The fact that she has pain during most of these activities would also increase her fatigue.”

Occupational Therapy Problem List

Decreased ability to perform morning activities of daily living, including bathing and dressing, because of shoulder weakness and low endurance.

Decreased ability to perform meal preparation tasks because of weak grasp and pinch.

Decreased ability to perform work-related tasks, including writing on the blackboard, decorating bulletin boards, and arts and crafts, because of weak shoulders bilaterally, poor endurance, and pain.

Decreased ability to garden because of weakness and pain.

Synthesize results

“Mrs. B. has problems with weakness, pain, and fatigue, which are all interrelated, and are all interfering with the activities she wants to be able to do. I will need to find out if she would be willing to make some adaptations to some of these occupations to reduce her pain and fatigue. I'm concerned that if I just add a home program to address her problems with strength, it will just compound her problems with endurance and fatigue.”

“I need to find out how flexible her work environment is, and whether she has any control of her daily schedule or activities when she is in the classroom. Maybe the students could help out with writing on the board or demonstrating the arts and crafts?”

“I wonder if there are any things that she is doing that are going well—any occupations with which she isn't have trouble? If not, I'm concerned about her emotional well-being.”

SUMMARY REVIEW QUESTIONS

1. Describe in general the correct placement of a goniometer.
2. What does it mean if AROM is less than PROM?
3. ROM limitations can be caused by a number of underlying conditions. State the short-term goal for treatment of elbow flexion contracture after removal of a cast used to immobilize a fractured humerus.
4. How is a break test used to determine strength?
5. Of what importance is the length-tension relationship of a muscle in manual muscle testing?
6. Describe the standardized procedures for testing muscle strength.
7. For what muscle test grades is treatment to increase strength an appropriate goal?
8. How is dynamic endurance measured?
9. How is static endurance measured?
10. What is your maximum heart rate? What percentage of $\dot{V}O_{2max}$ do you use to vacuum a room? Take a shower? Wash the dishes?

ACKNOWLEDGMENTS

Over the many editions of this textbook, several photographers have contributed to this chapter. They are Anne Fisher, ScD, OTR; Lucia Grochowska-Littlefield; Judith La Drew; and Keith Weaver. The models for the photographs are Brian Despres, OTR; Mark Erikson; Sam Fitzpatrick; Jim Morando; James Polga; and Christopher Trombly. To all of these people, without whom we could not have produced this chapter, we give our deepest thanks.

CHAPTER 6

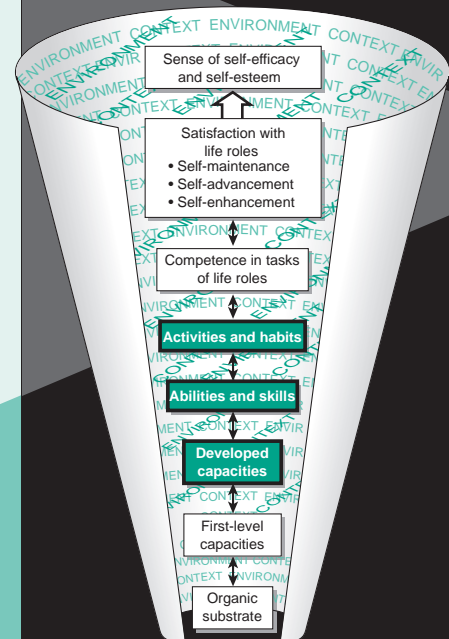

Assessing Abilities and Capacities: Motor Behavior

Virgil Mathiowetz and Julie Bass-Haugen

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Contrast the reflex-hierarchical and systems models of motor control.
2. Describe various types of motor dysfunction seen in persons with central nervous system lesions.
3. Compare the neuromaturational and systems theories of motor development.
4. Contrast the assumptions of the neurophysiological and task-related approaches to treatment.
5. Describe the different evaluation strategies that are used by the neurophysiological and task-related approaches.
6. Describe some additional evaluation strategies that are not associated directly with either approach.

Glossary

Closed-loop system—A control system that utilizes feedback to correct movement errors and achieve the planned movement (Schmidt, 1991).

Control parameter—A variable that changes behavior from one pattern of behavior to another. It does not control the change but acts as an agent for the shift in behavior (Heriza, 1991).

Coordinative structures—Groups of muscles, usually spanning several joints, that are constrained to act as a single functional unit (Magill, 2004; Turvey, 1977).

Degrees of freedom—Elements of a control system that are free to vary.

Heterarchical system or model—A system in which control is distributed among many systems; control emerges from the interaction of various subsystems; there is no strict order of command; subsystems in charge vary with task requirements.

Hierarchical system or model—A system with several levels of control, with each level subordinate to the one above it.

Knowledge of results (KR)—Awareness of the outcome of movement in relation to the goal.

Muscle tone—Resistance of a muscle to passive elongation or stretching.

Open-loop system—A control system that utilizes preprogrammed instructions (i.e., anticipatory, or feed-forward, control) to an effector; does not use feedback or error-detection processes (Schmidt, 1991).

Phase shift—Change, which is often nonlinear, from one preferred coordinated pattern to another (Heriza, 1991).

Self-organization—The idea that a system composed of a number of subsystems can organize itself through the dynamic interaction of the subsystems (i.e., no higher level control or motor program is required) (Heriza, 1991).

Splinter skill—The ability to do a specific task that does not generalize to other tasks.

Our understanding of motor behavior—motor control, motor development, motor learning, and motor skill—continues to evolve (VanSant, 1991a). Sophisticated technology has led to an explosion of information about the control, development, and acquisition of movement (Lister, 1991). Human movement scientists, neurophysiologists, neuropsychologists, and others contribute to this effort. In an attempt to impose order on the many pieces of information, they deduce models and theories of motor behavior. As these models and theories change, therapeutic approaches also must change.

As a result of changes in the motor behavior literature, some (e.g., Gordon, 1987; Shumway-Cook & Woollacott, 2001) have questioned the assumptions underlying the neurophysiological approaches, which include Rood's (1954) sensorimotor approach, Knott & Voss' (1968) proprioceptive neuromuscular facilitation, Brunnstrom's (1970) movement therapy, and Bobath's (1978, 1990) neurodevelopmental treatment. Two task-related approaches, a task-oriented approach (Horak, 1991; Mathiowetz & Bass-Haugen, 1994) (see Chapter 22) and Carr and Shepherd's (1987, 1998, 2003) approach (see Chapter 23), are proposed as alternatives to the neurophysiological approaches. The assumptions of these new approaches are derived from a systems model of motor control, systems theories of motor development, and recent motor learning theories.

Definition 6-1 provides an overview of this chapter, which contrasts the assumptions of the neurophysiological and task-related approaches, the models and theories of motor behavior that they are based on, and the evaluation

strategies associated with each approach. We believe the evaluation strategies used by the neurophysiological approaches still continue to influence clinical practice. Task-related evaluation strategies, however, have an increasing influence on current practice.

NEUROPHYSIOLOGICAL APPROACHES

Assumptions of the Neurophysiological Approaches

Definition 6-1 includes the assumptions of the four neurophysiological approaches as described by their original proponents. It is recognized that these approaches have evolved over time. For example, the neurodevelopmental treatment approach recently rejected most of the assumptions of the neurophysiological approaches and adopted most of the assumptions of the occupational therapy (OT) task-oriented approach (Howle, 2002). As a result, the theoretical differences between these approaches are much smaller today than they were 10 years ago. Unfortunately, clinical practice tends to lag behind changes in theory. Therefore, it is important to understand the differences between the neurophysiological approaches of the past and the current OT task-oriented approach. To understand the neurophysiological approaches, one must understand the reflex-**hierarchical model** of motor control and neuromaturational theories of motor development

DEFINITION 6-1

de·fin·i·tion

Comparison of the Neurophysiological and OT Task-Oriented Approaches

Neurophysiological Approaches

OT Task-Oriented Approach

Reflex-Hierarchical

- Movements are elicited by sensory input or controlled by central programs.
- Open-loop and closed-loop control is used.
- Feedback and feed-forward influence movements.
- Central nervous system (CNS) is hierarchically organized, with higher centers controlling lower centers.
- Reciprocal innervation is essential for coordinated movement.

Models of Motor Control

Systems

- Personal and environmental systems interact to achieve functional goals.
- Movement emerges from the interaction of many systems.
- Systems are dynamical, self-organizing, and heterarchical.
- Movement used for a task is the preferred means for achieving a functional goal.
- Changes in one or more systems can alter behavior.

Neuromaturational

- Changes are due to CNS maturation.
- Development follows a predictable sequence (e.g., cephalocaudal, proximal-distal).
- CNS damage leads to regression to lower levels and more stereotypical behaviors.

Theories of Motor Development

Systems

- Changes are due to interaction of multiple systems.
- Progression varies because person and environmental contexts are unique.
- CNS damage leads to attempts to use remaining resources to achieve functional goals.

Assumptions of Therapeutic Approaches

- CNS is hierarchically organized.
- Sensory stimuli inhibit spasticity and abnormal movement and facilitate normal movement and postural responses.
- Repetition of movement results in positive permanent changes in CNS.
- Recovery from CNS damage follows a predictable sequence.
- Behavioral changes after CNS damage have a neurophysiological basis.

- Personal and environmental systems, including the CNS, are heterarchically organized.
- Functional tasks help organize behavior.
- Occupational performance emerges from the interaction of persons and their environment.
- Experimentation with various strategies leads to optimal solutions to motor problems.
- Recovery is variable because personal characteristics and environmental contexts are unique.
- Behavioral changes reflect attempts to compensate and to achieve task performance.

Evaluation

Primary focus on performance components

- Abnormal muscle tone.
- Abnormal reflexes and stereotypical movement patterns lead to incoordination.
- Postural control.
- Sensation and perception.
- Memory and judgment.
- Stage of recovery or developmental level.

Primary focus on role and occupational performance using a client-centered view

- Task analysis to determine performance components and contexts that limit function and to identify preferred movement patterns for specific tasks in varied contexts.
- Variables that cause transitions to new patterns.

Secondary focus on occupational performance

Secondary focus on selected occupational performance components and contexts that limit function

from which these treatment approaches originated. A discussion of the motor learning theories that influenced the neurophysiological and task-related approaches is covered in Chapter 14.

Reflex-Hierarchical Model of Motor Control

Figure 6-1 illustrates a reflex-hierarchical model (Trombly, 1989), which synthesizes the basic science literature of the 1970s and 1980s. This model evolved from earlier separate reflex and hierarchical models, which were unsuccessful in explaining the variety of movements available to human beings. This combined model assumes that the central nervous system (CNS) is hierarchically organized and movement is controlled by central programs or elicited by sensory input. The model utilizes both **closed-loop** and **open-loop systems** to explain how slow and fast movements are controlled. Each step of the reflex-hierarchical model is discussed conceptually, using the example of a person reaching for a bottle of water. See the references listed at the end of this chapter for greater detail.

Motivation to Move Is Generated

Purposeful movement does not occur in the absence of a need to move, which is generated from within the person or as a response to external stimuli (Marsden, 1982). Thus, a person who is thirsty (internal stimulus) or sees a cold bottle of water (external stimulus) becomes motivated to reach for the bottle.

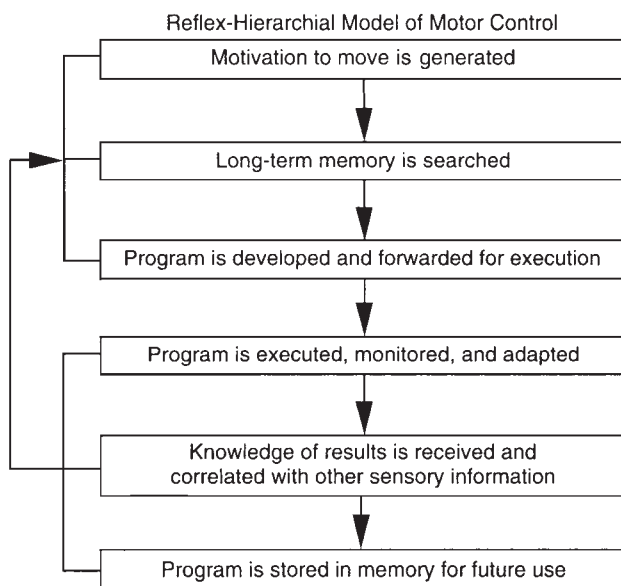

Figure 6-1 Reflex-hierarchical model of motor control, adapted from Trombly (1989), includes both open-loop and closed-loop control.

Long-Term Memory Is Searched

Once the person is motivated, the executive or programming center searches long-term memory (LTM) for a pattern of movement that would enable reaching for the bottle. All previous efforts to reach a bottle were stored in a generalized motor program that contains an abstract representation about the order, relative timing, and relative force of the reaching movement (Schmidt, 1988). It also includes the postural adjustments that will be needed, so that the person does not overbalance while reaching for the bottle.

A Program Is Developed and Forwarded for Execution

Using the selected generalized motor program, the reaching movement is organized and planned (Marsden, 1982). The program is adapted to take into account environmental factors and to designate the specific muscles needed, the force of the contractions, and the overall duration of the movement. In this way, the generalized motor program is modified to meet the requirements of this specific action (reaching for a bottle of water on a table in front of the person).

Postural muscles are activated automatically as part of the program to provide a stable base from which movement may occur. In addition, the γ -motor neurons are programmed so that spindle sensitivity is set and accurate information concerning the length and speed of length change can be continually monitored (Fredericks & Saladin, 1996). Different types of movements and environmental factors require different control strategies (Brooks, 1986). Strategies also differ among people and between trials by the same person.

Program Is Executed, Monitored, and Adapted

As the program for reaching a bottle of water is executed, the movements are monitored via cutaneous input, visual and auditory cues, and ongoing proprioceptive input (Brooks, 1986). If the movement appears to be progressing successfully (the bottle of water is reached and picked up), the program is continued as planned. If the movement is sensed to be wrong (e.g., the hand misses the target) or an unexpected event occurs (e.g., the bottle is empty instead of full), an adjustment is made while the movement is still in progress. In the latter case, it is the α - γ coactivation that keeps the muscle spindle sensitive to the unexpected event. The agonist lifter muscles were programmed to lift a full bottle. The antagonist muscles were programmed to relax enough to allow the movement and then to contract to brake the movement as the bottle reached the mouth. Because the bottle was lighter than expected, the person lifted faster initially than was programmed. As a result, the muscle spindles of the agonist muscles went slack because the agonists shortened faster than expected, while the muscle spindles of the antagonist muscles stretched because they

lengthened faster than was programmed. This information was returned to various levels of the CNS, which made adjustments for this unexpected event.

It is important to understand how the CNS adjusts for unexpected events because it is the basis of some therapeutic procedures and because it illustrates why active rather than passive movement is used for therapy. When the motor program is executed, the α - and γ -motor neurons are coactivated and excite the extrafusal and intrafusal muscle fibers according to the plan. When active movement is stopped by an unexpectedly full bottle of water or a therapist's hand (i.e., external stretch), the extrafusal muscle fibers are mechanically prevented from shortening as programmed. Meanwhile, the intrafusal fibers keep contracting as programmed. Soon the discrepancy between their length and the length of the extrafusal fibers is signaled to higher centers. Because the muscle spindle is held in place by connective tissue attached to the extrafusal muscle fibers, the spindle is mechanically prevented from shortening despite the intrafusal muscle contractions (i.e., internal stretch). As a result, external and internal stretch of the midportions of the spindle fibers add together, and stretch reflexes are activated (Brooks, 1986). Therapists use this technique to increase the strength of muscle contraction.

Knowledge of Results Is Received and Correlated with Other Sensory Information

Knowledge of results (KR) is awareness of the outcome of movement in relation to the goal. Open-loop movements are learned first as closed-loop movements in which attention is focused on the sensory feedback during the movement. Then the feedback is correlated to the outcome of the movement—KR—and the plan is modified for future movements. An open-loop movement can be executed exactly as programmed and yet be inaccurate for accomplishing the goal (Schmidt, 1988). For example, the person reaching for the bottle of water may miss the target, which illustrates the importance of KR and sensory feedback for improving motor learning.

The Program Is Stored in Memory for Future Use

Movements are generated from past experiences if success has been recognized (Brooks, 1986). Memories of successful movement are stored in long-term memory (LTM). “Successful” indicates that the sensory feedback generated by the movement matched the sensory outflow at the time the program was generated and accomplished the goal (Gentile, 1972). If attention is directed to the movement so that information concerning it remains in short-term memory (STM) for a time, the memory becomes stored in LTM for future use. If the information is lost from STM, however, it does not become part of LTM, and learning does not take place (Schmidt, 1988). The learned motor

skill must be practiced to be retained at the same level of expertise (Brooks, 1986). Expertise is improved by practice with intention to improve.

Reflex-hierarchical models of motor control have been challenged by three inter-related questions. (1) How can the CNS control the many **degrees of freedom** of each movement (i.e., the large number of joints, planes of motion within each joint, muscles that control each joint, and single motor units within each muscle) without specifying the details of the muscle activation pattern (Bernstein, 1967)? If the CNS does specify the details, each motor program would be extremely complex. (2) How many motor programs would be needed to perform the numerous tasks that humans perform in everyday life? It is likely that an extremely large number would be necessary, which creates a storage problem for the brain. (3) How many motor programs would be needed to perform a given task in varied contexts? Studies (Marteniuk, MacKenzie, & Jeannerod, 1987; Mathiowetz & Wade, 1995) have demonstrated that small changes in environmental context can result in unique movement patterns during simple reaching tasks. Thus, the environment has a larger role in motor control than the reflex-hierarchical model would suggest, and it seems that an incomprehensible number of motor programs would be necessary to respond to various contexts (Newell, 2003). Does the brain have unlimited storage capacity to accommodate all of the motor programs, even generalized motor programs? The answer is probably not; an alternative explanation of motor behavior is explored after the neurophysiological approach is fully presented.

Neuromaturational Theory of Motor Development

The neuromaturational theory of motor development (McGraw, 1945; Gesell, 1954) has influenced the neurophysiological approaches in various ways (Heriza, 1991). It suggests that changes in motor development are due to maturation of the nervous system. In other words, changes in neural structures cause changes in motor function (McGraw, 1945). This implies that the environment plays a minimal role in motor development. Current research suggests the opposite; sensorimotor experiences in response to environmental opportunities or problems organize or reorganize the central nervous system (Nudo, 2003).

Developmental sequences are also an integral part of neuromaturational theory. Gesell (1954) proposed that development progresses through a particular sequence. Although he acknowledged that the rate of development was variable among children, he believed that the sequence was invariant and that it followed a particular direction: cephalic to caudal and proximal to distal.

When neuromaturational theory and its developmental sequences are used as a guide in therapy, it is assumed that treatment must start at the patient's current developmental level. Developmental and reflex testing serve as

primary assessment tools (Bobath, 1978; Fiorentino, 1973). For treatment, it is assumed a patient must master the current developmental level before progressing to the next level (Rood, 1954). If patients master the developmental sequence, these motor skills are assumed to generalize to task performance. It is thought that working on specific functional tasks will result in **splinter skills**, which will not generalize and may in fact interfere with a child's progression through the developmental sequence. As a result, the development of movement skills is emphasized at the expense of functional performance.

Neuromaturational theories have also been used to explain motor problems seen in adults with CNS damage. It is believed that CNS damage frees lower centers from higher level control, resulting in a release of primitive reflexes and abnormal muscle tone (Bobath, 1990). Neurophysiological approaches focus on a progression through the developmental sequence, inhibition of primitive reflexes and spasticity, and facilitation of higher level control. Some of these concepts still influence practice; others have been modified or discarded.

Motor Dysfunction Caused by CNS Lesions

The view of the neurophysiological approaches is that motor dysfunctions that follow CNS damage (Definition 6-2) are understood best by knowing the site and extent of the lesions (Cheney, 1985). It is assumed that specific areas of the brain serve specific functions. Therefore, if a given area of the brain is damaged, its associated function is expected to be impaired.

Cortical Lesions

Local cortical lesions, such as occur as a result of cerebrovascular accident or penetrating injury, result in deficits in motor planning or execution of voluntary goal-directed movement, depending on the particular cortical area damaged. Although patients may be unable to move a segment of a limb in isolation, they are often able to move the whole limb in a stereotyped way because lower levels of the CNS that control this function are spared. Even in patients who seem to have similar lesions, however, dysfunction varies because of the complexity of the control options available to the CNS and the way each individual uses them (Scholz & Campbell, 1980). Diffuse lesions, such as those seen after closed head injury, can result in extensive damage to cortical areas and deeper structures of the brain. The motor dysfunction includes deficits described earlier plus any deficits associated with the lower level areas involved.

The motor deficits of cortical damage can be described as both positive and negative (Burke, 1988). The positive features are phenomena that are released from the inhibitory control of the cortex: exaggerated reflexes, spasticity, and the hemiplegic posture. The negative features are

weakness and abnormal coordination. The neurophysiological approaches assume that the positive symptoms have the most devastating effect on the motor function of cortically damaged patients. They also assume that, until the positive symptoms are corrected, the negative deficits cannot be improved (Bobath, 1978). There is growing evidence to doubt these assumptions (Bourbonnais & Vanden Noven, 1989; Shumway-Cook & Woollacott, 2001). In fact, Burke (1988) suggested that the negative features affect function more than the positive features.

Motor behavior is abnormal not only because of the motor deficits but also because of deficits in sensation, cognition, and perception. Patients with sensory loss due to a cortical lesion cannot use the affected limb spontaneously, but can compensate for the loss using intact sensory systems when directed to do so (Jeannerod, Michel, & Prablanc, 1984). The sensory loss seriously affects the ability to sustain a constant level of force needed to hold an object or to maintain a posture. In the case of impaired sensation, movement is affected by the distortion, and the patient needs to relearn the meaning of the new sensations through active movement. No relearning occurs during passive movement, even if the patient watches the movement (Gentile, 1972). Sensory problems are covered in more detail in Chapters 7 and 27.

Deficits in cognitive and perceptual processing can affect motor behavior as well. Perceptual processing entails accurate interpretation of sensory stimuli from the internal and external environment. A patient with poor depth perception has problems in reaching for objects. Cognitive processing involves orientation, attention span, memory, and problem solving. Patients with impaired memory have problems learning new tasks because they can't remember how they were instructed to perform them or the task itself. Cognition and perception are covered in more detail in Chapters 8, 9, 28, and 29.

Cerebellar Lesions

Symptoms of cerebellar lesions (Definition 6-2) reflect timing abnormalities and problems with the rate, range, and force of a movement. The basis for these deficits is a combination of delayed initiation of preprogrammed patterns and delayed termination of agonistic muscular activity, which results in delayed or missing initiation of the antagonist (Brooks, 1986). These patients are able to carry out voluntary programmed movement of a limb but lack the fine adjustments needed for end-point accuracy.

Basal Ganglia Lesions

The basal ganglia control automatic rhythmical patterned movements and the initiation of automatic (learned) movements. Lesions of the basal ganglia (e.g., Parkinson's disease) result in problems of voluntary movement, such

DEFINITION 6-2

definition

Motor Dysfunction Due to CNS Lesions

Cortical Lesions

- *Hemiplegic posture or pattern of spasticity* includes retraction and depression of the scapula; internal rotation of the shoulder; flexion of the elbow, wrist, and fingers; pronation of the forearm; lateral flexion of the trunk toward the involved side; elevation and retraction of the pelvis; internal rotation of the hip; extension of the hip and knee; supination of the foot; and plantar flexion of the ankle and toes (Bobath, 1990).
- *Hypotonia* (decreased muscle tone or flaccidity) is less than normal resistance to passive elongation; the affected limb feels limp and heavy.
- *Hypertonia* (increased muscle tone) is more than normal resistance of a muscle to passive elongation. Both neural (spasticity) and mechanical (soft tissue stiffness) factors cause it.
- *Spasticity*, the neural component of hypertonus, is characterized by a velocity-dependent increase in tonic stretch reflexes and exaggerated tendon reflexes (Katz & Rymer, 1989). It is commonly accompanied by muscle clonus and the clasp knife reflex.
- *Clonus* is the oscillating contraction and relaxation of a limb segment due to the alternating pattern of stretch reflex and inverse stretch reflex of a spastic muscle.
- *Clasp knife phenomenon or reflex* is resistance to passive stretch of a spastic muscle that suddenly gives way, like the blade of a jackknife.
- *Weakness* is the inability to generate the necessary force for effective motor action.
- *Loss of fractionation* is the inability to move a single joint without producing unnecessary movements in other joints, resulting in stereotyped movement patterns instead of selective, flexible movement patterns.
- *Apraxia* is the inability to perform goal-directed motor activity in the absence of paresis, ataxia, sensory loss, or abnormal muscle tone. Apraxia is characterized by omissions, disturbed order of submovements within a sequence, clumsiness, perseveration, and inability to gesture or use common tools or utensils.
- *Lead pipe rigidity* is characterized by hypertonus in both agonist and antagonist muscles, with resistance to movement that is not velocity dependent and that is felt throughout the range of motion.

Cerebellar Lesions

- *Intention tremor* is the rhythmic oscillating movement that develops during precise intentional movements due to involuntary alternating contractions of opposing muscles.
- *Dysmetria* is the inability to judge distances accurately; it results in overshooting or undershooting a specific target.

- *Decomposition of movement, or dyssynergia*, is characterized by movements that are broken up into a series of successive simple movements rather than one smooth movement involving multiple joints.
- *Dysdiadochokinesia* is impairment in the ability to perform repeated alternating movements, such as pronation and supination, rapidly and smoothly.
- *Adiadochokinesia* is the loss of ability to perform rapid alternating movements.
- *Ataxia* is unsteadiness, incoordination, or clumsiness of movement.
- *Ataxic gait* is a wide-based, unsteady, staggering gait with a tendency to veer from side to side.

Lesions of the Basal Ganglia

- *Tremors at rest or non-intention tremors* stop at the initiation of voluntary movement but resume during the holding phase of a motor task when attention wanes or is diverted to another task. Tremors at rest are fatiguing.
- *Cogwheel rigidity* is characterized by rhythmic interrupted resistance of the muscles being stretched when the wrist or elbow is flexed quickly.
- *Hypokinesia* is slowness or poverty of movement. It includes *akinesia*, difficulty initiating voluntary movements, and *bradykinesia*, slowness in carrying out movements. These symptoms are reflected in lack of facial expression, monotone speech, reduced eye movements, diminished arm swing during walking, and decreased balance and equilibrium responses seen in Parkinson's disease.
- *Festinating gait* is characterized by small, fast, shuffling steps that propel the body forward at an increasing rate and by difficulty stopping or changing directions.
- *Athetosis* is characterized by slow, writhing involuntary movements, particularly in the neck, face, and extremities. Athetosis ceases during sleep. Muscle tone may be increased or decreased.
- *Dystonia* is characterized by powerful, sustained contractions of muscles that cause twisting and writhing of a limb or of the whole body, often resulting in distorted postures of the trunk and proximal extremities.
- *Chorea* is characterized by sudden involuntary, purposeless, rapid, jerky movements and/or grimacing, primarily in the distal extremities and face (e.g., Huntington's chorea).
- *Hemiballismus* is unilateral chorea in which there are violent, forceful, flinging movements of the extremities on one side of the body, particularly involving the proximal musculature.

as akinesia and bradykinesia, and of involuntary movements, such as tremor at rest and rigidity (Phillips & Stelmach, 1996).

For the most part, diseases of the cerebellum or basal ganglia are degenerative, and recovery arising from neural changes is not expected. Therefore, treatment focuses on compensation for the deficits. In contrast, some recovery is expected after traumatic injury to the cerebellum and basal ganglia.

View of Recovery after CNS Lesions

The view of the neurophysiological approaches is that recovery after CNS lesions is due to changes in the CNS. Recovery from cortical lesions is believed to follow a developmental sequence from reflex to voluntary control, from mass to discrete movements, and from proximal to distal control. Recovery can stop at any level along the continua, and this is not totally predictable. The speed of early spontaneous recovery offers a clue to the ultimate level of function to be gained (Twitchell, 1951). This view of recovery is not supported by current neuroscience research (Nudo, 2003).

Evaluations Used by Neurophysiological Approaches

Given the assumptions of the neurophysiological approaches (Definition 6-1), the evaluations of patients focus primarily on abilities and capacities impaired by CNS damage. These include muscle tone, abnormal reflexes and movement patterns, postural control, sensation (see Chapter 7), perception (see Chapter 8), and cognition (see Chapter 9). In addition, it is important to determine the patient's stage of recovery or developmental level. Finally, areas of occupation (see Chapter 4) are evaluated secondarily on the assumption that any deficits in these areas are due to impaired performance skills. This bottom-up evaluation framework is not consistent with the model of occupational functioning (see Chapter 1).

Muscle Tone Evaluations

Muscle Tone and Associated Factors

Muscle tone is defined as the resistance of a muscle to passive elongation or stretching (Shumway-Cook & Woollacott, 2001). Slight resistance in response to passive movement characterizes normal muscle tone. When the therapist moves the arm, it feels relatively light, and if the therapist lets go of it, it is able to maintain the position. Hypotonia is less than normal resistance to passive elongation. When the therapist moves the arm, it feels floppy and heavy. If the therapist lets go of it, it cannot maintain the position or resist the effects of gravity. Hypertonia, which is more than normal resistance of a muscle to pas-

sive elongation, is due to neural and mechanical factors. The neural factor (i.e., spasticity) is due to hyperactive stretch reflexes frequently seen after CNS damage. In a spastic muscle, there is a range of free movement, then a strong contraction of the muscle in response to stretch (i.e., stretch reflex), and free movement again when the muscle suddenly relaxes (i.e., clasp knife phenomenon or reflex) (Fredericks & Saladin, 1996). Spasticity is not synonymous with hypertonus or muscle tone (Burridge et al., 2005). The mechanical factors of hypertonus are the elastic properties of connective tissue and the viscoelastic properties of muscle. The mechanical factors change if a muscle is immobilized in a shortened or lengthened position (i.e., there is increased or decreased resistance to passive stretching). The neural changes after CNS damage—spasticity—contribute to abnormal positioning of limbs, which causes secondary changes in the mechanical factors. Together the neural and mechanical factors account for increased resistance to passive elongation—hypertonus—that is seen after CNS damage (Burridge et al., 2005).

Muscle tone is measured clinically by observing the response of a muscle to passive stretch. A problem in measuring hypertonus, especially the neural factor, is the high variation in spasticity from day to day in the same subject. The reliability of a test is affected by the speed of the passive test movement because the tonic stretch reflexes are velocity dependent (Katz & Rymer, 1989). Reliability is also affected by effort, emotional stress, temperature, fatigue, changes in concurrent sensory stimulation, urinary tract infections, and head position (Sloan et al., 1992). Rigid standardization of the test procedure must be the rule; otherwise, the findings may be misleading (Burridge et al., 2005). Poor evaluation techniques that allow high test-retest variability may obscure therapeutic effectiveness. Although there are many assessments of muscle tone and spasticity described in the literature, most are not practical for clinical use and the *Modified Ashworth Scale* is the most widely used (van Wijck et al., 2001).

MODIFIED ASHWORTH SCALE

Ashworth (1964) proposed a qualitative scale for assessing the degree of spasticity as part of a drug study. The resistance encountered to passive movement through the full available range was rated on a 5-point scale (0–4). Although it was developed and described as a measure of spasticity, the scale is a measure of muscle tone or the resistance to passive movement (Burridge et al., 2005; Pandyan et al., 2002). Bohannon and Smith (1987) modified the Ashworth scale (Procedures for Practice 6-1) by adding an additional level (1+), by incorporating the angle at which resistance first appeared, and by controlling the speed of the passive movement with a 1-second count. The examiner performs five to eight repetitions of the movement before assigning the rating. Assessment Table 6-1 describes the psychometric properties of the *Modified*

PROCEDURES FOR PRACTICE 6-1

Modified Ashworth Scale for Grading Spasticity

Grade	Description
0	No increase in muscle tone
1	Slight increase in muscle tone manifested by a catch and release or by minimal resistance at the end of the range of motion when the affected part or parts are moved in flexion or extension
1+	Slight increase in muscle tone manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM
2	Marked increase in muscle tone through most of the ROM, but affected parts are easily moved
3	Considerable increase in muscle tone; passive movement difficult
4	Affected part or parts rigid in flexion or extension

Ashworth Scale, which has modest evidence of concurrent validity. Despite its limitations, the *Modified Ashworth Scale* is the best available measure of muscle tone and the most widely cited in the literature (Sloan et al., 1992).

Evaluation of Motor Function

Fugl-Meyer Assessment

The *Fugl-Meyer Assessment (FMA)* was developed to evaluate motor function, balance, some aspects of sensation, and joint function in persons after stroke (Fugl-Meyer et al., 1975). The items were based on earlier studies on the sequential stages of motor recovery after stroke (e.g., Brunnstrom, 1970; Twitchell, 1951). The maximum points are 66 for the upper extremity, 34 for the lower extremity, 14 for balance, 24 for sensation, 24 for position sense, 44 for range of motion, and 44 for joint pain (total possible score, 250). Each section can be scored separately. See Fugl-Meyer et al. (1975) for test procedures and scoring criteria. The procedures for the upper extremity subtest are described in Chapter 25. Assessment Table 6-2 describes the psychometric properties of the *FMA*. The *FMA* is the second most frequently used assessment of motor deficits of persons with central nervous system impairments (van Wijck et al., 2001), is widely used in outcome

studies, and is a recommended assessment of motor function in the Agency for Health Care Policy and Research clinical practice guidelines for post-stroke rehabilitation (Gresham et al., 1995).

TASK-RELATED APPROACHES

Assumptions of the Task-Related Approaches

The assumptions of the occupational therapy (OT) task-oriented approach are listed in Definition 6-1. They originate from a systems model of motor behavior, a systems view of motor development, and recent motor learning theories. Carr and Shepherd's (1987) *Motor Relearning Programme for Stroke* (see Chapter 23) is also based on this research. The assumptions of their program are (p. 5):

- Regaining the ability to perform motor tasks, such as walking, reaching, and standing up, is a learning process, and the disabled have the same learning needs as those who are not disabled; that is, they need to practice, get feedback, understand goals, and so on.
- Motor control is exercised in both anticipatory and ongoing modes, and postural adjustments and focal limb movements are inter-related.
- Control of a specific motor task can best be regained by practice of that specific motor task, and such tasks should be practiced in their various environmental contexts.
- Sensory input related to the motor task helps modulate action.

To understand the evaluation framework of the task-related approaches, it is important to understand the origins of the assumptions of these approaches.

Systems Model of Motor Control

Over the past 30 years, a new model of motor control has evolved from the ecological approach to perception and action (Gibson, 1979; Turvey, 1977) and from the study of complex dynamical systems in mathematics and the sciences (Gleick, 1987). The new model emphasizes the interaction between persons and environments and suggests that motor behavior emerges from people's multiple systems interacting with unique task and environmental contexts (Newell, 1986). Thus, the systems model of motor control is more interactive or **heterarchical** and emphasizes the role of the environment more than the reflex-hierarchical model.

In the systems model, the nervous system is only one system among many that influence motor behavior. The nervous system itself is organized heterarchically so that higher centers interact with the lower centers but do not

Assessment Table 6-1

Summary of Assessment of Muscle Tone or Resistance to Passive Movement

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<i>Modified Ashworth Scale</i> (Bohannon & Smith, 1987)	Ordinal scale with score for each motion from 0 (normal muscle tone) to 4 (rigid in flexion or extension). Modification is the addition of one additional rating level (1+).	1–2 minutes per motion tested.	Concurrent validity: $r_s = 0.39$ – 0.49 with quantitative spasticity measures (Allison & Abraham, 1995); $r = 0.50$ with motor and activity scores (Sommerfeld et al., 2004); $r_s = 0.51$ with resistance to passive movement (Pandyan et al., 2003); and $r_s = 0.40$ with the H-reflex (Pizzi et al., 2005).	Inter-rater reliability: $r_s = 0.67$ and 0.73 for elbow flexion and extension, respectively; $r_s = 0.45$ for knee flexion (Sloan et al., 1992); $Kw^1 = 0.49$ – 0.54 for shoulder, elbow, wrist, knee, and ankle joints (Mehrholtz et al., 2005). Test-retest reliability: $Kw = 0.77$ – 0.94 for elbow, wrist, and knee flexors; $Kw = 0.59$ – 0.64 for ankle plantarflexors (Gregson et al., 2000).	Significant reduction in <i>Modified Ashworth Scale</i> scores after treatment with botulinum toxin (Bakthet et al., 2000, 2001); non-significant reduction in <i>Modified Ashworth Scale</i> scores (Pandyan et al., 2002)	Strengths: It is a valid measure of muscle tone or resistance to passive movement (Pandyan et al., 2002); administration time is relatively brief; reliability is better for upper extremity than lower extremity joints. Weaknesses: Only moderate concurrent validity with measures of spasticity. It is questioned as a measure of spasticity (i.e., the neural component of muscle tone). Moderate to good inter-rater reliability; moderate to very good test-retest reliability.

¹ Kw = weighted kappa.

Assessment Table 6-2

Summary of Assessments of Motor Function

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<i>Arm Motor Ability Test (AMAT)</i> (Kopp et al., 1997)	13 unilateral and bilateral functional tasks scored on performance time, functional ability, and quality of movement (latter two on a 6-point scale).	30–45 minutes.	Concurrent validity: $r_s = 0.92-0.94$ with FMA ¹ (Chae, Labatia, & Yang, 2003); $r_s = 0.45-0.61$ with Motricity Index: Arm score (Kopp et al., 1997).	Inter-rater reliability: $r_s = 0.97-0.99$; $K = 0.68-0.77$. Test-retest reliability: $r = 0.93-0.99$. Internal consistency: $K = 0.94-0.99$ (Kopp et al., 1997).	Significant improvement in scores after 1 or 2 weeks of intensive therapy (Kopp et al., 1997); significant improvement in scores after constraint-induced movement therapy (Kunkel et al., 1999).	Strengths: Use of functional tasks; excellent reliability; evidence of validity. Weaknesses: Ceiling and floor effects for performance time (Chae, Labatia, & Yang, 2003); less sensitive to change than the WMFT ² (Morris et al., 2001).
<i>Fugl-Meyer Motor Assessment (FMA)</i> (Fugl-Meyer et al., 1975)	Most items are scored on a 3-point ordinal scale (0, cannot be performed; 1, performed partly; 2, performed faultlessly).	34–110 minutes for total FMA; 30–45 minutes for the upper and lower extremity sections; 8–12 minutes for the upper extremity alone.	Actual motor recovery post stroke parallels the test items (Fugl-Meyer et al., 1975). Concurrent validity: $r_s = 0.88$ with total MAS (Poole & Whitney, 1988) and $r = 0.68-0.85$ with the Barthel Index (Wood-Dauphinee, Williams, & Shapiro, 1990).	Inter-rater reliability: $r = 0.79-0.99$ for the upper and lower extremity subtests; intra-rater reliability: $r = 0.86-0.99$ across three test times and non-significant differences among the three means (Duncan, Probst, & Nelson, 1983).	Significantly greater improvement in experimental vs. control group at 6- and 12-month follow-ups (Feys et al., 1998).	Strengths: Administration time for upper extremity is acceptable; evidence supports its reliability, validity, and sensitivity. Weaknesses: Administration time for total FMA is lengthy; items have little relevance to everyday activities; validity of balance sub-scale was questioned (Malouin et al., 1994).

<p><i>Motor Assessment Scale (MAS)</i> (Carr et al., 1985)</p>	<p>8 areas of motor function are rated on a 7-point hierarchical scale: 0 = easiest task and 6 = hardest task.</p>	<p>15–30 minutes for total MAS (Carr et al., 1985); 18–60 minutes for total MAS (Malouin et al., 1994).</p>	<p>Concurrent validity: $r_s = 0.88$ with the total FMA²; $r_s = 0.91$ for total upper extremity; $r_s = 0.28$ for balanced sitting (Poole & Whitney, 1988); $r_s = 0.96$ with the total FMA (Malouin et al., 1994). Predictive validity: arm function at 1 week ($r_s = 0.84$) and at 1 month ($r_s = 0.91$) are good predictors of arm function at discharge (Loewen & Anderson, 1990).</p>	<p>Inter-rater reliability: $r = 0.95$ and average of 87% agreement between raters (Carr et al., 1985); $r_s = 0.99$ between raters (Poole & Whitney, 1988). Test-retest reliability: ($r = 0.98$) on clients post stroke (Carr et al., 1985).</p>	<p>Significant improvements for clients post stroke on all subtests as a result of clinical interventions (Ada & Westwood, 1992; Dean & Mackey, 1992).</p>	<p>Strengths: Items are functionally relevant; administration time is shorter. Evidence supports its reliability, validity, and sensitivity. Weakness: Sequence of the scoring hierarchy of the hand function and advanced hand activities scales was questioned (Dean & Mackey, 1992; Sabari et al., 2005).</p>
<p><i>Wolf Motor Function Test (WMFT)</i> (Wolf et al., 2001)</p>	<p>6 timed upper extremity movements and 9 timed functional tasks (Wolf et al., 2001). Modification includes adding functional ability scale (Morris et al., 2001).</p>	<p>30–45 minutes.</p>	<p>Discriminant validity: between normal subjects and persons post stroke (Wolf et al., 2001).</p>	<p>Inter-rater reliability: $r = 0.95$–0.99 (Wolf et al., 2001); ICC ≥ 0.93; test-retest reliability: $r = 0.90$–0.95; internal consistency: Chronbach's $\alpha = 0.86$–0.92 (Morris et al., 2001).</p>	<p>Significant improvement in scores after constraint-induced movement therapy (Kunkel et al., 1999; Taub et al., 1993).</p>	<p>Strengths: Combination of simple and complex movements; excellent reliability; more sensitive to change than the AMAT (Morris et al., 2001). Weaknesses: 9 individual items had less than adequate inter-rater reliability (Morris et al., 2001); several modifications of the test have been reported.</p>

² WFMT = Wolf Motor Function Test

³ FMA = Fugl-Meyer Motor Assessment

control them. Closed-loop and open-loop systems work cooperatively, and both feedback and feed-forward control are used to achieve task goals. The CNS interacts with multiple personal and environmental systems as a person attempts to achieve a goal.

Ecological Approach to Perception and Action

The ecological approach to perception and action emphasizes the study of interaction between the person and the environment during everyday functional tasks and the close linkage between perception and action (i.e., purposeful movement). Gibson recognized the role of functional goals and the environment in the relationship between perception and action. He stated that direct perception entails the active search for *affordances* (Gibson, 1977), which is defined as the functional utility of objects for persons and their unique characteristics (Warren, 1984). Thus, Gibson's concept of affordances explains the close relationship between perception and action in terms of what the information in the environment means to a specific person.

Bernstein (1967) recognized the importance of the environment and personal characteristics other than the CNS in motor behavior. He suggested that the role a particular muscle plays in a movement depends on the context or circumstances. Bernstein identified three possible sources of variability in muscle function. A first source is anatomical factors. For example, from kinesiology you know that the pectoralis major muscle will either flex or extend the shoulder, depending on the initial position of the arm. Another example relates to adducting the shoulder. If you want to adduct the shoulder quickly or against resistance, the latissimus dorsi contracts. In contrast, if you adduct the shoulder slowly against no resistance, the deltoid muscles contract eccentrically, and the latissimus dorsi does not contract. In both cases, the role of the muscle depends on the context in which it is used. A second source of variability is mechanical factors. Many non-muscular forces, such as gravity and inertia, determine the degree to which a muscle must contract. For example, a muscle must exert much more force to contract against gravity than in a gravity-eliminated plane. Likewise, because of the effects of inertia, the contraction of the elbow flexor muscles is different if the shoulder is flexing or extending at the same time. Again, the effect of a muscle contraction depends on the context. A third source of variability is physiological factors. When higher centers send down a command for a muscle to contract, middle and lower centers have the opportunity to modify the command. Lower and middle centers receive peripheral sensory feedback. Thus, the effect of the command on the muscle varies depending on the context and degree of influence of the middle and lower centers. As a result, the relationship between higher center or executive commands and muscle action is not one-to-one. Trombly and Wu (1999) demonstrated

the influence of context on movement. They reported that goal-directed, object-present activity elicited different and more efficient movement patterns than non-goal-directed exercise.

Thus, postures and movements are not triggered by external stimulation or central commands, as suggested by the reflex-hierarchical model, but instead, they are **coordinative structures** that are capable of adapting to changing circumstances. When learning a new task, a person tends to constrain or stiffen many joints to reduce the degrees of freedom to be controlled. This use of a coordinative structure enables the person to focus on controlling a limited number of joints. Natural tenodesis grasp and release is an example of a coordinative structure. The long flexor and extensor muscles of the forearm are constrained to work together for functional grasp and release. Fitch, Tuller, and Turvey (1982) suggested that perceptual information could modulate or tune the coordinative structures without intervention from the executive or higher centers. Reed (1982) suggested that postures and movements are modulated as needed by updated perceptual information to achieve the functional goal. Thus, the study of motor behavior or action evolved into "the study of how organisms use available information to modulate their actions" (Reed, 1982, p. 110).

Dynamical Systems Theory

The study of dynamical systems originated in mathematics, physics, biology, chemistry, psychology, and kinesiology, and it has been applied to occupational therapy, physical therapy, nursing, adapted physical education, and some areas of medicine (Burton & Davis, 1992; Lister, 1991). It has influenced the systems model of motor control as well. Dynamical systems theory proposes that behaviors emerge from the interaction of many systems. Because the behavior is not specified but emergent, it is considered to be self-organizing (Kamm, Thelen, & Jensen, 1990). This concept of **self-organization** is not compatible with the assumptions of the reflex-hierarchical model, which suggests that higher centers or motor programs prescribe movements. Evidence of self-organization is seen in the relatively stable patterns of motor behavior seen in many tasks in spite of the many degrees of freedom available to a person (Thelen & Ulrich, 1991). When we eat or write, we have many choices of ways to perform these tasks, yet we tend to use preferred patterns.

Behavior can change from stable to less stable as a result of aging or CNS damage. In fact, throughout life, behaviors shift between periods of stability and instability. It is during unstable periods, characterized by a high variability of performance, that new types of behaviors may emerge, either gradually or abruptly. These transitions in behavior, called **phase shifts**, are changes from one preferred pattern of coordinated behavior to another. An example of a gradual phase shift is when an infant decreases

automatic stepping between 2 and 4 months of age. An example of an abrupt phase shift is when a person in a hurry walks faster and faster and suddenly changes to a running pattern. How can these changes in behavior be explained?

In the dynamical systems view, **control parameters** are variables that shift behavior from one form to another. They do not control the change but act as agents for reorganization of the behavior to a new form (Heriza, 1991). Control parameters are gradable in some way. In the case of the infant, Thelen and Fisher (1982) demonstrated that the decrease in automatic stepping was due in part to the rapid weight gain during this time. Because infants' muscles are not strong enough to move the heavier body, automatic stepping decreases. This control parameter, the increase in body weight, shifts the behavior from automatic stepping to no stepping. In the other example, increasing the speed of locomotion elicits the change from a walking to a running pattern. Consequently, speed is considered a control parameter as well.

Explanations of changes in motor behavior in the systems model of motor control are quite different from earlier models. Thelen (1989) stated that an important characteristic of a system perspective is that the shift from one preferred movement pattern to another is marked by discrete, discontinuous transitions. These transitions in motor behavior are the result of changes in only one or a few personal or environmental systems (i.e., control parameters) (Davis & Burton, 1991). Thus, two important points are: (1) systems themselves are subject to change, and (2) there is no inherent ordering of systems in terms of their influence on motor behavior.

Systems View of Motor Development

A systems view of motor development suggests that changes over time are caused by multiple factors or systems such as maturation of the nervous system, biomechanical constraints and resources, and the influences of the physical and social environment (Heriza, 1991). A systems view also suggests that normal development does not follow a rigid intertask sequence, as the motor milestones suggest (VanSant, 1991b). In fact, children follow variable developmental sequences arising from their unique personal characteristics and environmental contexts. If the traditional inter-task developmental sequences are no longer sufficient as a guide for working with children, then they are certainly not appropriate as a guide for working with adults with CNS dysfunction (VanSant, 1991b). In contrast, intra-task sequences—developmental sequences within a single skill, such as rising without assistance or reaching to grasp an object—do provide guides for age-appropriate movement patterns (VanSant, 1991b).

Systems Model of Motor Behavior

Figure 6-2 depicts the theoretical basis of the OT task-oriented approach. It illustrates the interaction between the systems of the *Person* (cognitive, psychosocial, and sensorimotor) and the systems of the *Environment* (physical, socioeconomic, and cultural). *Occupational Performance Tasks* (i.e., activities of daily living, work, and play/leisure) and *Role Performance* emerge from the interaction between the person and the environment. Changes in any one of these systems can affect occupational performance tasks and ultimately role performance. In some cases, only one primary factor may determine occupational performance. In most cases, occupational performance tasks emerge from the interaction of many systems. The ongoing interactions among all components of the model reflect its heterarchical nature.

In addition, any occupational performance task affects the environment in which it occurs and the person acting. For example, a client with hemiplegia who has just become independent in making his own lunch may free his spouse from coming home from work during her lunch hour. It also may mean that certain objects in the kitchen must be kept in accessible places, and the kitchen may not be as orderly as the spouse is used to. Thus, the task of making lunch affects people and objects in the environment. It also affects the person and the associated performance skills and patterns. The ability to be less dependent on his spouse may improve the client's self-esteem (i.e., psychosocial subsystem). The process of making lunch provides the client the opportunity to solve problems and to discover optimal strategies for performing tasks. This influences a client's cognitive and sensorimotor subsystems and the ability to perform other functional tasks.

The various parts of the systems model of motor behavior can be related to the Occupational Therapy Practice Framework (OTPF) (American Occupational Therapy Association [AOTA], 2002) and the Occupational Functioning Model (OFM) (see Chapter 1). OTPF terminology has been added to the model in parentheses (Fig. 6-2). Thus, the *person* system includes client factors, performance skills, and performance patterns. The *sensorimotor* system includes components such as strength, endurance, range of motion, coordination, sensory awareness, postural control, and perceptual skills. The *psychosocial* system includes a person's values, interests, self-concept, social interactions, and self-management skills that can affect occupational performance tasks. The *cognitive* system includes orientation, attention span, memory, problem-solving skills, and learning ability. The *person* system in this model includes the four lowest levels of the OFM: organic substrate, first-level capacities, developed capacities, and abilities and skills. The *environment* system includes physical, socioeconomic, and cultural contexts and the related personal, spiritual, temporal, and virtual contexts that influence client performance. The *physical*

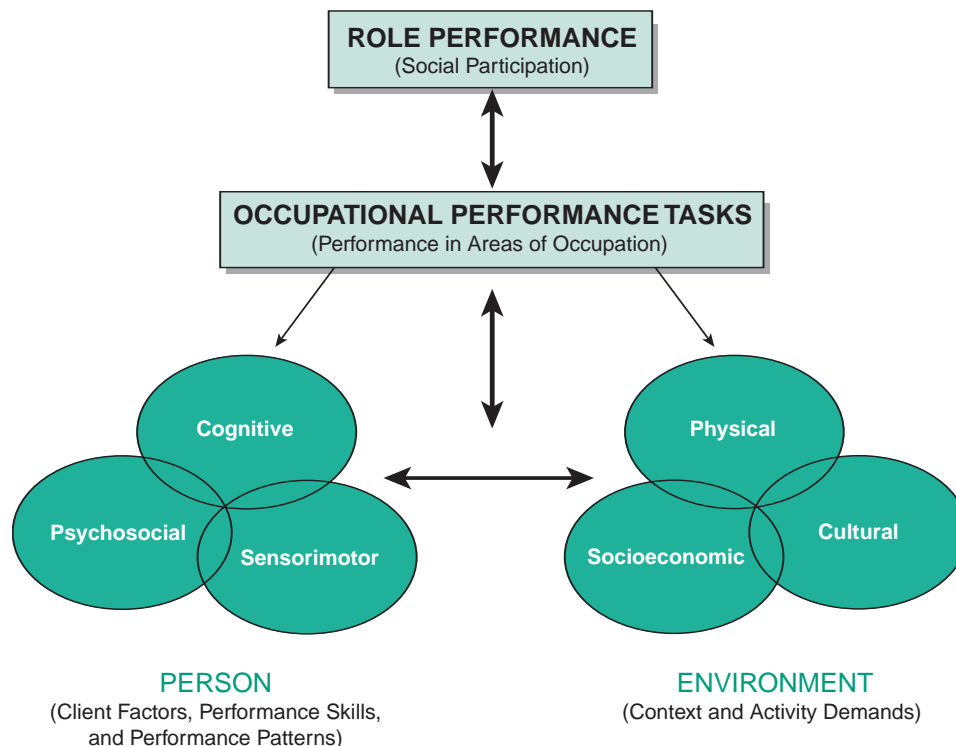

Figure 6-2 Systems model of motor behavior, which supports the OT task-oriented approach, emphasizes that occupational performance tasks and role performance emerge from an interaction of the person and the environment. In addition, occupational performance tasks impact the person and environment as well. There is a continuous interaction between role performance and occupational performance tasks. These interactions are ongoing across time. Adapted with permission from Mathiowetz and Bass-Haugen (2002).

environment system includes objects, tools, and the natural and built environment, which may limit or enhance task performance. The *cultural* environment system includes ethnicity, family, attitudes, beliefs, values, customs, and societal expectations, which also could affect occupational performance tasks. Finally, the *socioeconomic* system includes social supports provided by the family, friends, caregivers, social groups, and community and financial resources, which may influence choice in activities. The *environment* system is consistent with the OFM: environment and context.

The *Occupational Performance Tasks* are consistent with OTPF areas of occupation (activities of daily living, instrumental activities of daily living, education, work, play, and leisure), except for social participation, which we include under *Role Performance*. The *Occupational Performance Tasks* include the OFM activities and habits needed to perform the tasks required to fulfill self-maintenance, self-advancement, and self-enhancement roles. *Role Performance* includes the highest levels of the OFM: sense of self-efficacy and satisfaction with life roles.

The inclusion of *Role Performance* in this model (Fig. 6-2) reflects an occupational therapy perspective and does not originate from the motor behavior literature. Occupational therapists believe the roles that persons

want and need to fulfill determine the occupational performance tasks and activities that they need to do. Conversely, the tasks and activities persons are able to do determine what roles they are able to fulfill. Although this model may have applications to all areas of occupational therapy practice and to occupational therapy theory development, the focus of this chapter is its application to individuals with CNS dysfunction.

View of Recovery after CNS Dysfunction

A client with a damaged CNS attempts to compensate for the lesion to achieve functional goals. Recovery from brain damage is a process of discovering what abilities and capacities remain to enable performance of activities and tasks. CNS damage affects each system differently relative to occupational performance. Therapists must consider all systems as potential variables to explain behavior of each client at a specific time. For example, the flexor pattern of spasticity commonly seen after a stroke is caused by various factors in addition to spasticity, such as inability to recruit appropriate muscles, weakness, soft tissue tightness, and perceptual deficits (Bourbonnais & Vanden Noven, 1989; Shumway-Cook & Woollacott, 2001). This pattern may become obligatory because of abnormal

positioning and decreased use in functional contexts. Because each client is a unique person and functions in a unique environment, therapists should expect recovery for each client to vary even if the CNS damage is similar.

There is increasing evidence that neural reorganization after a brain lesion reflects the functional demands on the CNS. For example, forced use of the involved limb has improved functional performance in persons more than a year post stroke (Liepert et al., 2000; Taub et al., 1993). These changes can hardly be attributed to spontaneous recovery. Thus, providing appropriately challenging tasks and environments for those with CNS dysfunction, both in the hospital and at home, appears critical to the maximal rehabilitation of our clients (Bach-y-Rita, 1993; Nudo, 2003).

Evaluations

Evaluation Using the OT Task-Oriented Approach

Evaluation is conducted using a top-down approach consistent with the model of occupational functioning (see Chapter 1). A framework for evaluation is described in Procedures for Practice 6-2. Evaluation efforts focus initially on role and occupational performance because they are the goals of motor behavior. A thorough understanding of the roles that a client wants, needs, or is expected to perform and of the tasks needed to fulfill those roles enables therapists to plan meaningful and motivating treatment programs. After a client has identified the most important role and occupational performance limitations, therapists use task analysis to identify which person and/or environmental factors are limiting functional performance. This process may indicate the need for evaluation of selected person and/or environmental factors (Fisher & Short-DeGraff, 1993). The emphasis on role and occupational performance in the OT task-oriented approach suggests that evaluation in occupational therapy should be primarily at the participation and activities levels rather than the body functions and structures (impairment) level, using the World Health Organization (2001) terminology. The evaluation process necessitates use of both qualitative and quantitative measures (VanSant, 1990). Therefore, therapists use interviews, skilled observations, and standardized assessments to evaluate their clients. Although the client is the primary source of information, other sources, including the client's records, caregivers, family members, and the client's environment, contribute as well. Next, each step of the evaluation framework is described in more detail.

The first step in evaluation is the assessment of role performance. Trombly (1993) states that satisfactory fulfillment of roles is necessary for clients to achieve a sense of efficacy (i.e., competence and self-esteem). These roles may serve a variety of purposes, including development and maintenance of self (self-care), advancement of self or pro-

PROCEDURES FOR PRACTICE 6-2

Evaluation Framework for the OT Task-Oriented Approach Based on a Systems Model of Motor Behavior

1. Role Performance
 - Identify past roles and whether they can be maintained or must be changed.
 - Determine how future roles will be balanced: worker, student, volunteer, home maintainer, hobbyist, amateur, participant in organizations, friend, family member, caregiver, religious participant, other.
2. Occupational Performance Tasks: Areas of Occupation
 - ADL: feeding, grooming, functional mobility, dressing, oral and toilet hygiene, bowel and bladder management, and bathing/showering.
 - Instrumental activities of daily living: care of others and/or pets, communication device use, community mobility, home management, meal preparation and clean-up, safety procedures, and shopping.
 - Work: employment seeking and acquisition, job performance, volunteer exploration and participation, and retirement preparation and adjustment.
 - Play/leisure: exploration and participation.
3. Task Selection and Analysis
 - What performance components and/or performance contexts limit or enhance occupational performance?
4. Person: Performance Components
 - Cognitive: orientation, attention span, memory, problem solving, learning, and generalization.
 - Psychosocial: values, interests, self-concept, interpersonal skills, self-expression, coping skills, time management, and self-control.
 - Sensorimotor: strength, endurance, range of motion, sensory awareness and processing, perceptual processing, and postural control.
5. Environment: Performance Context
 - Physical: objects, tools, devices, animals, and built and natural environment.
 - Socioeconomic: social supports, including family, friends, caregivers, social groups, and community, and financial resources.
 - Cultural: ethnicity, family, attitudes, beliefs, values, customs, and societal expectations.

ductivity (work), and enhancement of self (leisure). Therapists must determine which roles clients had prior to the onset of disability and which roles they can and cannot do at this time. A discussion of which roles clients want or need to perform in the future helps therapists to determine which roles are most important to their clients. In addition, therapists must explore how any role changes have affected or will affect their client and their families, especially the primary caregivers. Jongbloed, Stanton, and Fousek (1993, p. 76) suggested that therapists ask questions such as the following: “How have roles changed since the disability? How have family members reacted to these changes? Is there role flexibility when needed? How competently do family members perform roles?” These questions may have to be adapted to the respondent’s level of understanding.

Although role performance can be assessed using a non-standardized, semi-structured interview, a standardized assessment tool, such as the *Role Checklist* (Barris, Oakley, & Kielhofner, 1988), is recommended. The *Role Checklist* is a written inventory designed for adolescents and adults with physical dysfunction. In part 1, clients indicate which of 10 roles (Procedures for Practice 6-2) they have performed in the past, are performing in the present, and plan to perform in the future. In part 2, clients indicate the value of each role to them. Other role assessment tools may be appropriate depending on the type of client and the setting. For example, if a client is undergoing major role changes and there is sufficient time for a comprehensive assessment, the *Role Change Assessment* for older adults (Rogers & Holm, 1999) or *Client-Oriented Role Evaluation (CORE)* (Toal-Sullivan & Henderson, 2004) are recommended. Detailed information on the assessment of role performance and other role assessment tools is presented in Chapter 4. After clients have identified the roles that they want or need to perform, it is easier for them to identify the tasks and activities needed to fulfill each role.

The second step in the evaluation process is the assessment of occupational performance tasks: activities of daily living (ADL), instrumental activities of daily living (IADL), work, and play/leisure (Procedures for Practice 6-2). Because roles, tasks, activities, and their contexts are unique to each person, a client-centered assessment tool, such as the *Canadian Occupational Performance Measure (COPM)* (Law et al., 1998) is recommended. It was designed to measure a client’s perception of his or her occupational performance over time. A semi-structured interview is used to administer the *COPM*. First, clients are asked to identify problem areas in self-care, productivity, and leisure. Second, the importance of each problem area is rated. Third, clients rate their own performance and their satisfaction with the performance. The importance ratings assist therapists in setting treatment priorities. The performance and satisfaction ratings can be used as outcome measures to assess change across time. When therapists are concerned that a client may not provide accurate information because of a cognitive impair-

ment, a caregiver may be interviewed or direct observation of selected activities can be used to validate the information. The information elicited by the *COPM* is unique to each client and his or her environmental context, which is critical to the OT task-oriented approach.

The *Assessment of Motor and Process Skills (AMPS)* is another recommended measure of occupational performance, specifically personal and instrumental ADL (Bray, Fisher, & Duran, 2001; Fisher, 2003). It is a client-centered assessment because the person chooses two or three ADL tasks to be performed, which ensures familiarity and relevance to the person being evaluated. The purpose of the *AMPS* is to determine whether or not a person has the necessary motor and process skills to effortlessly, efficiently, safely, and independently perform the ADL tasks needed for community living (Fisher, 2003). Because the *AMPS* has been standardized internationally and cross-culturally, it is appropriate for persons from diverse backgrounds and with diverse needs and interests. A unique feature of the *AMPS* is that it can adjust, through Rasch analysis, for the difficulty of tasks performed and the severity of the rater who scores the client’s performance. In addition, it allows a therapist to compare the performance of clients who performed one set of tasks on initial evaluation with the results of a reevaluation on a different set of tasks. A limitation of the *AMPS* is that it requires a 5-day training and calibration workshop to learn how to administer the assessment reliably and validly. Computer software, which is required to score the *AMPS*, is provided with the workshop. Because the *AMPS* requires observation of clients performing occupational performance tasks, it also assists the third step in the evaluation process.

While evaluating occupational performance tasks, therapists must observe both the outcome and the process (i.e., the preferred movement patterns, their stability or instability, the flexibility to use other patterns, efficiency of the patterns, and ability to learn new strategies) to understand the motor behaviors used to compensate and to achieve functional goals. It is important to determine the stability of the motor behavior because it will help determine the feasibility of achieving behavioral change in treatment. Behaviors that are very stable require a great amount of time and effort to change. Behaviors that are unstable are in transition, which is the optimal time for eliciting behavioral change. Thus, a compensatory approach may be most appropriate when behaviors are stable, and a remediation approach may be more appropriate when behaviors are unstable. Evaluation of the process of task performance is likely to require use of both quantitative and qualitative measures.

The third step is task selection and analysis. The tasks selected for observation should be ones that clients have identified as important but difficult. In most cases, observation of performance will happen as part of the second step. Therapists use task or activity analysis (see Chap-

ter 13) to determine whether there is a match between task requirements and personal characteristics that enables task performance within a relevant environment. If not, therapists attempt to determine which personal and/or environmental factors are interfering with occupational performance tasks. In dynamical systems theory, these are considered the critical control parameters or the variables that have the potential to shift behavior to a new level of task performance. Each person with CNS dysfunction has unique strengths, limitations, and environmental context. As a result, the critical control parameters that limit or support occupational performance tasks are also unique. As persons and their environments change over time, the critical control parameters also change.

The identification of critical control parameters is the most challenging part of the evaluation. Evidence in the research literature suggests that some performance components and/or environmental variables may be critical control parameters for persons with CNS dysfunction. Gresham et al. (1979) reported that psychosocial and environmental factors were significant determinants of functional deficits long after stroke. In a review, Gresham et al. (1995) reported that 11–68% of individuals post stroke have depression, with 10–27% meeting the criteria for major depression. In the cognitive area, Rao et al. (1991) reported that 43% of patients with multiple sclerosis had cognitive impairments of recent memory and sustained attention. In the sensorimotor area, weakness (Olsen, 1990), fatigue (Ingles, Eskes, & Phillips, 1999), impaired motor function (Bernspang et al., 1987), and visuospatial deficits (Titus et al., 1991) are associated with poorer functional outcomes. For example, Bernspang et al. (1987) reported that motor function measured with the *FMA* was moderately correlated ($r = 0.64$) with self-care ability.

One caution is that most of these studies were correlational, indicating relationships between these variables and functional performance, but they do not establish a causal link. Also, most correlations were moderate or low, which indicates that any one variable explains a relatively small percentage of the variance associated with functional performance. Reding and Potes (1988), however, provided evidence that, as the number of performance component impairments increased, functional outcomes decreased. Thus, multiple variables contribute to functional performance for most individuals with CNS dysfunction. The challenge is to identify the variables that are most important to your clients. Case studies by Flinn (1995) and Gillen (2000, 2002) illustrate the search for critical control parameters.

Bobath (1990) suggested that spasticity is the primary cause of motor deficits in individuals with CNS dysfunction and that weakness and decreased range of motion are due to spastic antagonists. However, there is increasing evidence that spasticity is not a critical control parameter (Bourbonnais & Vanden Noven, 1989). For example,

Sahrman and Norton (1977) reported EMG findings indicating that movements were limited not by antagonist stretch reflexes (spasticity) but by delayed initiation and cessation of agonist contraction. Similarly, Fellows, Kaus, and Thilmann (1994) found no relation between movement impairments and passive muscle hypertonia in the antagonist muscles. O'Dwyer, Ada, and Neilson (1996) found no relation between spasticity and either weakness or loss of dexterity. Thus, research evidence challenges the assumption that spasticity causes the weakness and decreased range of motion often seen in individuals with CNS dysfunction.

After identifying the variables that support or constrain occupational performance, the therapist must assess the interactions of these systems. Consider two clients who have small limitations in shoulder flexion. The role and tasks of client as worker may or may not be affected. If the worker is a carpenter, the interaction of this personal limitation with the demands of the work environment is likely to make nailing overhead, installing cabinets, and hanging doors difficult or impossible. A worker who does word processing, however, probably can do most tasks adequately because the interaction of personal characteristics and the performance context does not interfere with task performance. This part of the evaluation requires a qualitative assessment and clinical reasoning by the therapist using the information gathered.

The fourth step in the evaluation process is to perform specific assessments of the personal and/or environmental factors that are thought to be critical control parameters. The critical control variables are the only ones that must be evaluated. The evaluation of selected variables according to the OT task-oriented approach contrasts with bottom-up approaches that evaluate all component variables. This selective approach eliminates the need to evaluate variables that have little functional implication and saves therapists' time, which is critical for cost containment.

It is likely that occupational therapists will use a variety of measures in their evaluation of the client factors and/or environmental contexts that constrain or support occupational performance tasks or functioning. Some assessments are designed to examine one or more components within the context of occupational performance. The *Fatigue Impact Scale* (Fisk et al., 1994) was developed to evaluate the perceived effect of fatigue on the everyday lives of those with multiple sclerosis. Assessment of cognitive function through a functional task is the focus of the *Allen Cognitive Level Scale* (Allen, 1985; Allen, Kehrberg, & Burns, 1992). The *A-One Evaluation* (Arnadattoir, 1990) facilitates evaluation of perceptual and cognitive systems within the context of ADL. From a task-oriented perspective, these are preferred assessment tools because they closely link client factors to occupational performance. In contrast, most assessments of client factors are conducted independent of occupational performance (see Chapters 5 and 7–9 for specific assessments).

Evaluation of a client’s environment is an important part of the fourth step of the evaluation. The inclusion of physical, social, cultural, personal, spiritual, temporal, and virtual environments in AOTA (2002) clinical practice guidelines acknowledges their important influence on occupational performance. Dunn (1993) and Spencer, Krefting, and Mattingly (1993) emphasized the importance of assessing environmental context as part of the overall evaluation process. Chapters 10 and 11 review assessments for these variables.

Evaluation Using Carr and Shepherd’s Approach

Carr and Shepherd (1987, 1998, 2003) developed their approach in response to disillusionment with the neurophysiological approaches and attempts to apply recent motor behavior research to clinical practice. Although Carr and Shepherd are physical therapists, their approach to optimizing motor performance is relevant to occupational therapy because it emphasizes the relearning of daily activities and provides a task-related strategy for improving motor control (Sabari, 2002). Carr and Shepherd (1998) described in detail how they approach evaluation. Their most important contribution to evaluation is their *Motor Assessment Scale (MAS)*, a recommended test of motor function in the Agency for Health Care Policy and Research (AHCPR) clinical practice guidelines for post-stroke rehabilitation (Gresham et al., 1995). In addition, they deserve credit for their strong emphasis on task analysis as part of the evaluation (see Chapter 23).

Motor Assessment Scale (Assessment Table 6-2)

Carr et al. (1985) developed the MAS as an easily administered and relatively brief (15–30 minutes) assessment relevant to everyday motor activities (Procedures for Practice 6-3). The original version of the MAS included a ninth subtest, muscle tone, which has been deleted because it had poor reliability and questionable validity (Carr & Shepherd, 1998). The psychometric properties of MAS are described in Assessment Table 6-2. Because reliability and validity data for individual subtests of the MAS are available, one or more subtests can be used with each client, but the MAS total score across the subtests should not be used because it is an ordinal scale (Carr & Shepherd, 1998).

Assessments of Motor Function (Assessment Table 6-2)

The *Arm Motor Ability Test (AMAT)* was developed as an assessment of functional ability and quality of movement as a result of constraint-induced movement therapy (Kopp et al., 1997). Some of the 13 functional tasks are simulated (e.g., Cut Meat uses Play-Doh) and thus are not as natural as most functional assessments.

The *Wolf Motor Function Test (WMFT)* “quantifies upper extremity movement ability through timed single- or

PROCEDURES FOR PRACTICE 6-3

Scoring Sheet for the Motor Assessment Scale

Each subtest is scored on a 7-point scale according to specific criteria.

Subtests	0	1	2	3	4	5	6
Supine to side-lying onto intact side							
Supine to sitting on side of bed							
Balanced sitting							
Sitting to standing							
Walking							
Upper arm function							
Hand movements							
Advanced hand activities							

Reprinted with permission from Carr, J. H., Shepherd, R. B., Nordholm, L., & Lynne, D. (1985). Investigation of a new Motor Assessment Scale for stroke patients. *Physical Therapy*, 65, 175–180. Copyright 1985 by American Physical Therapy Association.

multiple-joint motions and functional tasks” (Wolf et al., 2001, p. 1635). It was also developed to assess the effects of constraint-induced movement therapy.

Assessments of Balance (Assessment Table 6-3)

The *Balance Scale* (Berg et al., 1992) is not associated with a particular neurophysiological or task-related approach. It is compatible with the task-related approaches because it evaluates clients’ performance on 14 items common in everyday life. The items include “the subject’s ability to maintain positions of increasing difficulty by diminishing the base of support from sitting, to comfortable stance, to standing with feet together, and finally tandem standing (i.e., one foot in front of the other) and single leg stance, the two most difficult items. Other items assess how well the subject is able to change positions from sitting to standing, transfer from chair to chair, turn, pick up an object from the floor, and sit down” (Berg et al., 1992, p. 1074). The *Balance Scale* is a recommended assessment of balance in the AHCPR clinical practice guidelines for post-stroke rehabilitation (Gresham et al., 1995).

The *Functional Reach Test* (Duncan et al., 1990) was developed as a quick, clinical measure of dynamic balance that uses a continuous scoring system to assess the risk of falls in the elderly. It was intended to be an alternative to sophisticated laboratory-based assessments of falls, which are not feasible for clinical use. For a broader review of balance assessments, see Whitney, Pool, and Cass (1998).

Assessment Table 6-3

Summary of Assessments of Balance

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<i>Balance Scale</i> (Berg et al., 1992)	14 items common in everyday life are “graded on a five-point scale, 0 to 4. Points are based on the time the position can be maintained, the distance the arm is able to reach forward, or the time to complete the task” (Berg et al., 1992, p. 1075).	About 15 minutes to administer and requires only a stopwatch and ruler.	Concurrent validity: $r = 0.91$ with the <i>Tinetti Balance Subscale</i> (Tinetti, 1986); $r = .67$ with <i>Barthel Mobility</i> ; $r = 0.76$ with <i>Timed Up-and-Go Test</i> (Podsiadlo & Richardson, 1991); and $r = 0.55$ average with 8 of 10 laboratory tests of balance. Discriminant validity: among persons using various types of walking aids (Berg et al., 1992).	Inter-rater reliability: ICC ¹ = 0.98 for total scale; ICC = 0.71–0.99 for individual items. Test-retest reliability: ICC = 0.99 for total scale. Internal consistency: Cronbach’s $K^2 = 0.96$ (Berg et al., 1989).	Significant changes in scores at 6 and 12 weeks post stroke (Wood-Dauphinee et al., 1997).	Strengths: Measures many aspects of balance; excellent reliability; evidence of validity. Weakness: Longest administration time.
<i>Functional Reach Test</i> (Duncan et al., 1990)	“The maximal distance one can reach forward beyond arm’s length while maintaining a fixed base of support in the standing position” (Duncan et al., 1990, p. M192).	1–2 minutes to administer and requires a 48-inch leveled ruler mounted on the wall at shoulder height (Weiner et al., 1993).	Concurrent validity: $r = 0.71$ with center of pressure excursion (Duncan et al., 1990); discriminant validity: significant difference between persons with high and low risk of falls; predictive validity: score ≤ 6 inches predictive of falls in elderly (Duncan et al., 1992).	Inter-rater reliability: $r = 0.98$; test-retest reliability: ICC = 0.92 (Duncan et al., 1990).	Marginal significant change ($p = 0.07$) after physical rehabilitation; responsiveness index = 0.97 (Weiner et al., 1993).	Strengths: Brief, functional test; excellent reliability; evidence of validity. Weakness: Sensitivity is borderline.

¹ ICC = intraclass correlation coefficient, a reliability index that depicts consistency of agreement

² K = kappa

CASE

EXAMPLE

Mr. B: Assessment of Motor Behavior Using a Task-Oriented Approach

Occupational Therapy Assessment Process

Clinical Reasoning Process

	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information</p> <p>Mr. B. is a 55-year-old man who worked as an administrator at a junior college until a week ago, when he had a left cerebral vascular accident with resultant right hemiparesis. His medical history includes insulin-dependent diabetes mellitus and two heart attacks in the past 5 years. He lives with his wife in a ranch-style house. She works as a middle manager at an electronics firm. They have two adult children who do not live nearby.</p> <p>The acute-care occupational therapist reported that he is independent in feeding, grooming, oral hygiene, and wheelchair mobility for short distances. He needs assistance with bathing, toilet hygiene, and dressing. Other occupational performance tasks were not assessed in acute care. He has weakness throughout his dominant right arm, with grade 2 muscle tone on the <i>Modified Ashworth Scale</i> for scapular depression, shoulder internal rotation, and elbow, wrist, and finger flexors. PROM is within normal limits except for a 20° limitation in shoulder external rotation and elbow extension.</p>	<p>Understand the patient’s diagnosis or condition</p> <p>Know the person</p> <p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>“Mr. B. has right hemiparesis and moderate disability one week post. Because his right arm is not flaccid and he is able to do some self-care already, his prognosis for recovery of functional ability appears to be good.”</p> <p>“Given his age and type of job, I expect that he will be motivated to return to work, but I can’t assume that.”</p> <p>“I wonder how his wife is reacting to his various health problems. Will she support his return to work or will she try to protect him? I wonder about the accessibility of his home and work environment.”</p> <p>“Given his diagnosis and history, I presume that sensorimotor, psychosocial, and cognitive client factors and the physical environment at home and/or work might limit his ability to perform occupational performance tasks and to assume his usual roles. Given his early recovery, he should be able to benefit from an intensive rehabilitation program.”</p>
<p>Assessment Process</p> <p>The <i>Role Checklist</i> was used to identify which roles were most important to him and to identify the tasks and activities that are associated with those roles. The <i>COPM</i> was used to determine the occupational performance tasks he wanted or needed to do and to determine his perception of his ability. Task analysis was used with specific tasks he perceived as difficult or impossible. The therapist observed him for client factors that might be limiting function and explored environmental factors that could support or limit his performance.</p>	<p>Consider evaluation approach and methods</p>	<p>“The primary aim of the assessment in the rehabilitation unit was to determine which roles and occupational performance tasks were most important to Mr. B. and to determine his ability on those tasks. The secondary aim was to determine if specific client or environmental factors were supporting or limiting his functional performance.”</p>
<p>Assessment Results</p> <p>It was clear from the <i>Role Checklist</i> that Mr. B.’s work role was important to him. His concerns about returning to work included problems with writing, word processing, and removing heavy manuals from shelves above his desk. His wife, however, was pushing him to consider early retirement because of his increasing health problems. He and his wife enjoyed entertaining friends at home, at which times</p>	<p>Interpret observations</p>	<p>“It is clear that work and cooking tasks are priorities for this client, followed by self-care tasks. It is not yet clear whether he will be able to return to work. Decreased strength and impaired sensation are limiting the function of the right hand. Decreased PROM</p>

he was the primary chef. This was an important activity for both of them. Although he was responsible for many home and yard maintenance tasks, these were not important to him. He thought friends would help them or they could hire help. On the *COPM*, return to work was ranked as most important, followed by cooking, toilet hygiene, dressing, and driving. He rated his performance and satisfaction for all of these tasks as very low.

His performance on several work-related, cooking, and self-care tasks were observed. He had difficulty holding a regular pen. A trial with an enlarged pen with a rubber grip, however, enabled him to hold a pen for about 3 minutes and write with very poor legibility. He was unable to use his right hand for keyboarding because he could not isolate individual fingers. He became frustrated while performing a simple cooking task (i.e., making pudding) because he could not walk and had difficulty using his right hand for bilateral tasks. He was able to toilet himself with verbal cueing and standby assistance. During dressing, he had difficulty raising his right arm, reaching down to put on his socks (concerned appropriately about balance), and difficulty performing bilateral tasks (e.g., tying his shoelaces). He complained about the time and energy needed to complete functional tasks. He used his right hand in half of the bilateral tasks he attempted. Thus, it appeared that sensorimotor client factors might be the cause of the difficulty performing occupational performance tasks, so these were evaluated further.

There was no evidence of unilateral visual neglect on a line bisection test. Sensory testing indicated loss of protective sensation and diminished light touch in the right hand (Semmes-Weinstein monofilaments) and impaired proprioception in the wrist and fingers only. Selective muscle testing indicated grade 3+ in scapular elevation, elbow flexion, and extension; 3– in shoulder flexion, abduction, and external rotation; and wrist flexion and extension. Grip strength in the right hand was 5 pounds, and in the left hand, it was 80 pounds; key pinch on the right was 3 pounds, and on the left, it was 19 pounds. He was able to reach forward nine inches on the *Functional Reach Test*.

of the shoulder external rotation is a concern because it is often associated with development of a painful shoulder. There is no evidence of cognitive or perceptual deficits. He has a mild deficit in balance. I chose the *Functional Reach Test* instead of the *Berg Balance Scale* to assess balance because it was specific to the balance problems observed and administration time is brief. Selected subscales of the *MAS* were considered because they are more functional than the other motor function assessments, but the two subscales—Hand Movements and Advanced Hand Activities—that would have provided the most useful information on Mr. B. have questionable validity. Therefore, I chose not to use the *MAS* with this client.”

Occupational Therapy Problem List

1. Decreased ability to perform work, cooking, and self-care tasks because of sensorimotor impairments
2. Decreased strength, PROM, sensibility, and dexterity in his right upper extremity; decreased endurance for activity; mild impairment of sitting balance
3. Insufficient information on home environments to prepare adequately for discharge

Synthesize results

“Although I have sufficient information to begin treatment with Mr. B., I will need additional information from him and his employer about job requirements and work environment. In addition, more details about the home environment, home management roles and responsibilities, and other leisure interests are necessary.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Impact of Theoretical Assumptions on Clinical Assessments

Post-acute care assessments for Mr. B. were approached using the assumptions of the OT task-oriented approach. How would the assumptions and assessment differ if you used a neurophysiological approach with Mr. B.? What would be the primary and secondary focus of assessments? Would those assessments make a difference in the problems you identified?

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Choice of Motor Function Assessment

Post-acute care assessments for Mr. B. were approached using the assumptions of the OT task-oriented approach. Which assessments of motor function, if any, would you choose for Mr. B.? Why?

SUMMARY REVIEW QUESTIONS

1. How do the reflex-hierarchical and systems models of motor control differ?
2. How do the neuromaturational and systems theories of motor development differ?
3. What types of motor dysfunction are associated with cortical, cerebellar, and basal ganglia lesions of the CNS?
4. What might account for the recovery seen after CNS damage?
5. What are at least four assumptions of the neurophysiological approaches?
6. How would you evaluate abnormal muscle tone and movement patterns?
7. What are at least four assumptions of the OT task-oriented approach?
8. How do evaluations used by the neurophysiological and task-related approaches differ?

ACKNOWLEDGMENT

We thank Nancy Flinn, PhD, OTR/L, who uses the OT task-oriented approach in her clinical practice and has provided us with constructive feedback.

CHAPTER 7

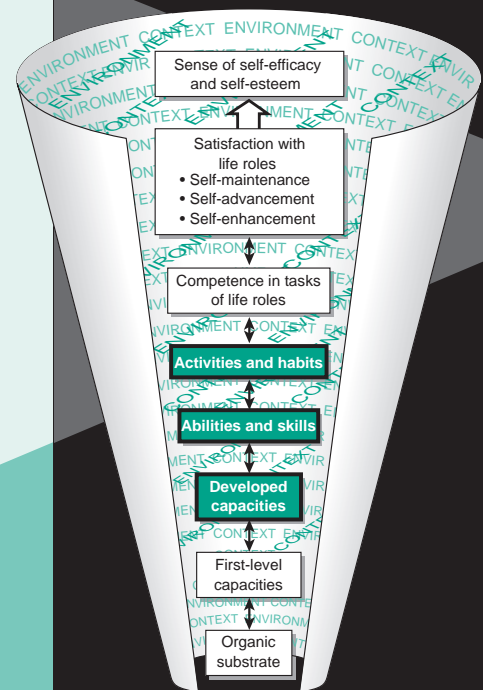

Assessing Abilities and Capacities: Sensation

Karen Bentzel

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the effects of sensory loss on occupational function.
2. Predict the pattern of sensory loss based on diagnosis or described lesion in the somatosensory system.
3. Demonstrate appropriate sensory testing techniques for tactile sensation when provided with appropriate tools or equipment.
4. Differentiate standardized and nonstandardized tactile tests.
5. Choose appropriate sensory testing techniques for a given patient or situation.
6. Correctly interpret the results of sensory testing for treatment planning.

Glossary

Aesthesiometer—Instrument designed for sensory testing. The term usually indicates a tool consisting of a ruler type of scale and two prongs that can be moved progressively closer or farther apart that is used for assessing two-point discrimination (Fig. 7-7). Monofilaments are occasionally called pressure aesthesiometers in the literature.

Hypersensitivity, hyperesthesia—A condition in which an exaggerated or unpleasant sensation is experienced in response to ordinary stimuli.

Kinesthesia—The ability to identify “the excursion and direction of joint movement” (AOTA, 1994, p. 1053).

Monofilament—Thin nylon strand resembling fishing line, of graded thicknesses, attached to a handle and used in testing the threshold of light touch sensation.

Paresthesia—An abnormal sensation such as a feeling of pins and needles, tingling, or tickling in the absence of tactile stimulation or in response to tactile stimuli that ordinarily do not evoke tingling or tickling.

Proprioception—Interpreting stimuli originating in muscles, joints, and other internal tissues that give information about the position of one body part in relation to another (AOTA, 1994, p. 1052).

Stereognosis—The ability to identify objects through proprioception, cognition, and the sense of touch (AOTA, 1994). Astereognosis is the term used to describe the absence of this ability.

Vibrometer—Instrument designed to test the threshold of vibration sensation. It consists of a vibrating head that is applied to the patient’s skin and a control unit that allows for gradual changes in the amplitude and frequency of vibration.

The American Occupational Therapy Association [AOTA] (1994, p. 1052) defines tactile sensory processing as “interpreting light touch, pressure, temperature, pain, and vibration through skin contact/receptors.” The tactile sense is necessary throughout the body for occupational functioning but is especially important in the hands. Moberg described hands without sensation as being like eyes without vision (Dellon, 1988).

Immediately after birth, an infant is bombarded with tactile sensations that are different from those in utero. Within a few months, the infant learns to interpret a multitude of tactile stimuli, such as soothing touch from a parent that brings comfort and contentment. This developed capacity supports further development of abilities and skills, as the infant uses touch to grasp an object, bring two hands together at midline, and reach out to stroke a parent’s face. These abilities are necessary for self-maintenance, self-enhancement, and self-advancement roles in childhood and throughout adulthood.

ROLE OF SENSATION IN OCCUPATIONAL FUNCTIONING

The role of sensation in occupational functioning is dramatically described in Cole’s (1991) account of Ian Waterman, who at 19 years of age acquired a rare neurological illness that resulted in the loss of all sensation of touch in his body from the neck down. He had no awareness of the positions of his arms, legs, or body. Although his muscles were not affected, any attempt at movement was wildly uncontrolled. Ian’s initial attempt at standing up resulted in him falling “in a heap . . . like a pile of wet

clothes” (Cole, 1991, p. 11). He was unable to feed himself, get dressed, or do any functional activity requiring control of movement. Over several years, Waterman learned how to complete functional activities by substituting vision for his lost sensation. Every movement had to be carefully watched and consciously controlled. The high level of concentration required and the energy expended to complete daily self-care and work activities led Cole to name the account of Waterman’s life, *Pride and a Daily Marathon*.

Although a loss of sensation like Waterman’s without any motor loss is unusual, it exemplifies the close connection between the motor and sensory systems. With sensory loss in the hand, fine motor coordination is impaired, and manipulative ability is decreased (Chapman, Tremblay, & Ageranoti-Belanger, 1996; Jones, 1996). The amount of force needed to maintain grasp on an object also depends on sensory feedback. Usually, we use force that is just sufficient to overcome the pull of gravity, taking into account the amount of friction afforded by the surface texture. Without adequate tactile sensation, the force used to grip an object is either lower or higher than the force needed, resulting in objects slipping from grasp, delicate objects (such as a plastic foam cup) being crushed by excessive grip force, or muscles developing fatigue from overactivity (Johansson, 1996).

Some activities require sensory feedback because they are totally dependent on the sense of touch, such as determining the temperature of a bowl taken from the microwave. Tactile sensations let us know whether the food is warm and whether the bowl is too hot to carry to the table. Finding coins or other objects in a pocket and fastening a necklace or closing a back zipper are examples of activities for which vision is not used; therefore, we rely entirely upon sensory feedback. It is the tactile sense that

tells us when our new shoes are a bit too tight and we had better remove them or we will get a blister. Impairment in the somatosensory system not only hinders movement but also increases the risk of injury.

PURPOSES OF SENSORY EVALUATION

The purposes of sensory testing, as defined by Cooke (1991), are as follows:

- Assess the type and extent of sensory loss.
- Evaluate and document sensory recovery.
- Assist in diagnosis.
- Determine impairment and functional limitation.
- Provide direction for occupational therapy intervention.
 - Determine time to begin sensory reeducation.
 - Determine need for education to prevent injury during occupational functioning.
 - Determine need for desensitization.

Before considering sensory evaluation, therapists need a good understanding of the neural structures responsible for tactile sensation.

NEUROPHYSIOLOGICAL FOUNDATIONS OF TACTILE SENSATION

Receptors for tactile sensation are present within skin, muscles, and joints. Each tactile receptor is usually specialized for a single type of sensory stimulation such as touch, temperature, or pain (Fredericks, 1996a). The types of sensation, specific kinds of receptors, and corresponding neurons that connect the sensory receptors with the spinal cord and ultimately with the cerebral cortex appear in Table 7-1. Neural impulses follow the described pathways to the brain, where the sensations are perceived and interpreted.

Each sensory neuron and its distal and proximal terminations can be considered a sensory unit. Each sensory unit has an area of skin that encompasses its defined receptive field. A stimulus anywhere in the field may evoke a response, but stimuli applied to the center of the receptive field produce sensations more easily. In other words, the center of a receptive field has a lower threshold than the periphery. Adjacent receptive fields overlap; therefore, a single stimulus evokes a profile of responses from overlapping sensory units.

The variation in the number of sensory units in a given area of skin is called innervation density. The face, hand, and fingers have high innervation densities. Areas with high innervation density are highly sensitive and

have a proportionately large representation area within the somatosensory area of the cortex, the postcentral gyrus of the parietal lobe (Fredericks, 1996a). Figure 7-1 shows the organization within the cortex of sensory receptors from various regions of the body.

Table 7-1 and the description of sensory pathways simplify a complex process. For example, tactile stimuli of sufficient strength elicit responses from both constant and moving touch receptors and perhaps also from the pain receptors (Fredericks, 1996a). Extremes of hot and cold stimuli activate the pain receptors rather than the temperature receptors (Lindblom, 1994). Perception of joint motion (**kinesthesia**) and joint position (**proprioception**) appear to be a result of information from multiple kinds of receptors. Researchers disagree about the relative contributions of joint, muscle, and skin receptors to proprioception and kinesthesia (Fredericks, 1996a; Jones, 1996).

Table 7-1. Neural Pathways of Sensory Stimuli

Type of Sensation	Sensory Receptor	Type of Afferent Neuron	Pathway	Termination of Pathway
Constant touch or pressure	Merkel's cell Ruffini's end organ	Type A-beta slowly adapting I and II myelinated neurons	Ascend in dorsal column and medial lemniscus of spinal cord in posterior pyramidal tract, cross to opposite side in medulla	Thalamus and somatosensory cortex
Moving touch or vibration	Meissner's corpuscles Pacinian corpuscles Hair follicles	Type A-beta rapidly adapting I and II myelinated neurons		
Proprioception and kinesthesia	Same as both moving and constant touch or vibration plus touch receptors found in skin and joint structures Muscle spindles Golgi tendon organs	Same as for moving touch or vibration plus A-alpha myelinated neurons	Same as for moving touch or vibration plus spinocerebellar tract	Same as for moving touch or vibration plus cerebellum
Pain (pinprick)	Free nerve endings	Type A-delta myelinated neurons	Immediately cross to opposite side and pass upward in anterior spinothalamic tracts of spinal cord	Brainstem, thalamus, and somatosensory cortex
Pain (chronic) Temperature	Free nerve endings Free nerve endings Warm receptors Cold receptors	Type C unmyelinated fibers Type A-delta myelinated neurons and type C unmyelinated fibers		

Based on information in Dellon, A. L. (1997). *Somatosensory testing and rehabilitation*. Bethesda, MD: American Occupational Therapy Association; Chapman, C. E., Tremblay, F., & Ageranioti-Bélanger, A. (1996). Role of primary somatosensory cortex in active and passive touch. In A. M. Wing, P. Haggard, & J. R. Flanagan (Eds.), *Hand and brain: The neurophysiology of hand movements* (pp. 329–347). San Diego: Academic; Fredericks, C. M. (1996). Basic sensory mechanisms and the somatosensory system. In C. M. Fredericks & L. K. Saladin (Eds.), *Pathophysiology of the motor systems: Principles and clinical presentations* (pp. 78–106). Philadelphia: Davis; and Fredericks, C. M. (1996). Disorders of the spinal cord. In C. M. Fredericks & L. K. Saladin (Eds.), *Pathophysiology of the motor systems: Principles and clinical presentations* (pp. 394–423). Philadelphia: Davis.

Therapists use a solid understanding of the neurophysiology of the tactile system to choose evaluation and treatment techniques for sensory deficits. They combine this understanding with knowledge of typical patterns of impairment from injury and illness prior to implementing assessment of sensation.

SOMATOSENSORY DEFICIT PATTERNS

Any interruption along the ascending sensory pathway or in the sensory areas of the cortex can lead to a decrease or loss of sensation. The extent and severity of the sensory deficit can generally be predicted in accordance with the mechanism and location of the lesion or injury. Patterns of sensory impairment are directly related to the involved neuroanatomical structures, which could be anywhere in the central or peripheral nervous system.

Cortical Injury

Patients with brain lesions caused by cerebrovascular accident (CVA) or head trauma demonstrate sensory losses related to loss of functioning of specific neurons within the

central nervous system. Approximately 60% of patients with stroke in the carotid artery system, which includes the anterior and middle cerebral arteries, have sensory deficits (Garrison et al., 1988). Effects of CVA on sensation depend on specific disruption of blood supply. For instance, occlusion of the middle cerebral artery (the most common site of CVA) is often associated with contralateral impairment of all sensory modalities on the face, arm, and leg. Occlusion of the anterior cerebral artery tends to cause more loss of sensation in the contralateral leg than in the arm because of this artery's supply to the medial aspect of the cerebral cortex (Fig. 7-1) (Saladin, 1996a). Patterns of sensory loss following head trauma are less predictable because of the more diffuse areas of brain damage associated with this condition (Saladin, 1996b). For patients with either CVA or head injury, perception of fine touch and proprioception are most affected, temperature sensation is affected less, and pain sensibility is affected least (Fredericks, 1996a).

Sterzi et al. (1993) compared patients with left and right CVA and found that loss of proprioception and pain perception were more common following right CVA than left CVA. Left neglect, an inability to recognize and use perceptions from the left side of the body and environment, was proposed as a factor underlying this difference. The study of Beschin et al. (1996) provides evidence to support the existence of tactile neglect; patients with right

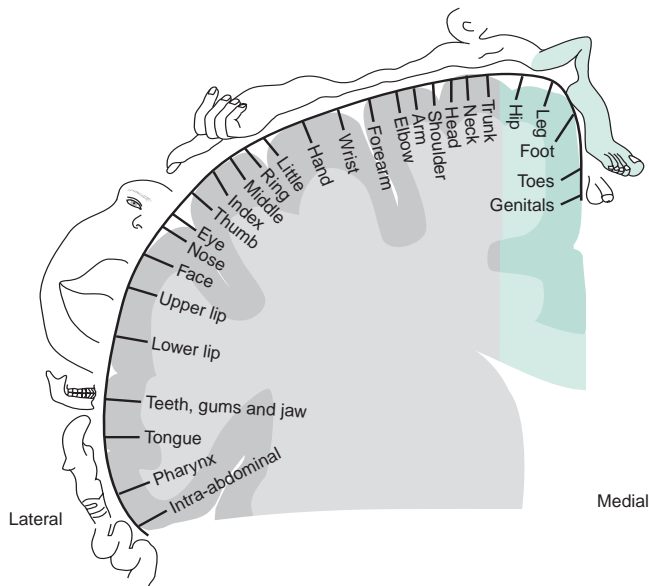

Figure 7-1 The areas responsible for sensation of body parts within the postcentral gyrus of the cerebral cortex. (Reprinted with permission from Kingsley, R. E. [1996]. *Concise text of neuroscience* [p. 185]. Baltimore: Williams & Wilkins.)

brain damage tend to ignore left space during active tactile exploration.

Partial recovery of sensation following cortical injury is attributed to decreased edema, improved vascular flow, cortical plasticity (adaptability of neurons to assume new functions), and relearning (Carr & Shepherd, 1998). Recovery of pain and temperature perception usually precedes recovery of proprioception and light touch (Fredericks, 1996a).

Use the following guidelines in planning assessments for patients with cortical injury:

- Quickly screen those areas of the body where sensation is likely to be intact, followed by a more thorough evaluation only if a deficit is found during screening.
- Assess more thoroughly those areas most likely to be affected, usually the side contralateral to the injury.
- If fine touch and proprioception are intact, assessment of temperature and pain is not necessary, as these protective sensations will also be intact. For patients with mild cortical impairment, begin the sensory assessment with light touch and/or proprioception.
- If pain and temperature are absent, assessment of light touch and proprioception is not necessary as these will also be absent. For patients with severe cortical impairment, begin with assessment of pain and temperature for greatest efficiency.
- Use the recovery sequence of pain and temperature before light touch and proprioception during reassessment to document recovery.

Spinal Cord Injury

Patients with complete lesions of the spinal cord demonstrate a total absence of sensation in the dermatomes (Fig. 7-2) below the level of the lesion. The level of the lesion determines the extent of the sensory loss, with the greatest loss occurring in patients with the lesions in the highest cervical regions of the spinal cord. **Paresthesia** (tingling or pins and needles sensation) may occur in the dermatome associated with the level of the lesion (Fredericks, 1996c).

Incomplete spinal cord lesions result in sensory losses that are related to damage within specific spinal tracts. For instance, damage to the anterior part of the spinal cord usually results in loss of pain and temperature sensation below the level of the lesion, whereas touch, vibration, and proprioception remain intact. Conversely, patients who have damaged the posterior portion of the spinal cord cannot feel light touch and vibration but can feel differences in temperature and painful stimuli. Patients with damage to one side of the spinal cord (Brown Sequard syndrome) display loss of touch, vibration, and proprioception on the side of the lesion and loss of temperature and pain sensation on the side opposite the lesion. This occurs because of the differences in the pathways of the ascending sensory fibers; neurons carrying temperature and pain sensations cross to the opposite side of the spinal cord immediately after entering it, whereas neurons carrying touch sensations ascend to the medulla before crossing to the opposite side (Fredericks, 1996c). Damage to the central spinal cord often results in bilateral loss of pain and temperature sensation below the level of the lesion because the neurons cross to the opposite side through the central portion of the cord. Mild to moderate compression of the spinal cord may result in decreased or absent sensation in the single dermatome at the level of the compression or could also involve dermatomes below the compressed area (Fredericks, 1996c).

Any sensory recovery following traumatic spinal cord injury usually occurs within the first year, with the greatest recovery in the first 6 months (Waters et al., 1993). Recovery of sensation is thought to occur because of resolution of ischemia and edema within the spinal cord.

Use the following guidelines in planning assessments for patients with spinal cord injury:

- Use a test with a strong stimulus (pinprick, cotton ball) to determine level of injury.
- The American Spinal Injury Association recommends key sensory points within each dermatome to utilize when assessing injury level. See Chapter 43 for further details.
- Bilateral testing is necessary following spinal cord injury because results may differ from side to side.
- For patients with known complete lesions, there is no need to test multiple sensory modalities.

Figure 7-2 Typical dermatome distribution. (Reprinted with permission from Bear, M. F., Connors, B. W., & Paradiso, M. A. [1996]. *Neuroscience: Exploring the brain* [p. 322]. Baltimore: Williams & Wilkins.)

- For patients with incomplete or unknown lesions, test for multiple sensory modalities, including at least one pain or temperature assessment and at least one measure of touch, vibration, or proprioception.

Peripheral Nerve Injury

Patterns of sensory loss following peripheral nerve injury vary with the nerve or nerves involved. Damage to a single nerve root as it exits the spinal cord affects sensation on one side of the body within a single dermatome (Fig. 7-2). Damage to a peripheral nerve distal to the brachial plexus affects sensation within the appropriate peripheral nerve distribution (Fig. 7-3) (Adams, Victor, & Ropper, 1997). For instance, in carpal tunnel syndrome, compression of the median nerve at the wrist produces sensory symptoms in the thumb, index, middle, and half of the ring finger on the affected side. For information about the typical patterns of sensory loss related to lesions of the trunks and cords of the brachial plexus, Callahan's chapter in *Rehabilitation of the Hand and Upper Extremity* (2002) is an excellent reference.

The severity of the sensory loss can vary widely. A complete transection of a peripheral nerve results in a total loss

of tactile sensation within the region. A mild nerve compression, such as in early stages of carpal tunnel syndrome, produces a slightly elevated threshold for sensing light touch or vibration. As the compression persists or increases in severity, further loss of sensation will occur, the threshold of light touch sensation will be higher, and the patient will begin to report symptoms such as frequently dropping items from the hand. Eventually, if the compression is not relieved, numbness and loss of protective sensation will develop.

Recovery of sensation following release of a nerve from compression is very likely if the compression was brief and mild. Significant recovery following prolonged compression is common, but sensory perception does not always reach normal levels. Recovery of sensation following total transection of a nerve is possible only with surgical intervention and adequate regrowth of neurons (Smith, 1995). Sensation of temperature and pain generally (but not always) recovers first, followed by touch sensation, because regrowth of pain fibers averages 1.08 mm per day, and regrowth of touch fibers averages 0.78 mm per day (Waylett-Rendall, 1988). Moving touch recovers before light touch. Accurate touch localization recovers last (Callahan, 2002).

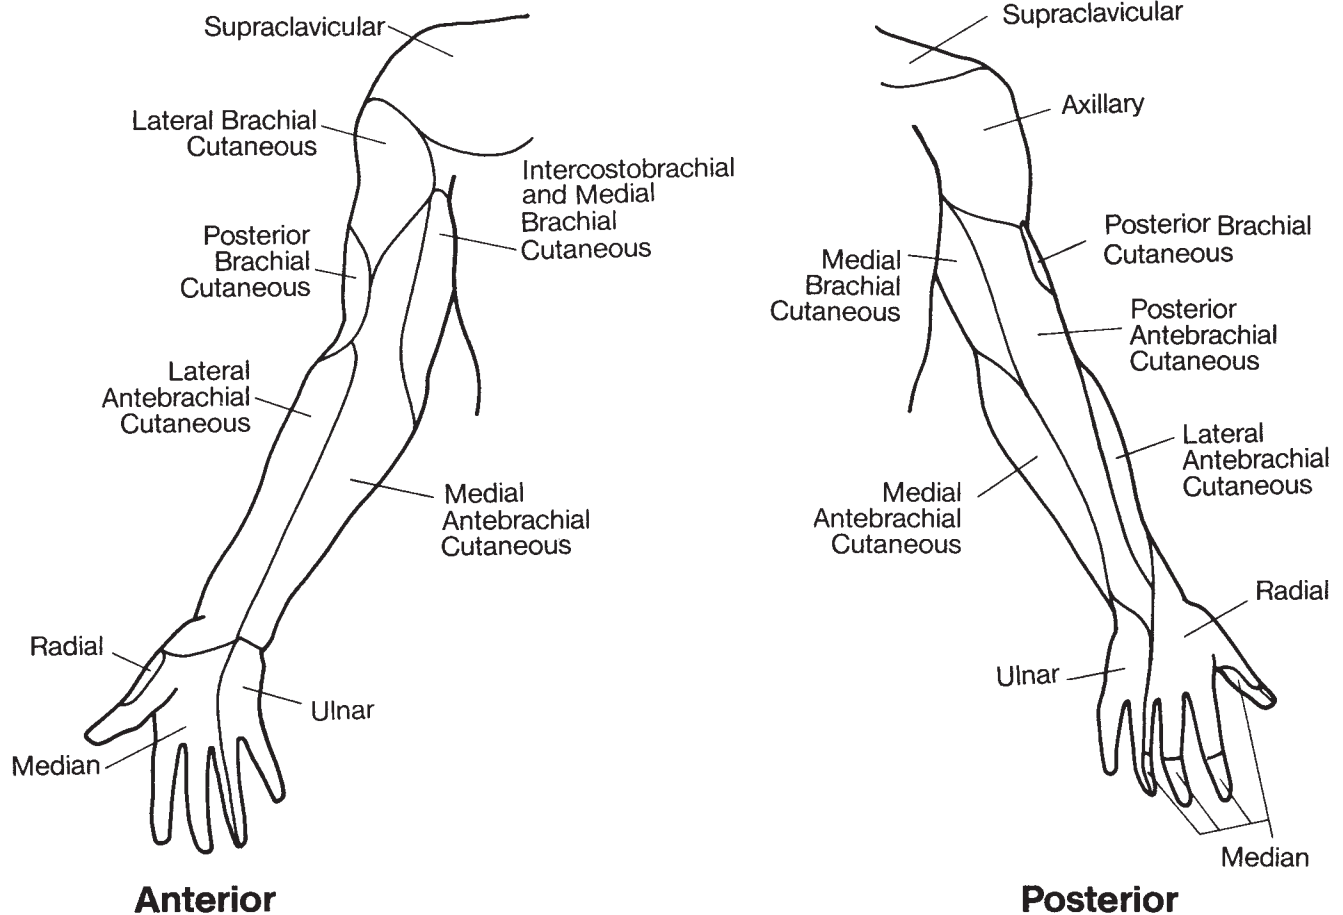

Figure 7-3 Typical sensory distribution of peripheral nerves within the upper extremity. (Reprinted with permission from Sieg, K. W., & Adams, S. R. [1996]. *Illustrated essentials of musculoskeletal anatomy* [3rd ed., p. 79]. Gainesville, FL: Megabooks.)

The pattern of sensory loss occurring as a result of peripheral polyneuropathies, which are associated with chronic conditions such as diabetes mellitus and alcoholism, is typically bilateral and symmetrical, usually beginning in the feet and hands (glove-and-stocking distribution) and spreading proximally. Paresthesia and pain may accompany peripheral neuropathy. Because of the chronic conditions associated with peripheral neuropathy, recovery of sensation is generally not expected (Fredericks, 1996b).

Use the following guidelines in planning assessments for patients with peripheral nerve injury:

- The purpose of evaluation in clients with peripheral polyneuropathy is to establish the impact of disease on protective sensation, so choose an assessment of protective sensation.
- The desired outcome of sensory evaluation in clients with involvement of a single peripheral nerve is an accurate map of both the body area and severity of sensory loss.
- Evaluation of nerve compression and subsequent recovery requires measures that are highly sensitive to show small changes in sensory function.

- Because functional tests of sensation requiring object or texture identification are completed with the thumb, index, and middle fingers, these assessments provide information about the functioning of the C6, C7, and C8 nerve roots and the median nerve.
- In documenting recovery of peripheral nerve function, keep in mind the recovery sequence of pain → moving touch → light touch → touch localization.

EVALUATION TECHNIQUES

There are numerous methods of testing sensation. Some are intended to evaluate a specific type of sensory receptor, such as the test for vibration awareness using a tuning fork that is believed to be specific to the Meissner's and Pacinian corpuscles (Dellon, 1997). Some are intended to evaluate the use of sensation in skills that support occupational functioning, such as the use of the hand to identify objects by touch in the test of **stereognosis**. Some are designed to detect very small changes in sensory perception, such as the touch threshold test using **monofilaments** (fine nylon strands).

The principles of sensory testing optimize the reliability of the testing results. These are listed in Procedures for Practice 7-1. The purpose of these principles is to eliminate non-tactile cues and to ensure that the responses from the patient accurately reflect actual sensation. Because many of the tests require subjective reports from the patient, results can be either deliberately or unconsciously manipulated by the patient to make the deficit appear better or worse. Careful attention to test administration and patient responses can minimize the possibility of testing manipulation by patients. For cases where the patient's responses are questionable and a determination of testing manipulation must be made, therapists may use a forced-choice testing methodology and statistical analysis described by Greve, Bianchini, and Ameduri (2003) in

PROCEDURES FOR PRACTICE 7-1

Principles of Sensory Testing

- Choose an environment with minimal distractions.
- Ensure that the patient is comfortable and relaxed.
- Ensure that the patient can understand and produce spoken language. If the patient cannot, modify testing procedures to ensure reliable communication.
- Determine areas of the body to be tested.
- Stabilize the limb or body part being tested (Fig. 7-4).
- Note any differences in skin thickness, calluses, and so on. Expect sensation to be decreased in these areas.
- State the instructions for the test.
- Demonstrate the test stimulus on an area of skin with intact sensation while the patient observes.
- Ensure that the patient understands the instructions by eliciting the correct response to the demonstration.
- Occlude the patient's vision for administration of the test. Place a screen (Fig. 7-5) or a file folder between the patient's face and the area being tested, blindfold the patient, or ask the patient to close his or her eyes.
- Apply stimuli at irregular intervals or insert catch trials in which no stimulus is given.
- Avoid giving inadvertent cues, such as auditory cues or facial expressions, during stimulus application.
- Carefully observe the correctness, confidence, and promptness of the responses.
- Observe the patient for any discomfort relating to the stimuli that may signal **hypersensitivity** (exaggerated or unpleasant sensation).
- Ensure that the therapist who does the initial testing does any reassessment.

Figure 7-4 Hand support during testing. **A.** Fingers must be carefully stabilized and supported during testing so that motion is prevented, avoiding inadvertent cues to the patient. **B.** A cushion of therapy putty can be used to provide the stabilization.

Figure 7-5 Vision must be occluded during testing. Using a screen such as this is usually more comfortable for patients than closing their eyes or being blindfolded.

which patients are required to identify whether they are touched with one finger or two. A statistically low percentage correct suggests an invalid response, since someone without sensation who merely guessed would be likely to get approximately 50% correct.

Fess (1995), in her article “Guidelines for Evaluating Assessment Instruments,” describes four essential criteria for all assessment instruments. The first is reliability, which includes accuracy of the instrument measurements as well as test–retest stability and inter-rater repeatability. Second, she describes validity as the tool’s ability to measure the sensory modality for which it was designed. Third, standards for the manufacture, administration, and scoring of the assessment and interpretation of the results must be set and followed. Finally, there must be normative data and, ideally, diagnosis-specific normative data. Fess states, “unfortunately, very few assessment tools in hand rehabilitation meet even the most basic measurement criteria” (p. 144).

Specific descriptions of the administration of commonly used sensory evaluations are shown in Tables 7-2 and 7-3. The more standardized evaluations of sensation appear in Table 7-2, and the less standardized evaluations are shown in Table 7-3. Sensory testing tools have been the target of much criticism for their lack of standardization, reliability, and validity. Although the sensory tests were divided into standardized and nonstandardized tests in Tables 7-2 and 7-3, few of the tests in Table 7-2, presented as standardized, meet all of the criteria described by Fess (1995).

Therapists must consider various qualities of the types of sensory tests as they choose and administer them. Threshold tests determine the smallest stimuli that can be noticed by the patient. They are the most sensitive and have numeric results that can easily be compared over time. Two-point discrimination measures innervation density in the fingers and is quite sensitive to change. Touch localization evaluates not only sensation but also whether that sensation is accurately perceived. Touch, temperature, vibration, and pain awareness are simple to administer but are not very sensitive to change. Tests of kinesthetic and proprioceptive sensations are less commonly used and are not very sensitive to change but are believed to be related to the specific type of sensory feedback required for coordinated movement. The picking-up test and stereognosis test are more functional but require combined motor and sensory function in the hand.

Computerized evaluations of sensation are often used for research and are becoming available in a limited number of clinics (Benton, 1994; Dellon, 1997; Riggle, 1999). The *Automated Tactile Tester*, for instance, measures touch, two-point discrimination, temperature, vibration, and pinprick thresholds (Horch et al., 1992). The *Pressure Specified Sensory Device* measures pressure threshold for one-point and two-point discrimination (Dellon, 1997).

Although sensory tests are usually administered with the patient rested and in a comfortable, supported position, exceptions to this principle occur in the case of patients with peripheral nerve compression. Provocative testing, which determines whether increases in symptoms occur as a result of additional stress or compression on the peripheral nerve, is completed. Increased sensory loss in the median nerve distribution with the wrist in flexion implicates compression of that nerve in the carpal tunnel area. Elbow flexion is the stress position for suspected cubital tunnel syndrome, which is compression of the ulnar nerve in the elbow area. Manual pressure over the nerve can be combined with the provocative position to further increase stress on the nerve (Callahan, 2002; Novak & Mackinnon, 2005; Szabo et al., 1999).

Recording Assessment Results

Documentation should include the type of test, the skin area tested, and the response. One easy way to document touch threshold testing with monofilaments is to use a color code on a drawing of the body part (Fig. 7-9). Standard colors used to document results for the Semmes Weinstein Monofilaments and Weinstein Enhanced Sensory Test (WEST) are indicated in Table 7-4. A series of sensory maps can easily and quickly demonstrate sensory recovery.

For standardized tests, results can be compared with norms; however, age should be taken into account because studies show a decline in sensation with age (Desrosiers et al., 1996). Normative monofilament expectations for adults over age 60 are shown in Table 7-5. For both standardized and nonstandardized tests, results from the affected area of the patient can be compared with results from an unaffected area.

Sensory evaluation findings are often summarized as absent, intact, or impaired. *Absent* describes a total loss of sensation or inability to detect a specific sensory modality. *Intact* describes normal sensation. Sensation is *impaired* when the patient is able to detect some but not all of the stimuli or when the perception of the stimulus is different from that of an area of skin that has intact sensation.

Interpretation of Evaluation Findings and Treatment Planning

In analyzing sensory evaluation findings, compare the results with those expected based upon the patient’s diagnosis. If the results differ from what was expected, further testing might be recommended. Individual sensory distributions sometimes vary from the illustrations of typical sensory distributions included in this and other texts. Furthermore, although there are clear lines of demarcation on the illustrations, humans generally have some overlapping

Table 7-2. Standardized Sensory Testing Techniques

Sensory Test	Test Instrument	Stimulus (S) and Response (R)	Scoring and Expected Results
<p>Touch Threshold</p> <p>Measures threshold of light touch sensation (Bell-Krotoski, 1995; Tomancik, 1987; Weinstein, Drozdenko, & Weinstein, 1997)</p>	<p>Semmes-Weinstein monofilaments</p> <p>OR</p> <p>Weinstein Enhanced Sensory Test (WEST)</p>	<p>Semmes-Weinstein</p> <p>S: Begin testing with filament marked 2.83; hold filament perpendicular to skin, apply to skin until filament bends (Fig. 7-6). Apply in 1.5 seconds, hold 1.5 seconds, and remove in 1.5 seconds. Repeat three times at each testing site, using thicker filaments if the patient does not perceive thin ones (except for filaments marked >4.08, which are applied one time to each site).</p> <p>R: Patient says yes upon feeling the stimulus.</p> <p>WEST</p> <p>S: Patient is prompted to stimulus, then filament is slowly applied perpendicular to skin and held for 1 second, then slowly lifted. Catch trials consisting of prompt without filament application are randomly inserted within test sequence.</p> <p>R: Patient responds with yes or no to indicate whether stimulus was felt.</p>	<p>Semmes-Weinstein</p> <p>Score is either the marking number or the actual force of the thinnest filament detected at least once in three trials; results are usually recorded according to a standard color code using colored pencils or markers and a diagram of the hand (Table 7-5 and Fig. 7-9). Normal touch threshold for adults is perception of the filament marked 2.83 (force 0.08 g) except for the sole of the foot, where the normal threshold is the filament marked 3.61 (force 0.21 g).</p> <p>WEST</p> <p>Results are recorded according to the color of the filament. Normal touch threshold is perception of the thinnest monofilament. There are two WEST devices, one for the hand and another for the foot.</p>
<p>Static Two-Point Discrimination</p> <p>Measures innervation density of slowly adapting fibers of the hand (Callahan, 2002; Dellon, 1997)</p>	<p>Disk-Criminator</p> <p>OR</p> <p>aesthesiometer (Fig. 7-7)</p>	<p>Static Two-Point Discrimination</p> <p>S: Begin with a 5-mm separation of points. Lightly (just to the point of blanching) apply one or two points (randomly sequenced) in a transverse or longitudinal orientation on the hand; hold for at least 3 seconds or until patient responds. Gradually adjust distance of separation to find least distance that patient can correctly perceive.</p> <p>R: Patient responds by saying 1, 2, or I can't tell.</p>	<p>Score is smallest distance at which perception of one or two points is better than chance. When the patient's responses become hesitant or inaccurate, require 2 of 3, 4 of 7, or 7 of 10 correct responses.</p> <p>Static Two-Point Discrimination Norms</p> <p>3–5 mm in fingertips ages 18–70 (Bell-Krotoski, 1997)</p> <p>5–6 mm in fingertips ages 70 and above (Desrosiers et al., 1996)</p> <p>5–9 mm for middle and proximal phalanges in adults ages 18–60; 0–12 mm for middle and proximal phalanges in adults ages 60 and above (Shimokata & Kuzuya, 1995)</p>

Table 7-2. Standardized Sensory Testing Techniques (continued)

Sensory Test	Test Instrument	Stimulus (S) and Response (R)	Scoring and Expected Results
<p>Moving Two-Point Discrimination</p> <p>Measures innervation density of quickly adapting fibers of fingertips (Callahan, 2002; Dellon, 1988, 1997)</p>		<p>Moving Two-Point Discrimination</p> <p>S: Beginning with a 5–8 mm distance, move one or two points randomly from proximal to distal on the distal phalanx with points side by side and parallel to the long axis of the finger; use just enough pressure for the patient to appreciate the stimulus. Gradually adjust distance of separation to find least distance that patient can correctly perceive.</p> <p>R: Patient responds by saying 1, 2, or I can't tell.</p>	<p>Moving Two-Point Discrimination Norms</p> <p>2–4 mm for ages 4–60 (Dellon, 1997; Hermann, Novak, & Mackinnon, 1995)</p> <p>4–6 mm for ages 60 and above (Dellon, 1997; Desrosiers et al., 1996)</p>
<p>Touch Localization</p> <p>Measures spatial representation of touch receptors in the cortex (Nakada, 1993)</p>	Semmes-Weinstein Monofilament number 4.17 or pen, pencil eraser	<p>S: Apply touch to patient's skin.</p> <p>R: Patient remembers location of stimulus. With vision no longer occluded, patient uses index finger or marking pen to point to spot just touched.</p>	<p>Score is the measured distance in millimeters between location of stimulus and location of response.</p> <p>Normal response is approximately 3–4 mm in digit tips, 7–10 mm in palm of hand, and 15–18 mm in forearm (Schady, 1994; Sieg & Williams, 1986).</p>
<p>Vibration Threshold</p> <p>Measures threshold of rapidly adapting fibers (Callahan, 2002; Dellon, 1997; Horch et al., 1992)</p>	Vibrometer, Biothesiometer, Vibratron II, Automated Tactile Tester, Case IV System	<p>Protocols vary with instrument.</p> <p>S: Generally, vibrating head is applied to area to be tested. Stimulus intensity is gradually increased or decreased.</p> <p>R: Patient indicates when vibration is first felt or no longer felt.</p>	Scoring varies with instrument; norms usually provided by manufacturer.
<p>Modified Picking Up Test (Dellon)</p> <p>Dellon's modification of Moberg's picking-up test measures the interpretation of sensation in the distribution of the median nerve (Dellon, 1988)</p>	A small box and 12 standard metal objects: wing nut, screw, key, nail, large nut, nickel, dime, washer, safety pin, paper clip, small hex nut, and small square nut	<p>Part 1</p> <p>S: Tape small and ring digits to palm to prevent use. With patient using vision, have him or her pick up and place objects in a box as quickly as possible; time performance on two trials.</p> <p>R: Patient picks up each object and deposits it in the box as quickly as possible.</p> <p>Part 2</p> <p>S: With patient's vision occluded, place one object at a time between three-point pinch in random order and measure speed of response.</p> <p>R: Patient manipulates object and names it as rapidly as possible.</p>	<p>Part 1</p> <p>Score is total time to pick up and place all 12 objects in the box for each of 2 trials.</p> <p>Normal response: Trial 1, 10–19 seconds Trial 2, 9–16 seconds</p> <p>Part 2</p> <p>Score is time to recognize each object on each of two trials (up to a maximum of 30 seconds).</p> <p>Normal response: 2 seconds per object</p>

Table 7-3. Nonstandardized Sensory Testing Techniques

Sensory Test	Test Instruments	Stimulus (S) and Response (R)	Scoring and Expected Results
Touch Awareness General awareness of touch input (Adams, Victor, & Ropper, 1997)	Cotton ball or swab, fingertip, pencil eraser	S: Light touch to a small area of the patient's skin. R: Patient says yes or makes agreed-upon nonverbal signal each time stimulus is felt.	Score is number of correct responses in relation to number of applied stimuli. Expected score is 100%.
Pinprick or Pain Awareness Measures discrimination of sharp and dull stimuli, which indicates protective sensation (Brand & Hollister, 1993; Reese, 1999)	New or sterilized safety pin	S: Randomly apply sharp and blunt ends of safety pin, perpendicular to skin, at pressure necessary to elicit correct response on uninvolved side of body. R: Patient says "sharp" or "dull" after each stimulus.	Score is number of correct responses divided by number of stimuli. Expected score is 100%. Correct responses to sharp stimuli indicate intact protective sensation; incorrect responses to sharp stimuli indicate some awareness of pressure but absent protective sensation.
Temperature Awareness (Fig. 7-8) Measures discrimination of warm and cool stimuli (Waylett-Rendall, 1988)	Hot and Cold Discrimination Kit or glass test tubes filled with warm and cool water	S: Apply cold (40°F) or warm (115–120°F) stimulus to patient's skin. R: Patient indicates hot or cold after each stimulus.	Score is number of correct responses divided by number of stimuli. Normal response is 100%.
Vibration Awareness Measures awareness of input to rapidly adapting A-beta fibers (Dellon, 1988)	Tuning forks: 30 cycles per second 256 cycles per second	S: Strike tuning fork with force to cause vibration; place prong tangentially to fingertip of injured and then uninjured hand; ask patient, "Does this feel the same or different?" R: Patient responds same or different and describes difference in perception.	Scoring is normal if stimuli to both hands feel the same or altered if stimuli feel different. The 30-cps tuning fork is used to test the Meissner afferents, and the 256-cps tuning fork is used to test the Pacinian afferents.
Stereognosis Measures the ability to identify objects, which requires interpretation of sensory input. Motor function is prerequisite. (Eggers, 1984)	A number of small objects known to the patient	S: Place a small object in the hand to be tested. R: Patient may manipulate object within the hand; patient names object.	Scoring is number of correct responses divided by total number of objects presented or time to identify each object. Normal response is correct identification of almost all objects within 2–3 seconds (Lederman & Klatzky, 1996).
Moberg's Picking-Up Test Measures the function of slowly adapting A-beta fibers in medial nerve injury (Callahan, 2002; Dellon, 1988)	An assortment of small objects and a small box	S: Instruct patient to pick up objects as rapidly as possible and place them in the box, using right and left hands, with and without vision. R: Patient quickly picks up objects and places them in box.	Scoring is total time to pick up objects. Compare scores of left and right hands and those with and without vision. Mean times for 12 standard objects were found by Ng, Ho, and Chow (1999) to be 10–12 seconds with vision and 20–23 seconds without vision.

continued

Table 7-3. Nonstandardized Sensory Testing Techniques (continued)			
Sensory Test	Test Instruments	Stimulus (S) and Response (R)	Scoring and Expected Results
<p>Proprioception</p> <p>Measures sense of joint position, which relies upon input from an unknown combination of muscle, joint, and skin receptors (Adams, Victor, & Ropper, 1997)</p>	None	<p>S: Hold body segment being tested on the lateral surfaces; move the part into different positions and hold.</p> <p>R: Patient duplicates position with opposite extremity.</p>	Graded as intact, impaired, or absent. Usually, reproduction of position can be accomplished within a few degrees. One study of the knee joint found, on average, 4 degrees of error in subjects under age 30 and 7 degrees of error in subjects over age 60 (Kaplan et al., 1985).
<p>Kinesthesia</p> <p>Measures sense of joint motion, which relies on input from an unknown combination of muscle, joint, and skin receptors (Adams, Victor, & Ropper, 1997)</p>	None	<p>S: Hold body segment being tested on the lateral surfaces; move the part through angles of varying degrees.</p> <p>R: Patient indicates whether part is moved up or down.</p>	Graded as intact, impaired, or absent. Nearly 100% correct identification is expected.

areas of innervation along the borders of sensory receptive areas (Adams, Victor, & Ropper, 1997).

Consider whether the actual and expected results are different enough to suggest that there might be neural issues other than the diagnosis. If a peripheral nerve is compressed at one site, it is more sensitive to compression at other sites. Double and multiple neural compression sites can produce unexpected patterns of sensory impairment (Novak & Mackinnon, 2005).

Touch threshold testing with monofilaments can be interpreted based upon categories of sensory loss as indicated in Table 7-4. With decreased light touch, patients often do not realize that they have a loss of sensation. There

is no effect on the motor use of the hand, and patients can identify temperatures, textures, and objects by touch. Diminished protective sensation results in decreased motor coordination, as evidenced by slower manipulation and dropping objects from grasp. Identification of temperatures and painful stimuli is intact. Loss of protective sensation causes an inability to use the hand when it is not in view. Patients will feel pinpricks and deep pressure but will be less able or unable to determine temperatures. Those patients who cannot feel the thickest monofilament may or may not be able to feel a pinprick but have no other feeling and require visual guidance for all hand function (Bell-Krotoski, 2002).

Figure 7-6 Testing of the median nerve distribution using Semmes-Weinstein monofilaments.

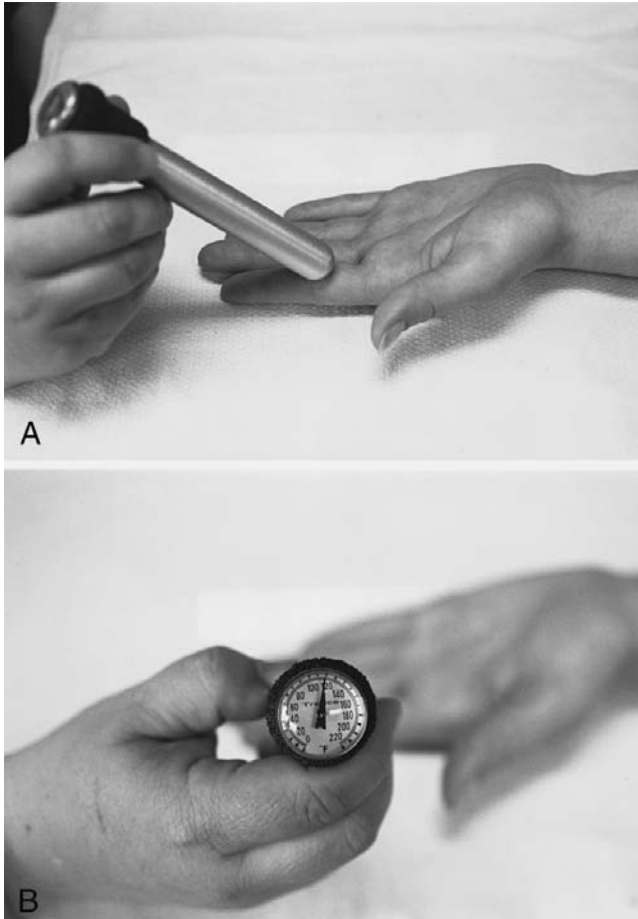

Figure 7-8 Temperature awareness testing. **A.** Metal probe is heated or cooled in water. **B.** The thermometer at the top helps to maintain consistency in testing.

In planning treatment, diminished or lost protective sensation or absence of sensation indicates that the patient is at risk for injury of the affected body part or parts. The patient must be taught to use vision and an adapted environment to compensate for lost sensation and avoid injury. Results that indicate impaired sensation need further investigation to determine the appropriate course of intervention. If there is hypersensitivity of the body part, a program of desensitization is indicated. If there is a decrease but not total loss of sensation within an area, the patient may be a candidate for sensory retraining, as long as the diagnostic prognosis indicates that there is a potential for improvement. Chapter 27 describes each of these interventions in detail.

CHOOSING EVALUATION METHODS

Therapists use clinical reasoning to select appropriate sensory evaluation techniques for each patient. Diagnostic and procedural reasoning suggest that certain tests are best

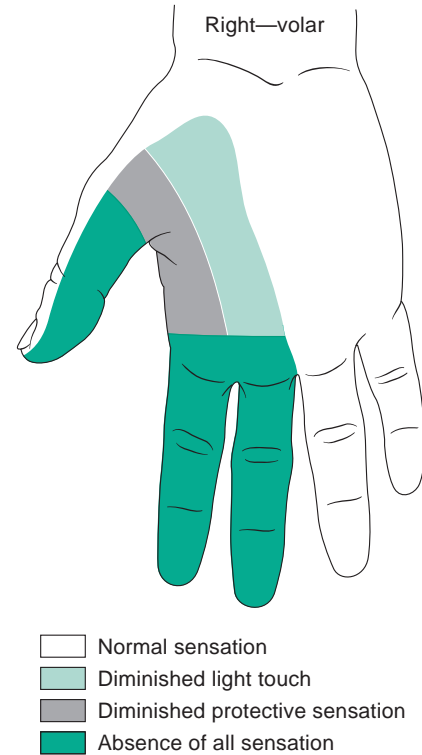

Figure 7-9 Results of monofilament testing for Mr. T. (see Case Example) 6 weeks following median nerve laceration and surgery.

at answering certain kinds of clinical questions. Ethical reasoning suggests that the tests should be the best available for each patient and that the practitioner has developed competence in test administration and interpretation. Pragmatic reasoning suggests that tests should be readily available and quickly administered (Schell, 1998).

Before choosing an evaluation method, decide why the test is necessary and what information is needed. Consider the diagnosis and the patient's description of the problem. For instance, for a patient with spinal cord injury, it is important to know whether sensation is present or absent in each region of skin. A touch awareness or pinprick test is common, with the results recorded on a drawing of the body (Waters et al., 1993).

If the purpose is to assist in the diagnosis of a nerve compression, such as carpal tunnel syndrome, it is necessary to use a highly sensitive test, such as a monofilament test. Sensation can be evaluated in positions that are likely to provoke more symptoms, for example with the wrist flexed (Szabo et al., 1999). A self-report of sensory loss has also been found useful in the diagnosis of carpal tunnel syndrome (Katz & Stirrat, 1990).

During observation of dressing or grooming by a patient with a diagnosis of CVA, a suspicion may arise that the observed errors are related to a loss of proprioception. An evaluation of proprioception can confirm or refute this hypothesis. For this same patient, it is important to know

Table 7-4. Semmes-Weinstein and WEST Hand Monofilaments

Filament Number	Diameter (mm)	Mean Force (g)	Color Code	Interpretation	Hand Function and Use
2.83	0.127	0.076	Green	Normal	Normal
3.61	0.178	0.209	Blue	Diminished light touch	Stereognosis and perception of temperature and pain are good, close to normal use of hand.
4.31	0.305	2.35	Purple	Diminished protective sensation	Decreased recognition of objects and painful stimuli, difficulty in manipulating objects.
4.56	0.356	4.55	Red	Loss of protective sensation	Greatly impaired perception of pain, temperature, and object recognition. No manipulation of object without vision. Marked decrease in spontaneous hand use.
6.65	1.143	235.61	Red-orange	Loss of all sensation except deep pressure	Unable to identify objects and temperature. Hand use only with visual guidance.
No response to 6.65	—	—	Red lines	Absence of all sensation	Unable to identify objects, temperature, and pain. Minimal hand use.

Based on information in Bell-Krotoski, J., & Tomancik, E. (1987). Repeatability of testing with Semmes-Weinstein monofilaments. *Journal of Hand Surgery, 12A*, 155–161; Tomancik, L. (1987). *Directions for using Semmes-Weinstein monofilaments*. San Jose, CA: North Coast Medical; Bell-Krotoski, J. A. (1997). Correlating sensory morphology and tests of sensibility with function. In J. M. Hunter, L. H. Schneider, & E. J. Mackin (Eds.), *Tendon and nerve surgery in the hand: A third decade* (pp. 49–62). St. Louis; Mosby.

whether there is risk of injury because of a loss of pain and temperature sensation (protective sensation). Either a pin-prick and temperature test or monofilament test can provide this information. The monofilament test is more standardized and therefore a better choice, although it usually takes more time.

A test of stereognosis is most appropriate to predict, for example, whether a patient with a hand injury who is a mechanic can feel for and locate unseen automobile parts. The result of a two-point discrimination test or a monofilament test correlates with but does not totally predict the ability to identify objects (Bell-Krotoski, 1997; Van Heest, House, & Putnam, 1993).

Table 7-5. Semmes-Weinstein Results for Subjects Over 60: Median Monofilament Marking Number by Gender and Age

Age	Women	Men
60–69	3.22	3.61
70–79	3.61	3.61
80+	3.61	3.84

Based on information from Desrosiers, J., Hébert, R., Bravo, G., & Dutil, É. (1996). Hand sensibility of healthy older people. *Journal of the American Geriatrics Society, 44*, 974–978.

Optimal Assessment of Sensation

Ideally, patients are thoroughly assessed using standardized, reliable assessments that are easy to perform and that provide a complete understanding of sensation. A battery of tests is recommended if it is desirable to get a complete understanding of tactile sensation because no one test can assess this complex sense (Callahan, 2002; Lundborg & Rosen, 1994; Rosen, 1996). In clinical practice, however, therapists must sometimes balance the ideal with practical constraints. Schell (1998) described pragmatic constraints that affect assessment and treatment, including sensory testing, in occupational therapy. These include the availability of equipment and supplies, the availability of treatment time, team roles and responsibilities, reimbursement, trends within the profession, culture of the health care organization, and the therapist’s clinical competencies or preferences.

Brand and Hollister (1993) charge that much time is wasted in sensory testing and the results are open to question. Therapists should carefully assess their practices periodically to ensure that they are providing intervention that is as close to the ideal as possible despite pragmatic constraints. Great improvements can and should be made in tests of sensation so that they are meaningful, quantitative, and meet the criteria for good test instruments (Peripheral Neuropathy Association, 1993).

Assessment Table 7-1

Summary of Assessments of Sensation

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Monofilaments Available from AliMed, North Coast Medical, or Sammons Preston Rolyan	Measures low threshold of touch perception on an ordinal scale. Results can be documented with a color-coded drawing or with numbers. 2.83 represents normal sensation and > 6.65 represents absent sensation.	5–30 minutes or more, depending on area tested.	Using Semmes-Weinstein monofilaments, diminished light touch associated with longer response time for object identification (King, 1997). WEST Monofilament testing compared to Distal Motor Latency using Electroneurometer revealed $r = 0.659$ – 0.886 for individual fingers (Schulz, Bohannon, & Morgan, 1998).	Repeatability of the force of application was demonstrated by Bell-Krotoski and Buford (1997). Test-retest reliability reported by Novak et al. (1993), $r = 0.78$ – 0.89 , and inter-rater reliability, intra-class correlation (ICC) = 0.965 .	72% sensitive in diagnosis of carpal tunnel syndrome (MacDermid & Wessel, 2004).	Strengths: Excellent reliability and validity; widely used. Weaknesses: Relies on subjective responses from patient. Filaments are easily damaged.
Disk-Criminometer and Aesthesiometer Available from Lafayette Medical Instruments, North Coast Medical, or Sammons Preston Rolyan	Measures two-point discrimination in millimeters, a ratio scale.	5–10 minutes.	Not established.	Test-retest reliability for two-point discrimination using the Disk-Criminometer was reported as: $r = 0.961$ for static and 0.922 for moving by Dellon, Mackinnon, and Crosby (1987); inter-rater reliability ICC = 0.989 for static and 0.991 for moving (Novak, et al., 1993); test-retest reliability of aesthesiometer in children, ICC = 0.54 (Menier, Forget, & Lambert, 1996).	Study by MacDermid & Wessel (2004) reported static testing has 24% sensitivity and 62% specificity in diagnosis of carpal tunnel syndrome.	Strengths: Excellent reliability; widely used; inexpensive, durable; useful in documenting nerve regeneration; most useful on fingertips. Weakness: Variation in force of application has been shown by Bell-Krotoski & Buford (1997), which may affect results.

continued

Assessment Table 7-1

Summary of Assessments of Sensation (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Tuning Forks Available from Sammons Preston Rolyan	Indicates whether or not vibration is perceived, a nominal scale.	5 minutes.	Not established.	Not established.	Sensitivity for diagnosis of carpal tunnel syndrome is reported at 55% and specificity at 81% (MacDermid & Wessel, 2004).	Strength: Low frequency useful to document regeneration of nerve. Weaknesses: Relies on subjective responses from patient; unknown validity and reliability; application techniques are not standardized.
Hot and Cold Temperature Probes Available from Sammons Preston Rolyan	Indicates whether or not temperature is perceived, a nominal scale.	5 minutes.	Not established.	Not established.	Not established.	Strengths: Assesses functional sensation; useful to identify loss of protective sensation. Weaknesses: Relies on subjective responses from patient. Tool does not test fine gradations of temperature discrimination and, therefore, may not be sensitive to change.

<p>Vibrometer Biomedical Instrument Company, Sensortek, Inc., or WR Medical Electronics</p>	<p>Determines lowest intensity of vibration that can be perceived, an interval scale.</p>	<p>20 minutes.</p>	<p>Not established.</p>	<p>Inter-rater reliability using Vibratron II, ICC = 0.982 (Novak et al., 1993).</p>	<p>In diagnosis of carpal tunnel syndrome, sensitivity is 50%, and specificity is 73% (MacDermid & Wessel, 2004).</p>	<p>Strengths: Multiple kinds; manufacturers provide protocols for testing; small gradations of scale. Weaknesses: Limited availability in OT clinics; expense.</p>
<p>Automated Tactile Testing Device Ztech, LC</p>	<p>Multiple modalities are tested, including temperature, pain, touch, vibration, and two-point discrimination.</p>	<p>15–30 minutes or more, depending on areas tested.</p>	<p>$r = 0.470$–0.529 when compared with monofilament and discriminator (Horch et al., 1992).</p>	<p>Test-retest reliability of Ztech using specific protocol, ICC = 0.86–0.89 (Hubbard et al., 2004). Intra-subject $r = 0.659$ (Horch et al., 1992).</p>	<p>In patients with carpal tunnel syndrome, 71% had abnormal results on the Automated Tactile Tester (Hardy et al., 1992).</p>	<p>Strengths: Computerized; quantifiable; tests multiple sensory modalities. Weaknesses: Limited availability in OT clinics; expense.</p>
<p>Pressure-Specified Sensory Device Neurotherapy DX</p>	<p>Measures pressure threshold and ability to feel and distinguish the distance between two points, with results graphically generated by a computer and quantified on an interval scale score with a range of 0.1–100 g/mm² for touch threshold.</p>	<p>10–20 minutes.</p>	<p>Results correlate well with timed object identification, $r = 0.691$. (Dellon, 1997).</p>	<p>Inter-test reliability is $r = 0.93$ for moving two-point discrimination, $r = 0.97$ for single-point static touch threshold test. Inter-rater reliability is $r = 0.61$ (Dellon, 1997).</p>	<p>In diagnosis of nerve entrapment, sensitivity is 100% (Tassler & Dellon, 1995).</p>	<p>Strengths: Computerized; quantifiable; measures both threshold and innervation density; excellent sensitivity. Weaknesses: Limited availability in OT clinics; expense.</p>
<p>Moberg Picking-Up Test (Dellon, 1988; Ng, Ho, & Chow, 1999) Available from Lafayette Instrument Company or Sammons Preston Rolyan</p>	<p>Picking up and identifying objects are timed, which results in an interval scale score.</p>	<p>10 minutes.</p>	<p>Not established.</p>	<p>Inter-rater reliability, $r = 0.67$ with eyes open and $r = 0.80$ with eyes closed (Ng, Ho, & Chow, 1999).</p>	<p>Not established.</p>	<p>Strengths: Simple, quick to administer; functional; easy to replicate; inexpensive; useful to assess function of median nerve. Weaknesses: Useful for limited diagnostic category; lack of standardized protocol.</p>

CASE

EXAMPLE

Mr. T. : Sensory Problems Following Median Nerve Laceration

Occupational Therapy Assessment Process

Clinical Reasoning Process

Patient Information

Mr. T. is a 25-year-old married man with a son aged 2. Mr. T.'s right wrist was injured by a broken window, resulting in a complete laceration of the median nerve and the flexor digitorum superficialis tendons to the middle and ring fingers. Both the nerve and tendons were repaired surgically the day after the injury.

Immediately after the injury, movement was restricted throughout the hand due to tendon healing precautions and protective splinting. Sensation was absent in the median nerve distribution of the palm and fingers, and there was loss of innervation to the thenar muscles. Mr. T. had a 7-cm incision scar on his volar wrist and palm area.

Mr. T. graduated from vocational-technical school with training in major appliance repair. At the time of his injury, he was working for a local company doing in-home repairs of refrigerators, washers, and dryers. His wife works in a secretarial position. He is right-handed, but he reported that since the injury, he has been using his left hand successfully in basic activities of daily living, such as feeding, dressing, and hygiene. He has not attempted using his right hand for any work, home management, or child care.

At 6 weeks after injury, protective splinting is discontinued, and Mr. T. is allowed to begin to use his right hand in functional activities with light resistance. The occupational therapist is now performing a comprehensive reassessment to determine the level of motor and sensory recovery of the median nerve, the sensibility and sensitivity around the area of the scar, and Mr. T.'s ability to use his right hand in functional activities.

Assessment Process

The occupational therapist selected the following sensory evaluation tools:

- Touch threshold test using Semmes-Weinstein monofilaments
- Static and moving two-point discrimination
- Touch localization
- Dellon's modification of the Moberg picking-up test

Objectives

Examples of Therapist's Internal Dialogue

Understand the patient's diagnosis or condition

"This was a really serious hand injury. Since the splinting was discontinued, the tendon and nerve repairs must have healed well."

Know the person

"Mr. T. seems like a hard-working man. His work is physically demanding. I wonder how he is dealing with being off from work for so long."

Appreciate the context

"I wonder how this hand injury affects the relationship Mr. T. has with his wife and son?"

Develop provisional hypotheses

"Given the history, I would expect that there has been about 1 1/2 inches of neural regrowth beyond the laceration. This should mean there will be some sensation in the palm but not yet in the fingers."

Consider evaluation approach and methods

"This is a good time to do a thorough sensory assessment because it will indicate how the neurons are regrowing and whether there are areas that still lack protective sensation. The monofilaments will give reliable information about all areas of the hand and indicate whether protective sensation is present or reduced. Because perception of moving touch recovers first, two-point discrimination testing might show recovery. The touch localization test will show how the brain is interpreting tactile sensations. The picking-up test relates sensation to functional hand use. These four tests will give good information for treatment planning and will demonstrate sensory recovery over time."

Assessment Results

The results of the Semmes-Weinstein monofilament test for the right palm and fingers are shown in Figure 7-9. Touch pressure threshold testing over the area of the scar revealed that Mr. T. disliked touch directly on the scar. The area was rubbed with textured items, and Mr. T. reported a marked preference for soft textures and no tolerance for rough textures, such as burlap and Velcro. Mr. T. was unable to feel the Disk-Criminator anywhere on the fingertips in the moving test and did not feel anything on the fingers or thumb in the static test. Touch localization in the radial portion of the right palm measured 18–25 mm. Mr. T.'s scores on Dellon's modification of the picking-up test were as follows:

Part 1: Left/Right

Trial 1: 17 seconds/55 seconds

Trial 2: 15 seconds/60 seconds

Part 2: No objects could be identified without vision

Interpret observations

“Sensation is returning pretty much as I expected it would. Return of some protective sensation in the palm is a positive sign that neuron regrowth is occurring. I expected absent sensation in the fingertips, because I remember the rate of regrowth is about 1 mm per day, or an inch per month. Mr. T. can use visual guidance to pick up small objects despite the sensory loss, but his movements are awkward. That incoordination could be due to either motor or sensory deficits. Because of lack of sensation in the fingertips, object identification is not possible now, but hopefully, Mr. T. will regain this ability because I suspect he will need to use his hand in places where he cannot see in his work as an appliance repairman.”

Occupational Therapy Problem List

1. Absent and decreased protective sensation in the thumb, index, and middle fingers and radial palm
2. Mislocalization of touch sensations in the radial portion of the palm
3. Hypersensitivity in the area of the scar
4. Decreased ability to pick up and manipulate objects
5. Decreased use of the right hand in functional activities

Synthesize results

“Mr. T. is probably at some risk for injury to the fingertips because he can now start using his hand in more functional tasks but lacks any protective sensation in the digit tips, which is a likely place for thermal injuries or lacerations. The presence of some protective sensation in the palm and the mislocalization of touch stimuli suggest that retraining of sensation in this area can now be started. He might have a tendency to avoid using his right hand due to his hypersensitivity and decreased coordination. I'll need to provide functional activities to encourage bilateral functional use. Perhaps some work simulation activities will be motivating for Mr. T.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Interpretation and Treatment Planning for Peripheral Sensory Problem**

Mr. T.'s touch threshold test performed 6 weeks post injury is shown in Figure 7-9. How will the mapping likely change when Mr. T. is reassessed after 6 more weeks? What kind of sensation (pain or touch) will he be able to feel first in his fingertips? Compare his current functional hand use with his expected hand use when his fingertips regain touch sensation.

SUMMARY REVIEW QUESTIONS

1. What pattern of sensory loss would be expected in a patient with a T10 complete spinal cord injury?
2. What pattern of sensory loss would be expected in a patient with peripheral polyneuropathy?
3. Which patient will have a better prognosis for recovery of sensation, one with a peripheral nerve compression or one with a middle cerebral artery stroke?
4. Name and describe the purposes of at least three standardized and three nonstandardized sensory tests.
5. Describe or demonstrate the administration and scoring of a touch threshold test, a pain awareness test, and a touch localization test.
6. Which sensory test or tests would you select for a patient with peripheral polyneuropathy? Justify your response.
7. What type of intervention is needed for a patient with absent protective sensation?

ACKNOWLEDGMENT

I extend my appreciation to Paul Petersen and Melanie Seltzer for their assistance with the photography for this chapter.

CHAPTER 8

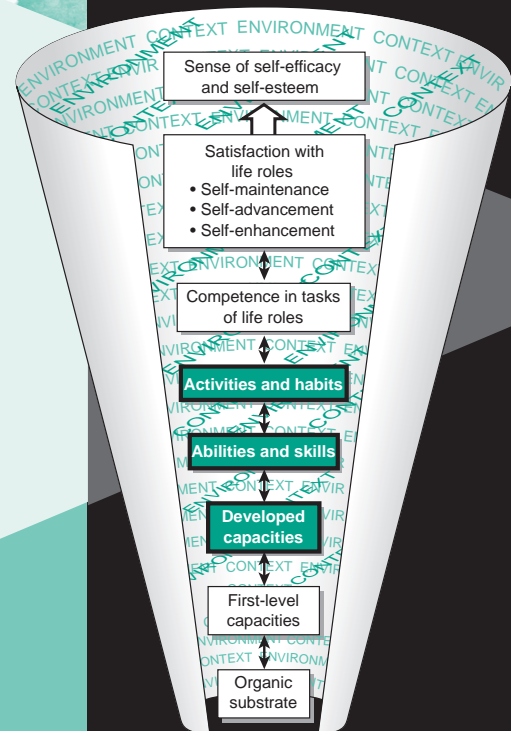

Assessing Abilities and Capacities: Vision, Visual Perception, and Praxis

Lee Ann Quintana

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Understand the importance of evaluating the visual foundation skills prior to higher level visual cognitive skills.
2. Identify and describe evaluation techniques for visual acuity, visual fields, and ocular motor control.
3. Describe and evaluate the two subtypes of unilateral neglect: sensory and motor.
4. Describe and evaluate apraxia.

Glossary

Accommodation—ability to adjust focus of vision at different distances; age related, and decreases with age.

Apraxia—the inability to carry out skilled movement in the presence of intact sensation, movement, and coordination.

Binocular vision—ability to resolve two images (one from each eye) into one.

Contrast sensitivity—ability to see with differing amounts of contrast.

Oculomotor control—ability of the eyes to move smoothly and in a coordinated manner through full range of motion.

Unilateral neglect—a constellation of symptoms that is manifested by a failure to respond or orient to stimuli presented contralateral to a brain lesion.

Visual acuity—ability of the eyes to make what is seen sharp and clear.

Visual fields—the scope of vision in each eye; central visual field: central 20° of vision; peripheral: area seen other than central vision.

Visual foundation skills—primary visual skills of visual acuity, visual fields, and oculomotor control upon which higher-level visual perception is built.

Vision is a critical channel by which we gather information from the environment. We depend heavily on vision for learning, decision making, social interactions, motor control, and postural control because of its critical role in attention, information processing, and movement detection (Titcomb, Okoye, & Schiff, 1997; Warren, 1999). It is the means by which we register information and decide what will happen next (e.g., move out of the way of a moving car, comfort a friend who is crying, pick up a tool lying on the table). Because of vision's importance to almost all activities of daily living, occupational therapists must know the basic status of the visual system of their clients.

The purpose of this chapter is to review evaluation of the visual system with more emphasis on **visual foundation skills** and less on the higher level visual cognitive skills. In addition, the chapter discusses assessment of praxis (motor planning).

VISUAL PERCEPTUAL HIERARCHY

Warren (1993a) developed a hierarchy of visual perception (Fig. 8-1), with each level built on and dependent on the one below it. Visual cognition, the highest level, is “the ability to mentally manipulate visual information and integrate it with other sensory information to solve problems, formulate plans, and make decisions” (Warren, 1993a, p. 43). Visual memory is below visual cognition in the hierarchy. If the car doesn't start and you look under the hood to check the battery, you need a picture in your memory of what a battery looks like, or you would fumble around for quite a while trying to find what was wrong. Likewise, pattern recognition subserves memory. You must be able to identify the features of an object before storing it in memory. To identify the features of an object, you must be able to scan it thoroughly. To scan thoroughly, you must be alert and

attentive. All of these higher skills depend upon the visual foundation skills: (1) **visual acuity**, which assures the accuracy of information sent to the brain; (2) **visual fields** (VF), which let the brain know what's going on in the environment; and (3) **oculomotor control**, which ensures efficient eye movements (Warren, 1993a).

Visual impairment changes the quality and amount of visual input to the brain and therefore decreases our ability to use vision to adapt (Warren, 1999) (Definition 8-1). If a person has poor **contrast sensitivity**, he or she may no longer want to go out in the evening because of the difficulty of maneuvering in poor light. Patients generally have

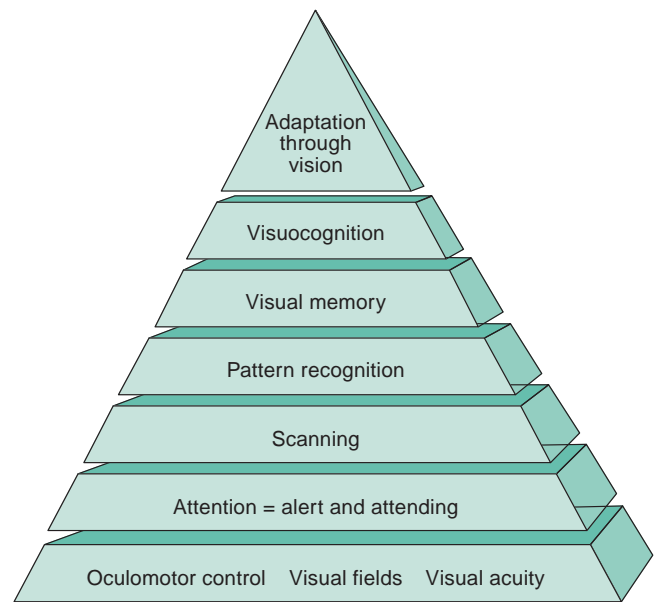

Figure 8-1 Hierarchy of visual perception. (From Warren, M. [1993a]. A hierarchical model for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury, Part 1. *American Journal of Occupational Therapy*, 47, 43. DEFINITION 8-1
de·fin·i·tion
Definitions and Descriptions of Vision, Visual Perception, and Praxis Deficits

Area of Deficit	Definition	Functional Description of Deficit
Visual acuity	Ability of the eyes to make what is seen sharp and clear.	Client complaints: blurred vision (near or far); print too small, too faint; headaches, squinting. Effect on function: holds objects too close to the face; ↓ facial recognition; fear of new environments; lack of interest in environment; difficulty localizing objects; ↓ interest in reading; vision fluctuates throughout the day; bumps into low-contrast objects.
Visual fields	Area that one sees when looking out into the environment. Central visual field (VF): central 20° where vision is clear and focused; peripheral VF: area seen other than central where vision is not as clear but used for motion detection and orientation in space.	Client complaints: bumps into objects; can't find things; difficulty reading. Effect on function: difficulty moving in crowded or busy environments; anxiety; startle response; difficulty with self-care; unsafe.
Binocular vision	Ability to resolve two images (one from each eye) into one. Motor component: muscles and nerves that align the eyes with the object. Sensory component: activity within the cortex that allows perception of one image.	Client complaints: double vision; difficulty sustaining visual work effort; eye fatigue with sustained work, eyes look crossed; blurred vision; headaches. Effect on function: poor eye contact; inability to concentrate; avoidance of activities at near distance; loss of vision; difficulty with activities requiring depth perception.
Accommodation	Ability to adjust focus of vision at different distances.	Client complaints: headaches; eye strain; difficulty with sustained activity at near distance; print moves while reading. Effect on function: under- and over-reaching; frustration when maneuvering in visually stimulating environments; road fatigue.
Ocular motility	Ability of the eyes to move smoothly and in a coordinated manner through full range of motion.	Client complaints: headaches; difficulty keeping eyes focused; dizziness; balance problems. Effect on function: excessive head movements; frequent loss of place and skipping lines when reading.
Anosognosia	Unawareness or denial of deficits.	Functional activities are unsafe; unable to learn compensatory techniques.
Unilateral neglect	Neglect of one side of the body or extrapersonal space. Types: motor (output/intentional) and perceptual (input/attentional).	Shaves only one side of face, dresses only one side of the body; eats food from only half of the plate; reads only a half of a page or half of a word; transfers and functional mobility are unsafe; bumps into objects on one side.
Body scheme	Awareness of body parts and position of body and its parts in relation to themselves and objects in the environment.	May result in dressing apraxia; may not recognize body parts or relationship between them; transfers may be unsafe.
Right/left discrimination	Ability to understand the concepts of right and left; with right brain damage (RBD), may be caused by a visuospatial deficit; with left brain damage (LBD) and aphasia, may be caused by language deficit or by general mental impairment.	May have difficulty dressing and understanding concepts of right and left.
Body part identification	Ability to identify parts on self and/or others.	May respond incorrectly when told to move a specific body part.

continued

DEFINITION 8-1 (continued)

de·fin·i·tion
Definitions and Descriptions of Vision, Visual Perception, and Praxis Deficits

Area of Deficit	Definition	Functional Description of Deficit
Position in space	Ability to understand the concepts of over and under, above and below, etc.	Difficulty moving through a crowded area; difficulty with dressing; difficulty following directions using these terms.
Spatial relations	Ability to perceive self in relation to other objects.	As above; transfers unsafe.
Topographical orientation	Ability to find one's way from one place to another.	Difficulty finding the way to a room, to therapy, or from one room to another.
Figure-ground perception	Ability to distinguish foreground from background.	Unable to find object in cluttered drawer, white washcloth on white sheet, brakes on wheelchair, food in refrigerator, etc.
Limb apraxia	Inability to carry out purposeful movement in the presence of intact sensation, movement, and coordination.	May experience difficulty with functional tasks involving objects, as client does not know how to use objects or attempts to use the incorrect object (e.g., uses knife to eat soup); difficulty with production and understanding gestures; may be clumsy and have trouble with writing, knitting, etc.
Constructional apraxia	Deficit in constructional activities: graphic and assembly; RBD: drawings are complex but exhibit disorganized spatial relations and poor orientation in space; LBD: drawings are simplified with few details.	May result in dressing apraxia; difficulty setting a table, making a dress, wrapping a gift, arranging numerical figures for mathematical processing, making a sandwich, assembling a craft project from a kit, etc.
Dressing apraxia	Inability to dress oneself.	Attempts to put clothes on inside out, backwards, or in the wrong order; dresses only one half of the body.

the most difficulty in dynamic environments. At home, we are best able to control and compensate for the deficits; community activities, such as shopping and driving, present more of a problem.

In the past, therapists often evaluated higher level visual perceptual skills without a good understanding of the optical system and how it provides the foundation for these skills (Warren, 1999). A deficit in one of the higher level visual perceptual skills, such as figure-ground or spatial relations, may be the result of a problem in one of the foundation skills. For example, clients who do poorly on a figure-ground test may have decreased visual acuity and be unable to get a clear picture of what they see or have poor convergence and therefore difficulty with any close work.

ASSESSING VISION AND VISUAL PERCEPTION

If higher level visual cognitive skills are the result of the integration of the skills that subserve them in the visual hierarchy, it seems that the therapist's limited time is best

spent evaluating the foundation skills, rather than higher level visual cognitive skills (Warren, 1993b). Evaluation includes the following:

- A basic eye history, including premorbid visual conditions (e.g., congenital strabismus, ocular trauma)
- Interviews with the client and/or family as to complaints or symptoms (e.g., difficulty concentrating, double vision, eyestrain, bumping into objects on one side)
- Observation of the client during functional activities
- Screening of the foundation skills

The therapist bases plans for further evaluation and intervention on the results and the client's goals and lifestyle. For example, if the client is 35 years old, has had a stroke, and works as a mechanic, the therapist may evaluate his constructional abilities in depth. If the client is 75 years old and retired and spends his time reading and watching television, detailed evaluation of constructional abilities may not be indicated. This idea is carried over into treatment as well. The 35-year-old mechanic will need a higher level of constructional skills than the 75-year-old retiree. In addition, the therapist may find that the client performs adequately on a test but exhibits difficulty in a

functional situation. This also indicates the need for further evaluation.

All neurologically impaired clients should have their visual foundation skills screened. Screening is also considered for older clients whose vision may have been affected by age. How in depth of a screening may depend on the team members who care for the patient. If working in a rehabilitation facility with the services of an eye care professional, the occupational therapist may only refer the patient to the eye care professional and collaborate on the findings and development of a treatment plan. On the other hand, the occupational therapist may be the only one on the team to specifically look at vision and its effects on functional activities. In this case, the occupational therapist may choose to screen all clients and, at any sign of difficulty, refer the client to an eye care professional.

Eye Care Professionals

The eye care professionals include the ophthalmologist and optometrist. The ophthalmologist is a medical doctor whose major concern is eye health (e.g., cataracts, macular degeneration, infections). Generally, “ophthalmologists are rarely trained, experienced or interested in visual system rehabilitation or function” (Gianutsos, 1997, p. 273). Optometrists receive 4 years of postgraduate training on diagnosis and treatment of eye disease, but the focus is on function and how vision affects performance and quality of life (Scheiman, 1999). Even with this focus, most optometrists specialize in refraction and contact lenses, and only a small percentage of optometrists do vision therapy (Scheiman, 1999). To find eye care professionals with a similar frame of reference, ask them questions such as these (Scheiman, 2002, p. 88):

- Do you have experience working with patients with acquired brain injury?
- Do you test accommodative amplitude and facility?
- Do you evaluate fusional vergence and facility?
- Do you evaluate visual information processing skills?
- Do you offer vision therapy as a service in your practice?

Once the decision has been made to refer the client to an eye care professional, therapists ideally go to the appointment with the client or send information such as this:

- Practical information: diagnosis, method of communication and reliability of responses, ability to transfer, and medications
- Description of functional behaviors that may indicate a problem with vision
- Visual history

If the therapist is able to attend the appointment, he or she can take notes, act as an interpreter between the client and family and the eye doctor, and interact with the doc-

tor to discuss treatment plans (Gianutsos, 1997). The therapist provides input on function and follows through with recommendations. If unable to attend the appointment, the therapist might send a form with the client for the doctor to complete, requesting information such as the following (Warren, 1999):

- Visual acuity
- Ocular motility
- Visual fields
- Pertinent ocular diagnoses
- Recommendations for follow-up and treatment

Visual Foundation Skills

The visual foundation skills include visual acuity, visual fields, and oculomotor control. Although deficits in these areas can affect function, clients may not complain of any problems, or they may make complaints that appear unrelated to vision and/or appear to be due to something else (Definition 8-1). Therefore, it is important that these areas are screened even if the client denies difficulty seeing things.

Visual Acuity

Visual acuity is the ability of the eyes to make what is seen sharp and clear. Most of us are familiar with the concept of 20/20 vision. The numerator denotes the distance at which the client recognizes the stimulus, and the denominator is the distance at which it would be recognized by someone with normal vision. For instance, a person with 20/200 vision is able to recognize a stimulus at 20 feet that a person with normal vision could recognize at 200 feet. Deficits in visual acuity may be the result of refractive errors, poor eye health with inability to process the image (e.g., cataract, macular degeneration, diabetic retinopathy), or poor transmission of the image by the optic nerve (Warren, 1999).

Visual acuity is most often screened using conventional letter charts (e.g., Snellen Chart). Test cards are available that use symbols rather than letters for use with aphasic, non-English-speaking, and severely impaired clients (e.g., Lea Symbol Test). Visual acuity should be examined in each eye for both near (16 inches or less) and far (20 feet or more) vision. Near acuity is important for any table top activity, and far vision is especially important for activities such as driving. Testing of visual acuity should be carried out with the best correction available; clients should wear their glasses. If the glasses are not available, have the client look through a pinhole in a piece of paper, as this helps the focusing power of the eye (Simon, Aminoff, & Greenberg, 1999).

Since conventional letter charts measure acuity by determining the smallest high-contrast detail a person can perceive at a given distance and most settings do not provide such high contrast, contrast sensitivity should

Figure 8-2 Contrast sensitivity test. (Reprinted with permission from Vistech Consultants, Inc., Dayton, OH.)

be evaluated as well. It indicates the person's ability to see objects in various levels of contrast and how he or she will perform functionally. The tester presents a series of sine wave gratings that vary in orientation, contrast, and frequency. The client must indicate the orientation of the grating; the poorer the acuity, the more contrast required to detect the orientation of the grating (Fig. 8-2). In addition, Warren (1996), in *Brain Injury Visual Assessment Battery for Adults* (biVABA), presents some clinical tasks and observations that can indicate a person's level of contrast sensitivity.

Visual Fields

Confrontation testing is typically used to screen for visual field deficits (Fig. 8-3). Visual fields are measured one eye

Figure 8-3 Confrontation test.

PROCEDURES FOR PRACTICE 8-1

Screening Visual Field Deficits: Confrontation Testing

Equipment

- Eye patch or patches.
- Interesting target mounted on a wand.

Set-Up

- Patient seated directly opposite examiner, approximately 20'' eye to eye.
- Background behind examiner should be dark and distraction free.

Procedure

- Patch the patient's left eye, and close or patch your own right eye.
- Instruct patient to look at your left eye, and tell him or her you will be moving a target in from the side and the patient is to indicate when the target is first seen.
- Move target in from all angles (e.g., begin at 12 o'clock, then 2, 4, 6, 8, 10).
- Compare the patient's response with yours.
- Position hands at 3 and 9 o'clock so that you can just see your fingers. Ask the patient how many fingers you are holding up.
- Patch the patient's right eye, and close or patch your own left eye. Repeat the previous 4 steps.
- A problem is indicated if the patient cannot see the target when you do or if the patient does not see both fingers simultaneously.

Adapted from Scheiman, 2002.

at a time, and the client's visual fields are compared to the examiner's supposedly normal visual fields (Procedures for Practice 8-1). The normal limits of visual field are 60° superior, 75° inferior, 60° nasal, and 100° temporal (Simon, Aminoff, & Greenberg, 1999). Confrontation testing has been found to be relatively unreliable (Trobe et al., 1981) and should therefore be used in conjunction with functional observations. Scheiman (2002) has suggested a method of confrontation testing with two examiners when possible. Warren (1999) suggests observation of the client during a dynamic functional activity, such as walking through a crowded area with moving objects, as a means of screening for visual field deficit. Warren also presents some other methods of confrontation testing as part of the biVABA (1996).

Automated perimetry provides a more accurate description and printout of the client's visual field deficit. Figure 8-4 shows the results of a client with visual field

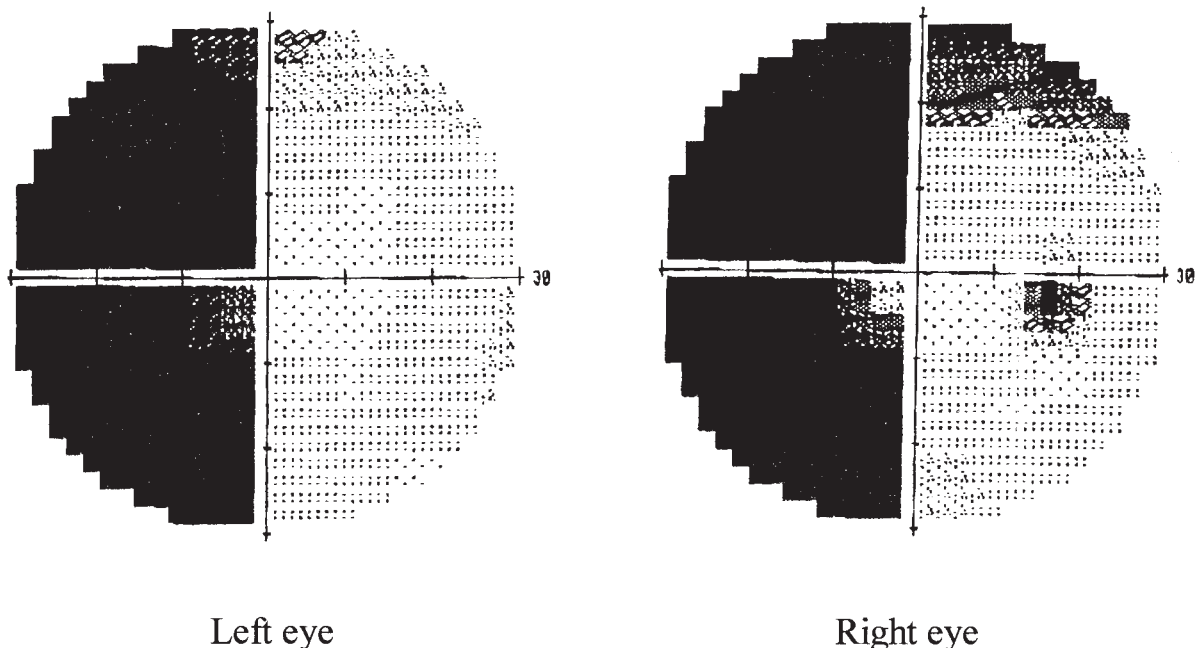

Figure 8-4 Automated perimetry results of a patient with RBD. The patient is unable to see anything in darkened areas (almost entire left visual field). There is some macular sparing on the left and a loss in the superior visual field in the right eye.

deficit. The results of the test are effectively used to teach the family and client regarding visual field losses. There are several limitations:

1. The test can require up to 20 minutes of sustained concentration if there are significant deficits, and therefore, clients unable to maintain that level of concentration cannot be accurately tested.
2. The test requires a motor response to push a button within 1–3 seconds of the presentation, which could exclude evaluation of clients with significantly delayed motor responses or motor planning deficits.
3. The equipment is expensive.

The client is generally referred to an eye care professional for perimetry testing. If the automated perimetry results are not available, the therapist can use the confrontation test along with close observation of the client during daily activities.

Oculomotor Control

Control of eye movements depends upon a complex interaction at cortical and subcortical levels. The role of the occupational therapist in screening oculomotor function is “not to diagnose the deficit, but to describe its functional effect and formulate the critical questions for the ophthalmologist or optometrist” (Warren, 1993b, p. 68). **Binocular vision** allows us to resolve two images, one from each eye, into one. It depends on good eye alignment and the ability of the eyes to converge and

adjust focus at different distances. The therapist screens binocular vision, including eye alignment and convergence, and **accommodation**, smooth pursuits, and saccades.

Eye Alignment

Eye alignment is generally measured by observation of the reflection of light on the cornea. Seated in front of the client, the therapist asks him to gaze at a penlight held in different quadrants of the visual field. The therapist observes the light reflection in each eye; the reflection should be in the same position in both eyes. Directions that the eye or eyes turn are noted (Definition 8-2). Scheiman (2002) describes a method of evaluation of alignment using phoria cards (near and far), penlight, and a red Maddox Rod. Using this method, the therapist should be able to determine the amount of strabismus present.

Convergence

Convergence is tested by having the client follow a target moving slowly toward and away from the face (Procedures for Practice 8-2). Double vision normally occurs when the target is within 2–4 inches of the face, and recovery of a single image takes place at 4–6 inches. The client may not report double vision because of suppression of vision from one eye. Therefore, it is important to observe the eyes and note when one eye drifts out during convergence and pulls back in with fusion.

DEFINITION 8-2

fixation

Eye Movement

- Accommodation: ability of the eye to adjust focus at different distances.
 - Accommodative facility: speed of response and ability to maintain response over time.
 - Accommodative amplitude: amount of accommodation available (decreases with age).
- Convergence: ability to maintain focus as an object moves toward you.
 - Convergence insufficiency: unable to focus on a “near” object due to an exophoria at near distance.
- Diplopia: double vision.
- Phoria: tendency for the eyes to turn that is controlled with muscular effort.
 - Esophoria: tendency for the eye to turn inward.
 - Exophoria: tendency for the eye to turn outward.
 - Hyperphoria: tendency for the eye to turn upward.
 - Hypophoria: tendency for the eye to turn downward.
- Presbyopia: age-related loss of accommodation.
- Saccades: quick eye movements that change the fixation from one point to another and allow us to redirect our line of sight.
- Smooth pursuits: those eye movements that maintain continued fixation on a moving target.
- Stereopsis: depth perception; visual perception of three-dimensional space.
- Strabismus: misalignment of the eyes.
- Suppression: visual information from one eye is ignored (usually when there is a discrepancy between the two eyes).
- Tropia: synonym for strabismus.
 - Esotropia: strabismus in which the eye turns inward.
 - Exotropia: strabismus in which the eye turns outward.
 - Hypertropia: strabismus in which the eye turns upward.
 - Hypotropia: strabismus in which the eye turns downward.

Accommodation

Accommodation is the ability to adjust the focus of vision at a range of distances, such as the automatic focusing of the eyes when you look up from the speedometer to the road while driving. It decreases with age. Presbyopia, a condition of decreased near vision secondary to decreased accommodative ability, sets in at around 40–45 years of age. Information regarding the client’s

PROCEDURES FOR PRACTICE 8-2

Screening: Convergence

Equipment

- Penlight or target.
- Ruler

Set-Up

- Patient seated directly opposite the therapist.
- Patient’s head should be vertically erect.

Procedure

- Slowly move the penlight or target toward patient at eye level (do not shine light directly into the patient’s eyes; direct it at the brow slightly above eye level).
- Ask patient to keep eyes on the light and to report when two lights are seen. Note the distance at which diplopia occurs.
- Once two lights are seen, move the target in another inch or so and begin to move it away from the patient.
- Ask patient to let you know when he or she can see one light again. Note the distance at which the patient reports single vision.

Adapted from Scheiman, 2002.

accommodative ability is typically picked up by observing and listening to the client’s complaints. If the client is over 40–45 years old, expect accommodation to be decreased. With younger clients, Scheiman (2002) presents a method for the occupational therapist to determine their accommodation.

Visual Tracking

Visual tracking (smooth pursuits) are eye movements that maintain continued fixation on a moving target. Smooth pursuits, which are influenced by age, attention, and motivation, play a significant role in activities entailing movement of either the person or the object of regard (e.g., driving, playing sports). If smooth pursuits are impaired, acuity is impaired when motion is involved (Haarmeier & Thier, 1999). Smooth pursuits are usually evaluated by asking the client to track a moving object (Procedures for Practice 8-3). Warren (1999) suggests using a penlight in a slightly darkened room. Scheiman (2002) presents a method of scoring in which performance is scored on: (1) ability to complete two rotations in both directions; (2) accuracy (number of refixations required); and (3) head and body movement during the test.

PROCEDURES FOR PRACTICE 8-3

Screening: Smooth Pursuits and Visual Tracking

Equipment

- Small, interesting target.

Set-Up

- Patient seated directly in front of the examiner.
- Hold target approximately 16 inches from the patient's face.

Procedure

- Give no instructions regarding head movement.
- Tell patient, "Watch the target and don't take your eyes off it."
- Move target clockwise for two rotations and counter-clockwise for two rotations.
- Observe:
 - Number of rotations the patient is able to complete.
 - Ability to maintain fixation, that is, the number of times the patient has to refixate.
 - Movement of the head or body.

Adapted from Scheiman, 2002.

PROCEDURES FOR PRACTICE 8-4

Screening: Saccades

Equipment

- Two interesting targets (e.g., two tongue depressors, one with a green circle on the end and the other with a red circle on the end).

Set-Up

- Patient seated directly in front of the examiner.

Procedure

- Hold wands approximately 16 inches from the face, separated by approximately 8 inches.
- Give no instructions regarding head movement.
- Tell patient, "Look at the red dot when I say red. Look at the green dot when I say green, and remember to wait until I say to look."
- Tell patient to look from one target to the other for a total of 10 fixations, 5 round trips.
- Observe:
 - Ability to complete 5 round trips.
 - Accuracy of eye movements (overshooting or undershooting target).
 - Movement of the head or body.

Adapted from Scheiman, 2002.

Saccades

Saccades are quick eye movements that change fixation from one point to another and allow us to redirect our line of sight. These eye movements are more closely related to reading and close work and may appear more problematic following brain injury (Gianutsos, 1997). Saccades are tested by holding up two targets and asking the client to keep looking from one target to another (Procedures for Practice 8-4). Performance of saccades is scored on: (1) ability to complete five round trips; (2) accuracy (amount of over- and undershooting); and (3) head and body movement during the test (Scheiman, 2002).

Considerations for the Minimally Responsive Patient

Because visual testing requires attention and cooperation, it is often put off until clients have recovered and their neurological systems have settled down. It is imperative that we begin to look at the visual system as early as possible. How much better may clients do in therapy if corrective action is taken early in their stay? Whyte and DiPasquale (1995) present a method of assessing vision in minimally responsive clients (Procedures for Practice 8-5). The evaluation takes only a short time to administer

and can be given frequently by various team members to provide a pattern of responses that are "more interpretable than clinician's unstructured observations" (Whyte and DiPasquale, 1995, p. 810). The relationship between side, stimulus, and frequency of eye movements is analyzed: (1) total number of eye movements in each direction (unequal distribution of eye movements suggests gaze preference, asymmetric visual fields, or visual attention deficit); (2) frequency of eye movement to stimulus side (contingent orienting); (3) difference in orienting to photos versus cards (as evidence of visual perception); and (4) comparison of bilateral to unilateral presentations. The authors found that they were able to identify hemifield deficits, extinction, and monocular pathology with this method (Whyte & DiPasquale, 1995).

Unilateral Neglect

Visual attention allows us to determine the what (object identification) and where (orientation in space) of things in our environment (Warren, 1999). Visual attention is influenced by general alertness, both nonspatial and spatial. It is evaluated through scanning tasks because a change in

PROCEDURES FOR PRACTICE 8-5

Assessment of Vision in Minimally Responsive Patients

Equipment

- Six brightly colored snapshots from patient’s family.
- Plain white card, same size as photos.
- Eye patch as needed.

Set-Up

- Examiner stands 6 feet in front of patient, at patient’s visual midline.
- Use eye patch for patients with dysconjugate gaze.

Procedure

- Pictures are presented at ear level, 30–40° lateral to midline.
- May give alerting stimulation prior to presentation as needed.
- Pictures are present in 6 combinations (order can be varied from session to session):

Left Field	Right Field
Photo	—
—	Photo
Card	—
—	Card
Photo	Card
Card	Photo

- Record the direction of the first lateral eye movement for each presentation. Record “no response” if there is no movement in 5 seconds.

Adapted from Whyte & DiPasquale, 1995.

visual attention is manifested as a change in visual search (Warren, 1999). Visual attention can be influenced by the perceptual load, whether it be visual, tactile, or auditory (Matingley et al., 1997; Robertson et al., 1997).

Unilateral neglect, a constellation of symptoms affecting both perceptual and exploratory behavior, has variously been called unilateral neglect, hemispacial neglect, and hemi-inattention. It is a heterogeneous condition that includes both behavioral components and related disorders (Table 8-1). Unilateral neglect manifests as a failure to respond or orient to stimuli presented contralateral to a brain lesion (Heilman, Watson, & Valenstein, 1993). It is observed functionally in the client who eats the food on only half of

the plate, shaves only one side of his face, and so on. It is most commonly caused by a lesion in the right hemisphere; it does occur following left brain damage (LBD), although the deficit is usually not as severe as for right brain damage (RBD) (Heilman, Watson, & Valenstein, 1997; Mennemeier et al., 1997; Stone, Halligan, & Greenwood, 1993).

The incidence of neglect varies widely in the literature. This is most likely because of a lack of a common definition, differences among tests used to evaluate neglect, and/or laterality of motor response (Mercier, Hebert, & Gauthier, 1995; Maeshima et al., 2001).

Although it is generally agreed that neglect is related to a deficit in attention, just how this happens is still under discussion. Kinsbourne (1993) proposes a model in which attention to right and left space is controlled by the contralateral hemisphere. When one hemisphere is damaged, the other becomes disinhibited and biases attention toward the contralateral side. Another view focuses on the hyporesponsiveness of the damaged hemisphere (Heilman & Watson, 1977). Posner and Rafal (1987) suggest that the problem is an inability to disengage attention from objects in ipsilateral space.

Visual field deficits and unilateral neglect frequently occur together and are difficult to separate. Warren (1999) suggests that it is possible to differentiate the two by observing how clients organize their search patterns during a scanning task (Table 8-2). A client who exhibits the behaviors listed for visual field deficit probably has no more than mild neglect, whereas if he or she demonstrates the neglect behaviors, you cannot assume that there are no field cuts.

Table 8-1. Unilateral Neglect Syndrome

Main Behavioral Components:

- Hemi-inattention: inability to orient to or respond to stimuli from one side of the environment, irrespective of the modality.
- Hemispacial visual neglect: inability to orient to relevant contralateral visual stimuli.
- Extinction: failure to report a contralesional stimulus when it occurs simultaneously with a more ipsilateral stimulus, even though able to do so if either is presented alone.
- Allesthesia: consistently attributing sensory stimuli on one side of the body to the other side, or moving limbs on one side when requested to move the limb on the other side.
- Hemiakinesia: motor neglect.

Related Disorders:

- Anosognosia: lack of awareness or denial of hemiparesis.
- Gaze paresis.
- Visual field deficit.

Adapted from Stone, Halligan, & Greenwood, 1993; Stone et al., 1998.

Table 8-2. Scanning: Visual Field Deficit Versus Unilateral Neglect

Visual Field Deficit	Unilateral Neglect
Abbreviated scanning pattern	Disorganized, random scanning pattern
Scanning pattern is organized	Asymmetrical search pattern in hemispace
Re-scanning is observed	Scanning pattern is carried out with reduced effort and little or no re-scanning
Length of time/effort are appropriate for the task	Task is completed swiftly, or if patient is aware of deficit, will take an inordinate amount of time in an attempt to compensate

Adapted from Warren, 1999.

Sensory Neglect

Two major subtypes of unilateral neglect have been described: sensory (input or attentional) and motor (output or intentional) (Bisiach et al., 1990; Coslett et al., 1990; Tegner & Levander, 1991). Sensory neglect can include awareness of all stimuli on one side of the space (spatial neglect) or be confined to one side of the body (personal neglect) (Heilman, Watson, & Valenstein, 1997). It may be evident in any of the modalities, including auditory, tactile, and visual. Historically, neglect has generally been referred to in the horizontal (right-left) dimension, although some research has been done on neglect in the vertical and radial (near and far space) dimensions (Cowey, Small, & Ellis, 1994; Kageyama et al., 1994; Ladavas, Carletti, & Gori, 1994). Neglect of visual imagery (e.g., mental images of familiar places, spelling, drawing from memory) has been termed representational neglect (Beschin et al., 1997).

Evaluating neglect can be confusing because the client can exhibit neglect in one situation but not in another (Halligan & Marshall, 1998; Riddoch & Humphreys, 1994). Neglect can vary as follows:

- **Locus of lesion:** The inferior and posterior parietal cortex are critical for monitoring and directing attention in the visual environment; anterior and frontal lesions result in difficulty executing movement in or toward the side contralateral to the lesion.
- **Task:** For example, verbal tasks versus spatial tasks; complexity and perceptual load of the task (e.g., one object vs. several objects).
- **Mode of response:** Verbal versus contralateral extremity versus ipsilateral extremity.
- **Modality:** Visual, auditory, tactile.

Unilateral neglect has traditionally been evaluated in a variety of ways, largely with paper and pencil tasks, including drawing tasks, cancellation tasks, line bisection, and reading (Chatterjee & Mennemeier, 1997).

Drawing and Copying Tasks

Drawing and copying tasks, although easy to give, are subjective in their scoring. In all such tasks, the therapist

looks for omissions and errors concentrated to one side (Fig. 8-5). The therapist also observes how the client approaches the task, variations between copying and free drawing, and missing elements on one side of the picture or on one side of objects within the picture. These tasks can alert you to a moderate or severe neglect but should be used in conjunction with other tests of neglect and functional activities to provide a clear picture of mild neglect.

Cancellation Tasks

Another common evaluation method is cancellation tasks. These tests are easy to administer and score and are sensitive to neglect (Sea, Henderson, & Cermak, 1993; Stam & Bakker, 1990; Ferber & Karnath, 2001; Maeshima

Figure 8-5 Drawings by patients with RBD and unilateral neglect.

et al., 2001). The client is presented with a sheet of paper with several lines of letters or shapes and is asked to mark a specific stimulus letter or shape that is scattered randomly throughout the page. Cancellation tasks can be varied in many ways, including overall density, whether the display is organized or random, density of stimuli in ipsilateral space, complexity of stimuli in ipsilateral space, and amount of similarity between the target and distracters (Dawson & Tanner-Cohen, 1997; Heilman, Watson, & Valenstein, 1997; Kartsounis & Findley, 1994). The score is usually based on the number of omissions (targets not marked) and commissions (cancellations of items other than the target) as well as where on the page the errors are made. Because of these many variations, it is important that various tasks, as part of a neglect battery, should be used to fully detect neglect (Maeshima et al., 2001).

Line Bisection

Line bisection, another traditional test, requires the client to divide a line or lines in the center (Schenkenberg, Bradford, & Ajax, 1980). The therapist will note the direction and amount of deviation from center. The following factors can increase the percentage of error on line bisection tests: longer line, line placement in contralesional space, and cues placed on the ipsilateral end of the line (Heilman, Watson, & Valenstein, 1997). Ferber and Karnath (2001) compared line bisection tests with cancellation tests and found that cancellation tests were better able to detect spatial neglect than line bisection. They felt that line bisection could be influenced by such things as presence of a visual field deficit or what hand was used.

Functional Tests

Appelros et al. (2003) stress the “importance of not relying completely on test instruments when diagnosing unilateral neglect” (p. 478). As a result, there has been an emphasis on evaluation of unilateral neglect during functional activities (Assessment Table 8-1). The occupational therapist is in a position to observe the client in a variety of daily activities that can provide vital information for the team. A client is likely to perform differently in a quiet test room than in an everyday situation, such as dressing or preparing a simple meal.

Motor neglect

Motor neglect presents as impaired initiation or execution of movement into contralateral hemispace by either limb (Bisiach et al., 1990; Tegner & Levander, 1991). Heilman, Watson, and Valenstein (1997) describe several types of motor neglect (Definition 8-3). It is often difficult to differentiate between sensory and motor neglect because tests of motor neglect entail some form of sensory input. Consequently, the therapists wonder whether clients fail to

DEFINITION 8-3

definition

Motor Neglect

- Limb akinesia—failure to move limb.
- Hypokinesia—limb moves but only after a long delay and much encouragement.
- Hypometria—movements are of decreased amplitude.
- Impersistence—inability to maintain a movement or posture.
- Motor perseveration—inability to disengage from a motor activity.
- Motor extinction—delay or failure to move the contralesional limb when also required to move the ipsilateral limb.

Adapted from Heilman, Watson, & Valenstein, 1997.

respond to a stimulus on the involved side because they don't see it or because they cannot initiate movement toward it. If motor neglect is suspected, one way to distinguish between the two entails contrasting a task that requires a hand response with one that has minimal motor response (e.g., naming letters on the involved side as opposed to pointing to the same letters). In other words, the stimulus (letters on the involved side) stays the same, and the motor response is varied (Riddoch & Humphreys, 1994).

Although there are no standardized tests of motor neglect (Appelros et al., 2003), observations of clients and how they use the extremity can provide insight into the presence of motor neglect. One may note reluctance to move the arm and movement only after a delay (hypokinesia) or movement only with strong encouragement (akinesia), a tendency to undershoot a target when asked to move along a given line (hypometria), or inability to sustain a posture (impersistence) (Heilman, Watson, & Valenstein, 1997). Different limbs can be observed, as can the direction of the movement required (ipsilateral vs. contralateral) and the hemispace in which the movement is to occur (ipsilateral vs. contralateral).

ASSESSING PRAXIS

People rapidly conceive of and plan motor acts in response to the environment (Crepeau, 1998). This innate capacity is referred to as praxis. **Apraxia** is the inability to carry out skilled movement in the presence of intact sensation, movement, and coordination (Heilman & Rothi, 1993). Apraxia is generally seen in patients with LBD (Goodglass & Kaplan, 1972; Haaland, Harrington, & Yeo, 1987; Poeck,

Assessment Table 8-1

Summary of Functional Assessments for Unilateral Neglect

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Catherine Bergego Scale (CBS)</i> (Azouvi et al., 1996; Azouvi et al., 2002; Azouvi et al., 2003)</p>	<p>10 items from everyday life situations (e.g., grooming left side of face, collisions with people or objects on the left). Unilateral neglect scored on 4-point scale: 0 = no neglect observed; 3 = severe neglect; client only able to access right hemisphere.</p>	<p>Unknown, but would be observed during the occupational therapist's evaluation of ADLs.</p>	<p>Internal consistency: Rho ranged from 0.58–0.88. CBS score correlated significantly with performance on 5 paper and pencil tests (Rho = 0.50–0.74). Significant correlation between CBS and <i>Barthel Index</i> (Rho = -0.63)</p>	<p>Inter-rater reliability: K ranged from 0.59–0.99 (Rho = 0.96).</p>	<p>Authors found it more sensitive than conventional paper and pencil tests.</p>	<p>Strengths: It is a direct observation of a client's function during everyday activities and provides the client with insight into their deficits. Weaknesses: Training recommended for inexperienced therapists unfamiliar with unilateral neglect. Difficulty differentiating sensory and motor neglect.</p>
<p><i>Wheelchair Collision Test (WCT)</i> (Qiang et al., 2005)</p>	<p>Patient propels a wheelchair around 4 chairs arranged in 2 rows placed at 2 different distances apart (120 cm and 140 cm). Patient collisions with chairs are considered abnormal.</p>	<p>10 minutes.</p>	<p>Relationship between number of collisions and CBS total score: $r = 0.72$ at 120 cm and $r = 0.75$ at 140 cm.</p>	<p>Test-retest reliability = 0.68–0.97.</p>	<p>Not established.</p>	<p>Strengths: Easy to set-up and score in clinic setting; short time to complete. Weaknesses: Small number of subjects (19); no scoring range given; possible learning effect; only looked at one aspect of neglect; did not address RBD.</p>

<p><i>Baking Tray Task</i> (Tham & Tegner, 1996)</p>	<p>Patient is asked to spread out 16 'buns' on a 'baking tray.' The number of cubes in each half field are counted. Distribution of cubes skewed greater than 7 on one side and 9 on the other is considered abnormal.</p>	<p>Task is not timed.</p>	<p>Did not significantly correlate with conventional neglect tests (e.g., line cancellation, line bisection, drawing).</p>	<p>Not established.</p>	<p>Relative sensitivity for visual spatial neglect is 66.7% (Bailey, Riddoch, & Crome, 2000).</p>	<p>Strengths: Short and easy to present and evaluate. Weaknesses: Addresses one area of neglect only; doesn't correlate with other tests of neglect; task is somewhat gender specific.</p>
<p><i>Comb & Razor/ Compact Test</i> (Beschlin & Robertson, 1997)</p>	<p>Patient is asked to comb the hair and shave (males) or use a compact (females) for 30 seconds. The number of strokes and where they occurred (right, left, and ambiguous) are counted. Score is determined by dividing the number of strokes on the left by the total of all strokes. A score of <0.35 indicates neglect.</p>	<p>30 seconds for each of 2 tasks plus set-up and explanation.</p>	<p>Significant difference between 4 groups of experimental subjects (F = 18.0; d.f. = 3,57; $p < 0.0001$).</p>	<p>Test-retest: $r = 0.94$.</p>	<p>Not established.</p>	<p>Strength: Short, simple test of personal neglect. Weakness: Must be combined with tests of extrapersonal neglect for clear picture of neglect.</p>
<p><i>Behavioral Inattention Test (BIT)</i> (Wilson, Cockburn, & Halligan, 1987)</p>	<p>15-item standardized test battery: 6 pen and paper tests and 9 behavioral tasks. Cut-off scores are used to indicate neglect.</p>	<p>Approximately 30 minutes.</p>	<p>Correlation between BIT and <i>Barthel Index</i>: $r = 0.642$ (Cassidy et al., 1999); correlation between BIT behavior subtests and items on an ADL checklist: $r = 0.77$ (Hartman-Maeir & Katz, 1995).</p>	<p>Test-retest: $r = 0.99$; inter-rater reliability: $r = 0.99$.</p>	<p>Behavioral subtests were found to differ between groups: neglect and no neglect (Hartman-Maeir & Katz, 1995).</p>	<p>Strength: Includes functional as well as conventional tests. Weaknesses: Two subtests (map navigation and picture scanning) were found to not correlate with a functional ADL activity (Hartman-Maeir & Katz, 1995); measures neglect in peripersonal space only and cannot distinguish between sensory and motor neglect.</p>

1985). These patients generally can spontaneously use the extremity in such everyday tasks as eating, shaving, or opening a door, but if they are asked to pantomime an activity or carry out a series of steps, their performance is not correctly or smoothly executed.

Research has shown that LBD patients are clumsy, with more dexterity errors than normal controls (Sunderland et al., 1999). When meal-time eating behavior of apraxic patients was compared to that of normal subjects, the patients were found to be less efficient, be less well organized when sequencing activities, and produce more action errors (Foundas et al., 1995). These findings suggest that limb apraxia can affect activities of daily living. How it impacts a particular client depends upon his or her goals and lifestyle. For instance, if the client is aphasic as well, understanding and production of gestures is an impor-

tant part of communication with others, and apraxia may need to be considered more closely.

There are five types of apraxia: verbal, buccofacial, limb, constructional, and dressing. The first two, which are usually evaluated by a speech and language pathologist, are not discussed in this chapter.

Limb Apraxia

Limb apraxia is usually associated with LBD in right-handed patients and RBD in left-handed patients (Heilman, Rothi, & Watson, 1997), although variations have been described (Marchetti & Della Sala, 1997). According to Heilman, Rothi, & Watson (1997), there are six types of limb apraxia: limb kinetic, ideomotor,

Table 8-3. Types of Limb Apraxia

Type of Apraxia	Error Type	How Elicited	Functional Example
Ideomotor	Production errors	Most errors are made on pantomiming transitive tasks; improves with imitation and usually does best with the actual object.	Movements will be awkward but will bear a resemblance to the intended movement. Able to use tools to complete tasks but may appear clumsy or awkward.
Conceptual	Content errors: <ul style="list-style-type: none"> • Tool-action knowledge • Tool-association knowledge • Mechanical knowledge • Tool fabrication 	Use of tools; actions associated with specific tools, association between tool and object.	Patient has obvious difficulty with tool use: may use a tube of toothpaste to brush teeth, comb hair with fork, etc.
Disassociation	Thought to be a disconnection between hemispheres; therefore, there is no recognizable movement on command.	Pantomime to command is impaired; imitation and use of object will be much better.	Unable to pantomime movements, but since able to imitate and use tools, minimal effect on functional activities.
Conduction	Difficulty decoding and understanding gestures.	Impaired imitation of gestures; does better when asked to pantomime.	A client with aphasia might have difficulty understanding and using gestures.
Ideational	Difficulty with a series of tasks.	Tasks requiring a series of activities (e.g., clean pipe, put in tobacco, and light pipe).	Task may be completed more skillfully than with ideomotor apraxia, but client will have difficulty sequencing steps in the correct order (e.g., client might try to light the empty pipe, then put the tobacco in, then clean it).

Adapted from Heilman, Watson, & Rothi, 1997.

ideational, dissociation, conduction, and conceptual (Table 8-3). Limb kinetic apraxia is characterized by a loss of ability to make finely graded precise finger movements and is thought to be a motor problem rather than a true apraxia (Heilman, Watson, & Rothi, 1997).

Testing has traditionally consisted of gesture production. The client is asked to pantomime a task on command (e.g., “Show me how you comb your hair”), to imitate the tester, or to use an object. These assessments require various types of gestures, including transitive gestures that entail object use (e.g., “Show me how a man shaves”), intransitive gestures that are meant to express ideas or feelings (e.g., “Show me how you wave goodbye”), meaningless or non-symbolic gestures (e.g., “Put your hand under your chin”), proximal gestures (e.g., “Show me how you bounce a ball”), and distal gestures (e.g., “Show me how you would use a telegraph key”). Transitive gestures are especially sensitive to apraxia (Haaland, 1993). Generally, clients with apraxia would have least difficulty with proximal intransitive gestures away

from the body (e.g., waving goodbye) and most difficulty with distal transitive gestures on the body (e.g., putting on makeup) (Haaland, 1993; Helm-Estabrooks & Albert, 1991). In the last decade, gesture comprehension and discrimination have been added to the list of apraxia testing methods (Heilman & Rothi, 1993; York & Cermak, 1995; Joseph, 1996; Heilman, Watson, & Rothi, 1997) (Table 8-4).

Apraxia often occurs in conjunction with aphasia, and it is sometimes difficult to distinguish between the two. Therefore, it is important when evaluating a client with aphasia to include (besides the regular commands, e.g., “show me how you would . . .”) questions that can be answered by yes/no responses and by pointing at the correct answers (Heilman & Rothi, 1993). If the client performs poorly but can answer yes/no questions, he or she may be apraxic. Similarly, if the client is unable to respond to yes/no questions, failure to make the appropriate movement to command may be due to a language problem rather than apraxia. If the client has only a mild language deficit but uses a body part as object or makes a

Method	Example
Gesture to command: Should include both transitive movements (tool use) and intransitive movements (nonverbal communication).	Transitive: “Show me how you would open the door with a key, use a hammer.” Intransitive: “Show me how you hitchhike, salute, wave good-bye.”
Gesture to imitation	Examiner produces a gesture and asks the client to “do it the same way I do it; don’t name the gesture and don’t start until I’m finished”; can be familiar gestures or nonsense gestures (e.g., hand to the forehead).
Gesture in response to tool	Visual: Examiner shows the tool and says, “Show me how you use this.” Tactile: With eyes closed or covered, client examines the tool by hand and examiner says, “Show me how you use this.”
Gesture in response to seeing object on which the tool acts: tool selection task	Examiner presents client with object representing an incomplete action (e.g., if the target is sawing, client is shown a partially cut piece of wood); client must choose the correct tool from a choice of three, one of which is the saw.
Actual tool use	Patient is given a tool (e.g., hammer) and asked, “Show me how you use this.”
Gesture decision: discrimination between correctly and incorrectly pantomimed movements	Examiner makes a gesture and asks the client, “Is this the correct way to . . .” (e.g., use a pair of scissors).
Gesture comprehension	Examiner makes a gesture and asks the client, “Tell me what I am doing.” “What tool am I using?” “Am I using a hammer or a saw?”
Serial acts	Examiner tells client, “Fold letter, put it in an envelope, seal envelope, and place stamp on it.”

Adapted from Heilman & Rothi, 1993; Rothi, Raymer, & Heilman, 1997.

Table 8-5. Sample Items from the *Florida Apraxia Screening Test—Revised*

Show me:

How you salute.

How to use a saw to cut a piece of wood out in front of you.

How you hitchhike.

Stop.

How to use a salt shaker to salt food on a table out in front of you.

How to use a spoon to stir coffee on a table out in front of you.

Rothi, Raymer, & Heilman, 1997.

clumsy but recognizable response, it is probably due to apraxia rather than language. When assessing people with severe aphasia, provide a model for the client to imitate or place the object out of reach and ask the client to pantomime its use. Use the tactile modality in testing by having the client handle the object while blindfolded and then show how it is used.

There are few standardized tests available for limb apraxia. Rothi and her colleagues have developed the *Florida Apraxia Screening Test—Revised (FAST-R)* for use in the research of neurologically impaired patients (Rothi, Raymer, & Heilman, 1997). This test consists of 30 items that are presented verbally (Table 8-5). The patient uses the dominant arm if possible. Prior to testing, patients practice pantomiming such that they pretend they hold the imagined tool and act on the imagined object. This rehearsal is important to discourage use of a body part as the imagined tool itself. Normal subjects may use a body part as tool, but with instruction, they correct their performance, whereas apraxic patients continue to do so even with the instruction (Raymer et al., 1997). Scoring for the *FAST-R* includes multiple error types based on content of the pantomime, timing and sequencing of the response, and spatial features (Table 8-6).

Tests of apraxia described in the literature all rely on observer judgment of errors made during movement performance (Assessment Table 8-2). Some researchers suggest more than one observer or even videotaping the response during testing. Butler (2002) advises to not rely on one test of apraxia, but rather to consider functional indices in ADL tasks as more clinically relevant. van Heugten et al. (1999b) developed an assessment of disability in stroke patients with

apraxia that looks at an independence measure and three aspects (initiation, execution, and control) of four activities (personal hygiene, dressing, preparing food, and another activity that is chosen by the therapist). This allows the therapist to determine in what area the person is having difficulty and better focus treatment.

Constructional Apraxia

Constructional apraxia is a specific deficit in spatial-organizational performance (Benton & Tranel, 1993). Patients with constructional apraxia have difficulty with copying, drawing, and constructing designs in two and three dimensions. Constructional apraxia has been found to correlate with deficits of activities of daily living (Baum & Hall, 1981; Neistadt, 1993; Warren, 1981). It can be seen functionally as difficulty with such activities as setting a table, making a sandwich, and making a dress and with any mechanical activity in which parts are to be combined into a whole.

Constructional apraxia can be found in both RBD and LBD patients. Because of qualitative differences noted in the performance of RBD and LBD patients (Definition 8-1), constructional apraxia in RBD is believed to be the result of visuospatial deficits, while that in LBD is thought to be caused by an executive or conceptual disorder (Benton, 1967; Piercy, Hecaen, & Ajuriaguerra, 1960). Constructional apraxia has often been found to be more frequent and more severe in RBD patients (Arrigoni & DeRenzi, 1964; Benton & Fogel, 1962; Piercy, Hecaen, & Ajuriaguerra, 1960; Warrington, James, & Kinsbourne, 1966).

There are two types of constructional activities used in assessment: graphic tasks (e.g., copying line drawings and drawing to command) and assembly tasks (e.g., block and stick designs). Both types are included in an evaluation of constructional apraxia. The most common example of a graphic task is copying geometric shapes (from simple to complex) and drawing without a model (e.g., house, clock, flower). It is best to use a simple task (e.g., simple geometric figures, three-dimensional block design) because a more complex task involves a greater number of skills and becomes less specific (DeRenzi, 1997).

Goodglass and Kaplan (1972) describe the test of drawing to command. This test includes having the client draw a clock, daisy, elephant, cross, cube, and house; scoring criteria are given in Table 8-7.

Assembly tasks include such activities as stick arrangement and three-dimensional block designs. Common errors on stick arrangement include selecting sticks of incorrect length; failing to reproduce parts of

Table 8-6. Apraxia Error Types

Error Type	Description
Content Errors	
Perseveration	Patient's response includes all or part of a previously produced pantomime.
Related	Pantomime is correctly produced but only related to the action requested (e.g., playing the trombone instead of playing a bugle).
Nonrelated	Pantomime is accurately produced but unrelated to request (e.g., playing the trombone for shaving).
Hand	Performs the action without use of a real or imagined tool (e.g., turning a screw with the fingers rather than an imaginary screwdriver).
Temporal	
Sequencing	Addition, deletion, or transposition of the movement elements of a sequence.
Timing	Any alteration in the timing or speed of a pantomime: abnormally increased, decreased, or irregular rate of production.
Occurrence	Any multiplication of characteristically single-cycle movements (e.g., unlocking a door) or reduction of a characteristically repetitive cycle (e.g., screwing in a screw) to a single event.
Spatial	
Amplitude	Any increase, decrease, or irregularity of the characteristic movement.
Internal Configuration	Any abnormality of the required finger/hand posture and its relationship to the target tool (e.g., when pretending to brush the teeth, the hand may be closed tightly into a fist with no space allowed for the imagined toothbrush handle).
Body Part as Tool	Patient uses finger, hand, or arm as the imagined tool, even when requested to pretend he or she is holding the object (e.g., uses the finger to brush the teeth).
External Configuration	Difficulties orienting the fingers/hand/arm to the object or in placing the object in space (e.g., brushing teeth with the hand so close to the mouth as to not allow room for the imagined toothbrush).
Movement	Any disturbance of the characteristic movement used when acting on an object (e.g., movement at incorrect joint; when pantomiming a screwdriver and rotation occurs at the shoulder rather than at the forearm).
Other	
Concretization	Patient performs pantomime not on an imagined object but, instead, on a real object not normally used in the task (e.g., instead of pretending to saw wood, they pantomime sawing on their leg).
No Response	
Unrecognizable	Response shares no temporal or spatial features of the target; it is unrecognizable.

Adapted from Rothi, Raymer, & Heilman, 1997.

the model, especially lateral; making lines more oblique than the model indicates; tending to remove part of the model to make the copy; and crowding in (the client's copy rests on top of or touches the model) (Critchley, 1966). Assembly tasks can be varied in numerous ways. For example, constructing from memory may be more difficult than copying from a model (representational or actual). Patients may be asked to choose the correct pieces from a large number of blocks and sticks versus providing them with the correct number and type of blocks and sticks, which would structure the task and make it simpler.

In general, these tasks are not standardized and rely on subjective judgment of the results. It is important to note the client's method of completing the task; the client's comments; any emotional display, hesitancy, indecision, and change of mind; and the type of errors made.

The *Lowenstein Occupational Therapy Cognitive Assessment (LOTCA)* battery was standardized on brain-injured adults and contains a section on visuomotor organization (Katz et al., 1989). This section contains block design, copying, drawing, and pegboard design (see Assessment Table 9.1 in Chapter 9).

Assessment Table 8-2

Summary of Assessments for Apraxia

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Florida Apraxia Screening Test—Revised (FAST-R)</i> (Rothi, Raymer, & Heilman, 1997)</p>	<p>30-item, gesture to verbal command test: 20 transitive and 10 intransitive pantomime items; scored on multiple error types. Normal cut-off score is 15 out of 30 correct.</p>	<p>Unknown; includes time to train and practice pantomime and then to complete a 30-item test.</p>	<p>Not established.</p>	<p>Not established. Recommend that the responses are videotaped for later scoring.</p>	<p>Not established.</p>	<p>Strength: Can be completed with one hand only. Weaknesses: Coexisting aphasia can be a problem due to verbal presentation. Relates to limb apraxia only. Scoring can be difficult and requires too much time for clinic use. No psychometric characteristics established.</p>
<p>Screening for Apraxia (Almeida, Black, & Roy, 2002)</p>	<p>5 gestures (3 transitive, 2 intransitive); 5 dimensions for each task are scored on a 3-point scale (see Roy et al., 1998 for scoring).</p>	<p>Authors feel that this can be used to detect apraxia and then decision can be made to follow-up with a more comprehensive assessment battery.</p>	<p>Not established.</p>	<p>Not established on screen; kappa coefficient for inter-rater reliability ranged from 0.71–0.78 on the full battery (Roy et al., 1998).</p>	<p>Not established.</p>	<p>Strength: Short 5-item screening test. Weakness: Scoring is unclear and requires knowledge and practice on the part of the examiner.</p>

<p>Assessment of Apraxia (van Heugten et al., 1999a)</p>	<p>2 subtests: demonstration of object use (3 sets of objects presented under 3 different conditions) and imitation of gestures (6 gestures to be imitated). Each is scored from 0 (movement not recognizable) to 3 (performance is correct and appropriate). Maximum subscore is 54 for object use and 36 for imitation of gestures, with a total score of 90. Total score below 86 is considered to identify apraxia.</p>	<p>Unknown.</p>	<p>Not established.</p>	<p>Internal consistency good (Cronbach's alpha = 0.96; Mokken coefficient of reliability, Rho = 0.96); interrater reliability kappa > 0.60 on all but 3 items (Zwinkels et al., 2004).</p>	<p>At cut-off score of 86 (mean score – one standard deviation), sensitivity was 91%.</p>	<p>Strength: Uses common gestures and objects. Weakness: Includes items for ideational and ideomotor apraxia only.</p>
<p>Assessment of Disabilities in Stroke Patients with Apraxia (van Heugten et al., 1999b)</p>	<p>Set of standard ADL observations for assessment of disabilities due to apraxia: personal hygiene, dressing, preparing food, and another of the therapist's choice. Scoring: 4 measures (independence, initiation, execution, and control) scored from 0 (no observable problems) to 3 (therapist has to take over). Then these scores can be added together to get a total score.</p>	<p>Unknown, but could easily be observed during the occupational therapist's evaluation of ADL.</p>	<p>Not established.</p>	<p>Coefficient of reliability, Rho = 0.94. Interrater reliability: kappa value highest for independence scores (0.81–0.97), increased variability on aspect (initiation, execution, control) scores.</p>	<p>Not established.</p>	<p>Strengths: Can be easily incorporated into the therapist's ADL evaluation; task specifically related to the client can be addressed; allows therapist to determine where the breakdown is occurring (initiation, execution, or control) to develop treatment program. Weakness: Training is recommended to improve reliability.</p>

Table 8-7. Scoring for Drawing to Command

Shape	Instruction	Scoring
Clock	“Draw the face of a clock showing the numbers and the two hands.”	0 to 3: one point each for approximately circular face, symmetry of number placement, and correctness of numbers
Daisy	“Draw a daisy.”	0 to 2: one point each for general shape (center with petals around it) and symmetry of petal arrangement
Elephant	“Draw an elephant.”	0 to 2: one point each for general shape (legs, trunk, head, body) and relative proportions correct
Cross	“You know what the Red Cross looks like? Draw an outline of it without taking your pencil off the paper.”	0 to 2: one point each for basic configuration and ability to form all corners adequately with a continuous line
Cube	“Draw a cube-shaped block in perspective, as it would look if you could see the top and two sides.”	0 to 2: one point each for grossly correct attempt and correctness of perspective
House	“Draw a house in perspective, so you can see the roof and two sides.”	0 to 2: one point each for grossly correct features of house and accuracy of perspective

Dressing Apraxia

Dressing apraxia refers to an inability to dress oneself. It is usually due to RBD and secondary visuospatial disorganization. It is evaluated functionally by watching clients

dress themselves. The underlying problem needs to be determined (e.g., visual deficits, unilateral neglect, apraxia, constructional apraxia), rather than evaluating dressing apraxia per se.

CASE
EXAMPLE

Assessing Vision After Stroke

Occupational Therapy Assessment Process

Patient Information

S.D. is a 21-year-old male who suffered a right CVA as a result of an arterial malformation 15 months ago. He was in a coma for 4 months. After the coma, he was in acute rehabilitation for 2 months and subsequently in outpatient therapy. Prior to the CVA, S.D. attended college where he was a math major and a basketball player. He is currently living with his family, taking one class at college, and is beginning

Clinical Reasoning Process

Objectives

Understand the patient’s diagnosis or condition

Examples of Therapist’s Internal Dialogue

“S.D. had a stroke involving the right side of his brain. From the history, he has been left with severe physical impairments that require a PCA. What visual skills might be affecting his ability to read, participate in school, and carry out self-care tasks? What type of neglect does he demonstrate and how does it affect personal independence and ability to interact in the community? Is he aware of the neglect and/or visual

to assist in coaching sports at a local school. He has a personal care attendant (PCA) 2–4 hours a day who assists with self-care activities.

He presents with left hemiplegia, moderate tone throughout the left side, with little controlled movement in either extremity. He is unable to walk and uses the wheelchair for all mobility. He has a left neglect and mild cognitive deficits, especially in short-term memory.

He was referred to occupational therapy by his physiatrist because S.D.'s vision and left neglect were limiting him in school and with mobility.

Know the person

Appreciate the context

Develop provisional hypotheses

deficits and does he become very frustrated? Or is he unaware and does he put himself in dangerous situations?"

"It must be difficult for someone who was a sports player to be in a wheelchair and sit on the sidelines coaching others. There is no mention of any behavior problems. I wonder what roles he plays now and how he is dealing with the changes."

"Given health care today, I wonder how long S.D. will have the services of a PCA? Is his family willing and/or able to provide personal care?"

"S.D.'s visual skills/deficits, level of neglect, and level of awareness of his deficits appear to be his biggest barriers to school and mobility."

Assessment Process

The occupational therapist wanted to determine the status of S.D.'s visual system and how it impacts on his daily functioning. The therapist used a symptom questionnaire to determine the patient's symptoms and complaints, as well as interview to determine his level of daily functioning. She then evaluated the visual foundation skills, including: acuity (near and far), visual fields, binocular vision, convergence, scanning, saccades, and pursuits. Because reading was a particular concern, she also included the *Pepper Test*, which is a standardized reading test used to determine accuracy and reading rate with unfamiliar text. Observations of where errors occur, how and where he uses his right upper extremity, and when and if he becomes frustrated will be made during the assessment.

Consider evaluation approach and methods

"Because he is having difficulty in school and with mobility, the visual foundation skills need to be assessed first to determine their effect on his ability to read and complete self-care tasks. If he does well on these but continues to have difficulty with self-care tasks and reading, then I would look at neglect in more depth."

Assessment Results

Based on the interview, S.D. indicated that he had difficulty with eating (secondary to not always seeing the entire plate), mobility, reading, doing his homework, and being able to track the kids he was coaching. The symptom questionnaire appeared to indicate problems with accommodation, ocular motility, and visual fields.

Acuity: Within normal limits with the glasses that he wears at all times for distance.

Visual fields: On confrontation testing, he exhibits moderate difficulty with stimuli on the left, especially in the lower left quadrant.

Binocular vision: No diplopia or suppression present, but he appears somewhat impaired on test of stereopsis/depth perception.

Convergence: Tested with 5 trials. Right eye broke at 8'', 3'', and 3 times at 6'', which indicates convergence insufficiency.

Interpret observations

"His difficulty with convergence and poor ocular motor skills indicate that he would have a problem reading."

"His accommodation deficits impact his ability to copy work from blackboard to table top, and it is not surprising that he has difficulty in the classroom."

"Visual field deficit or neglect? It's difficult to know at this time; he does demonstrate neglect, which can impact how well he does on confrontation testing."

"His inefficient scanning and left neglect impacts on his mobility and ability to successfully track the kids he is coaching."

"Although S.D. appeared to be aware that he had difficulty with functional tasks such as eating, reading, and coaching, he was unable to compensate fully for the visual deficits or the neglect. I feel that he is a good candidate for outpatient therapy at this time."

Scanning: During all scanning tasks, he exhibited an inefficient scanning pattern; during table top activities, he missed 75% of items on the left side of the page; and when scanning the room for specific numbers sequentially, although he located all numbers, he required maximum cues and increased time.

Pursuits: He demonstrated a lag and occasionally lost the item, especially in lower left quadrant. He has great difficulty following with his eyes and usually will turn his head.

Saccades: He was unable to shift vision between two pens without head movement.

Reading test: 60 WPM with 80% accuracy.

Throughout testing, he was cooperative and motivated. He demonstrates awareness of his neglect but still requires maximum cues and increased time to compensate

Occupational Therapy Problem List

1. Decreased ocular motor skills
2. Decreased convergence
3. Inefficient scanning skills
4. Decreased accommodation
5. Unilateral neglect

Synthesize results

“Overall, S.D. demonstrates convergence insufficiency, poor ocular motor skills, decreased accommodation, inefficient scanning and left neglect. I think that he would benefit from an evaluation by an optometrist who specializes in vision therapy and who can work with S.D. and me to provide what S.D. needs to manage school and sports.”

“Because of the neglect and decreased awareness at 15 months post injury, I am afraid that he will not be able to overcome the neglect and will require compensation from within, in which case activities will take a long time to complete, or he will require ongoing compensation from without, provided by others such as family or PCA. It will be important to determine which activities are most important to him.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of Functional Roles on Assessment of Vision, Visual Perception, and Praxis

S.D. was 21 years old, a math major in college, and involved in playing basketball at the time of his CVA. How might the evaluation have differed if he had been 71 years old, retired, and enjoyed watching TV? Or 45 years old with an active dental practice?

SUMMARY REVIEW QUESTIONS

1. What are the visual foundation skills and why should they be evaluated before higher-level visual perceptual skills?
2. Your head-injured client does poorly on a test of figure-ground. List at least four possible reasons this might happen.
3. Why is it important to assess contrast sensitivity?
4. Under what circumstances might you evaluate visual foundation skills in a neurologically intact person?
5. Who are the eye care professionals and in what ways would you interact with them? What information might you request, and what information might you be able to give them?
6. How might you try to differentiate between a visual field deficit and unilateral neglect?
7. Why is it important to screen vision as early as possible?
8. What are the two major types of unilateral neglect, and how is each evaluated?
9. Your client has LBD with resultant right hemiparesis and non-fluent aphasia. Why and how would you evaluate for the presence of apraxia?
10. When should you include evaluation of apraxia in a client?

ACKNOWLEDGMENT

Thanks to Stephanie Singleton, OTR, for her assistance with research.

CHAPTER 9

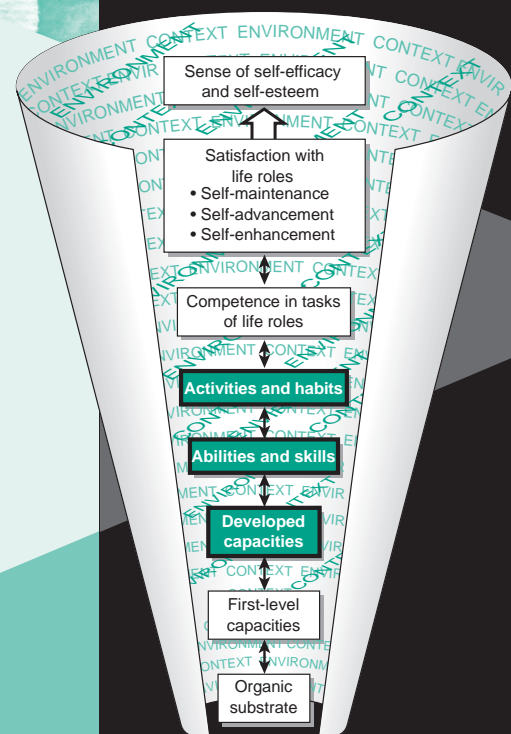

Assessing Abilities and Capacities: Cognition

Mary Vining Radomski

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe specific cognitive capacities and abilities and analyze their influence on occupational function.
2. Select cognitive assessment methods and tools based on individual clients' characteristics and requirements.
3. Anticipate and describe factors that may confound performance during cognitive assessment.
4. Distinguish occupational therapy's contribution to multidisciplinary cognitive assessment from that of other rehabilitation disciplines.

Glossary

Attention—The ability to deploy limited mental resources for purposes of concentration. Human activities have various attentional demands, including sustained attention (length of time), selective attention (competing stimuli), divided attention (multiple simultaneous stimuli), and alternating attention (shifts back and forth to various stimuli).

Cognition—The general term that reflects the mental enterprises related to absorbing information, thinking, and goal-directed action.

Concept formation—The ability to analyze relationships between objects and their properties (Sohlberg & Mateer, 1989).

Executive function—Metaprocess that enables a person to initiate, plan, self-monitor, and correct his or her approach to goal-directed tasks. Executive disorders often result from frontal lobe damage and are evidenced by problems with self-control, self-direction, and organization (Lezak, 1995).

Higher order thinking abilities—Complex mental operations that include problem solving, reasoning, and concept formation. Thinking generally entails the manipulation of remembered information (Mayer, 1992) and depends on intact primary cognitive capacities (orientation, attention, and memory) (Sohlberg & Mateer, 1989).

Memory—The result of interactive cognitive systems that receive, code, store, and retrieve information.

Neuropsychological evaluation—A long battery of standardized tests for purposes of diagnosis, patient care and planning, rehabilitation evaluation, and research (Lezak, 1995). Typically, the examiner is a doctor of psychology with specialized training in cognitive processes and brain-behavior relationships.

Orientation—The awareness of self in relation to one's physical and temporal environment that depends upon reliable integration of attention, memory, and perception (Lezak, 1995). Impaired orientation is strongly suggestive of cerebral dysfunction (Lezak, 1995).

Problem solving—The multistage process consisting of identifying a problem, generating possible solutions, implementing a preferred solution, and evaluating the results. Everyday problem solving, however, does not always follow this logical sequence of steps.

Reasoning—The ability to draw inferences or conclusions from known or assumed facts.

Self-awareness—The capacity to objectively perceive the self (Prigatano & Schacter, 1991) and (with a reasonable degree of accuracy) to compare that conception to a pre-morbid standard.

Cognition refers to the integrated functions of the human mind that together result in thought and goal-directed action. Simply put by Diller (1993), “Cognition involves the acquisition, processing, and application of information in daily life” (p. 9). Cognition is at the core of an individual's essence or personhood. In fact, Schacter (1996) suggested that without the capacity to remember the past, humans lose a sense of self. Cognition not only influences what a person chooses to do (Bandura, 1986), but it also dictates how an experience is remembered and interpreted.

Cognition clearly influences the selection, performance, analysis, and learning of everyday activities. In addition to its central role in occupational functioning, a person's cognitive function influences the acquisition of new activities of daily living (ADL) skills after the onset of disability (Walker, Walker, & Sunderland, 2003) and a person's capacity to perform IADL with progressive conditions such as dementia (Nygard et al., 1998) and human immunodeficiency virus (HIV) (Heaton et al., 2004). Cognition also predicts rehabilitation outcome after injury and illness. MacNeill and Lichtenberg (1997) found that, for geriatric inpatients, levels of cognitive function predicted ability to return home alone at discharge from rehabilitation. Sandstrom and Mokler (1999) also de-

scribed cognitive function as a key outcome variable for persons with severe motor stroke, and Hanks et al. (1999) found that cognition predicted functional abilities and social integration 6 months after discharge from acute rehabilitation. To identify and remove barriers that interfere with occupational functioning and to anticipate rehabilitation outcomes, occupational therapists examine patients' cognitive function as part of a comprehensive occupational therapy assessment.

This chapter begins with descriptions of specific cognitive capacities and abilities and follows with a discussion of various influences on cognitive function. I review clinical reasoning considerations pertinent to cognitive assessment and describe specific methods and tools based on two complementary approaches to cognitive assessment.

DEFINING COGNITIVE CAPACITIES AND ABILITIES

Cognition consists of an interactive hierarchy (Ben-Yishay cited in Goldstein & Levin, 1987) that includes primary cognitive capacities (orientation, attention, and memory),

higher level thinking abilities (reasoning, concept formation, and problem solving), and metaprocesses (executive functions and self-awareness).

Primary Cognitive Capacities

The primary cognitive capacities of orientation, attention, and memory largely reflect the neuroanatomical and physiological integrity of the brain (Radomski, 1998). They are thought to be prerequisite to higher level thinking abilities and to influence metaprocessing.

Changes in primary cognitive capacities are seen in many recipients of occupational therapy services. After a severe traumatic brain injury (TBI), many patients enter a confusional stage of recovery in which they are disoriented (Levin, O'Donnell, & Grossman, 1979). Stroke and TBI often result in problems with attention, memory, and language (Capruso & Levin, 1992; Claesson et al., 2005; Hochstenbach et al., 1998). Persons with chronic conditions, such as multiple sclerosis (Benedict et al., 2005), epilepsy (Helmstaedter et al., 2003), systemic lupus erythematosus (McLaurin et al., 2005), and HIV/acquired immunodeficiency syndrome (AIDS) (Heaton et al., 2004; Poutiainen et al., 1996), may also experience deterioration in attention and memory.

Orientation

Orientation refers to the awareness of self in relation to person, place, time, and circumstance (Sohlberg & Mateer, 1989). Orientation deficits are typically symptoms of brain dysfunction, with disorientation to time and place being most common (Lezak, 1995).

Attention

Attention is the deployment of mental resources for concentration. Each person is thought to have a limited capacity for consciously attending to information—a hard-wired upper limit that dictates how many inputs can be simultaneously processed (Lezak, 1995). Let us

examine four levels of attention in the context of preparing a meal.

1. *Sustained attention* is the capacity to maintain attentional performance over time (Sohlberg & Mateer, 2001). To prepare a meal with several dishes, an individual must stay focused for the duration of the task.
2. *Selective attention* occurs when an individual concentrates on one set of stimuli while ignoring competing stimuli (Sohlberg & Mateer, 2001), as when the cook ignores the noise from the television while measuring or counting ingredients.
3. *Divided attention* allows a person to respond to more than one task at a time and is a more complex mental skill than sustained and selective attention (Sohlberg & Mateer, 2001). The cook browns the meat while talking with a family member.
4. *Alternating attention* is necessary as one flexibly shifts attention between multiple operations (Sohlberg & Mateer, 2001). The cook interrupts meal preparation to answer the telephone and then quickly resumes setting the table while monitoring the status of food simmering on the stove.

Memory

Memory broadly refers to information storage and retrieval (Lezak, 1995). There are many conceptions of the way this process occurs (Baddeley, 1990; Lezak, 1995). Atkinson and Shiffrin's (1971) Information-Processing Model of memory highlights stages of acquiring and employing new knowledge and skills (Fig. 9-1). Definition 9-1 outlines terms commonly used in the discussion of memory.

Sensory Registers

Information from the environment is briefly (milliseconds) held in registers (or stores) specific to the human senses (Lezak, 1995). This registration stage has been called the intake valve for determining what data from the

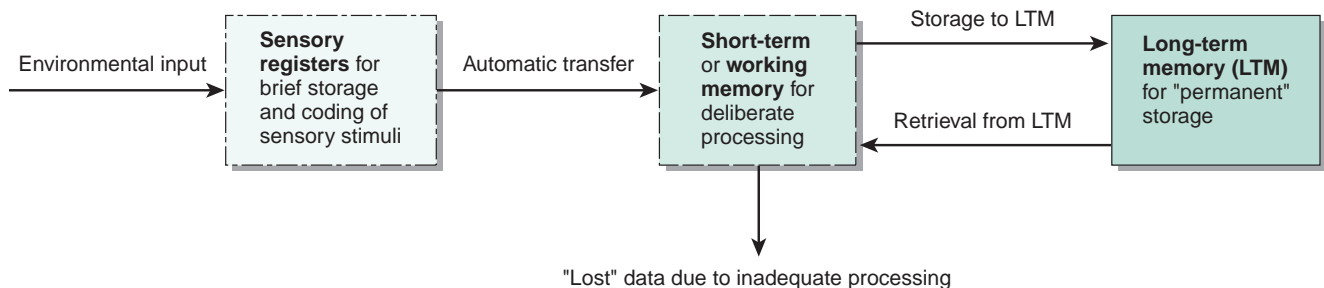

Figure 9-1 Human information-processing diagram.

DEFINITION 9-1 *definition*

Memory Terms

Term	Definition
Memory	
Recent	Usually corresponds to long-term memory; includes memory hours to months post stimulus presentation
Remote	Very long-term memory, as from childhood
Episodic	Memory of one's personal history (e.g., what you had for breakfast this morning)
Semantic	Personal knowledge of the world (e.g., that horses are big and ants are small)
Amnesia	
Retrograde (RA)	Loss of ability to recall events that occurred before the trauma
Anterograde	Decreased memory of events occurring after trauma
Post-traumatic (PTA)	Period following trauma during which the patient is confused and disoriented and seems to lack the ability to store and retrieve new information

environment are ultimately stored. This phase is influenced by acuity of the senses (such as hearing and vision), affective set, and perception.

Short-Term Memory

The short-term phase of information processing has many labels: immediate memory, short-term memory, and working memory. The term *working memory* connotes the effortful deployment of cognitive resources during this stage. In short, for input from sensory registers to proceed to storage in long-term memory, it must be the subject of deliberate concentration in working memory for approximately 30 seconds (Lezak, 1995). Without this focused attention, the memory trace decays, and the memory is not retained (Lezak, 1995). Unlike long-term memory, which is thought to have an infinite capacity, working memory has a restricted holding capacity of seven plus or minus two chunks of information (Miller, 1956). In addition to its role in information processing, working memory is the seat of conscious thought used in concentration and

problem solving (Baddeley, 1990). Based on electrochemical activity in the brain, working memory reflects the contribution of attention to the memory process (Lezak, 1995).

Long-Term Memory

Whereas data in working memory has a short shelf life, information in long-term memory can be stored for a lifetime (Lezak, 1995). When we remember information (an event that occurred an hour ago or a year ago), we have located and retrieved data from long-term memory and are holding it for conscious attention and thought in limited-capacity working memory. Storage in long-term memory is based on relatively permanent changes in brain cell structure (Glover, Ronning, & Bruning, 1990), although there does not appear to be a single local storage site for stored memories (Lezak, 1995). Long-term memory is thought to consist of two subsystems, declarative memory and procedural memory. Declarative memory holds factual information, which is subdivided into episodic memory (knowledge of personal information and events) and semantic memory (knowledge of facts about the world) (Eysenck & Keane, 1990). Procedural memory holds information related to knowing how to do things; it allows us to learn and perform skilled motor actions (Eysenck & Keane, 1990).

Higher Level Thinking Abilities

Higher level thinking abilities are the result of complex and dynamic interactions between a number of brain structures united in functional systems (Hochstenbach et al., 1998); they depend on intact primary cognitive capacities (Sohlberg & Mateer, 1989). After brain injury, people may have difficulty with reasoning and abstraction (Scherzer et al., 1993) and with sequencing and categorization (Adamovich, Henderson, & Auerbach, 1985), all of which interfere with higher level thought. Sohlberg and Mateer (1989) described three inter-related categories of higher level thinking abilities: problem solving, reasoning, and concept formation.

Problem Solving

Most people use problem-solving skills hundreds of times a day. Problem solving occurs whenever the situation is different from a desired situation or goal and the person does not immediately know what series of actions to take (Bransford & Stein, 1984). In fact, at a basic level, all human responses that are not routine or habitual can be construed as problem solving (Radomski, 1998). Problem

solving is usually conceptualized as the following multi-stage process:

- Identify the problem
- Define the problem
- Generate possible solutions and select one
- Implement the preferred solution
- Evaluate the outcome against the desired goal

Everyday problem solving, however, does not always follow this logical sequence. In his discussion of managerial problem solving, Wagner (1991) reported that high-level managers most often employ nonlinear problem solving in which they rely on tacit knowledge and base their actions and decisions on intuition rather than deliberation. Therefore, occupational therapists use the aforementioned sequence to organize their observations during assessment of problem solving rather than as a singular “right” sequence against which to judge effectiveness.

Reasoning

Reasoning entails drawing inferences or conclusions from known or assumed facts. It can make use of sequencing, categorization, and deduction (Sohlberg & Mateer, 1989). Sequencing is ordering information properly (Sohlberg & Mateer, 1989), whereas categorization involves grouping objects or ideas according to characteristics (Goverover, 2004). During deductive reasoning, a thinker uses evidence to make inferences, that is, uses available information to generate and test hypotheses (Goverover, 2004). For example, a client who is doing a task observes the therapist signaling that a high degree of accuracy is required. The client deduces from general feedback that she should slow down and periodically check the work.

Concept Formation

Closely linked to reasoning, concept formation is the ability to analyze relationships between objects and their properties (Sohlberg & Mateer, 1989). Sohlberg and Mateer (1989) suggested that “forming a concept requires that an individual identify critical features of instances of that concept and also determine how those features interrelate” (p. 267). A person forms a concept when sorting a box of assorted kitchen tools, for example, determining whether to organize them by function, size, or color. Thinking can be further qualified on a continuum of concrete to abstract (Mosey, 1993). Concrete thinking is characterized by the tendency to be bound to obvious stimulus properties and the inability to remove oneself from the immediate task (Sohlberg & Mateer, 1989); it is the most common sign of impaired conceptual thinking (Lezak et al., 2004). On the other end of the continuum, abstract thinking involves the ability to transcend the immediate situation, appreciate various aspects of the problem, and think symbolically (Sohlberg & Mateer, 1989). In the sorting example, a concrete thinker might choose to organize the kitchen tools by color, whereas the more abstract thinker might organize by common function.

Metaprocessing Abilities

Executive functions and self-awareness are metaprocesses that contribute initiation, planning, monitoring, reflection, and self-evaluation to cognitive function (Sternberg, 1990). Bewick et al. (1995) depicted these abilities as cognitive directors because they facilitate the interplay of primary cognitive capacities and higher level thinking in the execution of complex tasks.

Figure 9-2 Tinker toy test.

The importance of executive functions and self-awareness to satisfying and productive role performance cannot be overstated. Impairments in executive functions are major factors associated with loss of everyday competence (Goverover, 2004), social autonomy, and inability to return to work long after TBI (Mazaux et al., 1997). Decreased self-awareness after TBI prevents the survivor from recognizing the deficits that limit performance and diminishes motivation to participate in rehabilitation therapies. Interestingly, some family members view unawareness as a blessing in persons with dementia (Fleming, Strong, & Ashton, 1996), whereas for other caregivers, it is associated with higher levels of subjective distress (Prigatano et al., 2005).

Executive Functions

Intact executive functions are necessary for the successful performance of unstructured multistep tasks (such as the Tinkertoy test in Fig. 9-2) and an array of everyday occupations. Lezak et al. (2004) described four components of executive functions: volition, planning, purposive action, and effective performance.

1. Volitional behavior is dictated by determining what one needs or wants and then formulating a goal or an intention to act (Lezak et al., 2004). It is influenced by self-awareness because needs, wants, and goals are often moderated by people's understanding of their circumstances and the ability to realize an objective (Lezak et al., 2004).
2. Planning is identifying and sequencing steps to move toward the goal or end point (Lezak et al., 2004).
3. Purposive action is "the translation of an intention or plan into productive, self-serving activity [requiring] the actor to initiate, maintain, switch, and stop sequences of complex behavior in an orderly and integrated manner" (Lezak, 1995, p. 658).
4. Effective performance requires that an individual monitor and self-correct while regulating the intensity, speed, and strategies used during the task (Lezak, 1995).

Self-Awareness

Prigatano and Schacter (1991) suggested that self-awareness is the highest of all integrated activities of the brain. It is the ability to process information about the self and compare it to a longstanding self-evaluation (Dougherty & Radomski, 1993). Self-awareness has two primary dimensions: (1) appreciation of personal attributes, such as physical and cognitive strengths and weaknesses; and (2) initiation of compensatory strategies in response to known personal attributes. In general, persons with TBI tend to be more aware of physical deficits than cognitive or emotional changes (Anderson & Tranel, 1989), and

typically, the more severe the brain injury, the more problems the individual has with self-awareness (Sherer et al., 2005).

Crosson et al. (1989) proposed a three-level self-awareness hierarchy consisting of intellectual awareness, emergent awareness, and anticipatory awareness:

1. Intellectual awareness is a person's ability to understand at some level that a particular function is impaired. Severe deficits in memory impede intellectual awareness because such awareness requires recall of the past.
2. Emergent awareness is the ability of a person to recognize a problem when it is actually happening.
3. Anticipatory awareness, which depends on the existence of intellectual and emergent awareness, is the ability to anticipate a challenge or problem resulting from physical or cognitive impairments.

Metacognition, knowledge and regulation of one's own cognitive capacities and strategies (Ownsworth & Fleming, 2005; Katz, 2005), is closely linked to anticipatory awareness. For a person to begin taking notes in response to novel instructions (a metacognitive strategy), he or she must appreciate vulnerability from memory deficits and anticipate the challenge the activity represents (intellectual and anticipatory awareness).

Executive functions reciprocally influence self-awareness. Self-knowledge informs the selection of reasonable goals for a given undertaking and drives selection of strategies that best facilitate performance. Ongoing monitoring of task performance with adjustment of strategies and incorporation of feedback can in turn affect self-awareness, altering percepts of personal strengths and weaknesses.

MULTIPLE-DETERMINANT MODEL OF COGNITIVE FUNCTION

The dissection of specific cognitive capacities and abilities for purposes of description belies the complexity of their inter-relationships and redundancies. In actuality, an individual's cognitive state is dynamic, determined by many interacting variables, including neurobiological, affective, experiential, social, and cultural influences, all of which are mediated by the task and environment. Changes in any of these domains improve or detract from a person's cognitive state and thereby his or her occupational functioning. To assess cognition and interpret findings, occupational therapists must appreciate how variables can affect performance during cognitive assessment. What follows is a brief summary of each influence, supported with specific examples from the literature.

Neurobiological Influence on Cognition

The neurobiological influence on cognition is best understood as foundational cognitive capacities resulting from dynamic neural networks (Hochstenbach et al., 1998). This influence is most apparent following changes to the anatomy and physiology of the brain, as with injury and aging. Persons with stroke have local damage to brain tissue that often results in predictable and specific cognitive deficits, such as frontal lobe damage leading to executive dysfunction and temporal lobe damage affecting memory. Neurobiological changes that accompany aging also seem to affect thinking abilities and memory. Crystallized intelligence (well-practiced, overlearned skills and knowledge) is reportedly maintained or strengthened into the eighth decade of life, whereas fluid intelligence, which entails reasoning and problem solving for unfamiliar challenges, begins a slow decline in the sixth decade of life (Lezak, 1995). Small et al. (1999) found that healthy adults aged 70 and older demonstrated a decline in specific aspects of memory performance when compared with subjects 60–69 years old. They suggest that this profile of age-related memory decline is related to changes in the hippocampal formation (Small et al., 1999).

Changes or deterioration of other functions of the human body have secondary neurobiological influences on cognition. For example, visual-perceptual impairments alter the inputs into the memory process, limiting what a person can accurately remember. Medications can also have a neurobiological influence on cognition. Researchers suggest a link between adjuvant chemotherapy for operative primary breast cancer and cognition (Schilling et al., 2005).

Affective Influences on Cognition

Although it is clear that emotions affect cognition, the underlying mechanism is not known. Anxious people differ from others in several aspects of attentional functioning. Anxious people are more likely to attend to threat-related stimuli and use limited-capacity working memory for worry, self-concern, and other task-irrelevant distractions (Eysenck & Keane, 1990). Persons with depression also frequently complain about poor memory but often do not demonstrate memory deficits on neuropsychological testing (Lezak, 1995). Depressed individuals are thought to show passive disengagement with the environment in that their attentional focus is on internal concerns rather than environmental events (Eysenck & Keane, 1990). Depressed people also demonstrate a negative recall bias (a tendency to recall more negative information about themselves than others do) (Baddeley, 1990; Eysenck & Keane, 1990). Memory problems associ-

ated with depression seem to have a secondary effect on executive processes. Channon and Green (1999) found that otherwise healthy but depressed individuals performed worse than controls who were not depressed on three measures of executive function. They explained this difference as possibly related to alterations in neurotransmitter activities and/or distractions by dysfunctional negative thoughts that occupy limited-capacity working memory during problem solving and task performance.

Similarly, transient mental distractions can impair cognition. Pain and fatigue are thought to be irrelevant inputs that diminish the function of limited-capacity working memory by occupying attention that is therefore unavailable to incoming data (Denburg, Carbotte, & Denburg, 1997). Therefore, clients who are exhausted or in physical or emotional pain are unlikely to be able to demonstrate their cognitive capabilities during assessment, with or without neurobiological impairments (Bryant, Chiaravalloti, & DeLuca, 2004; Heyer et al., 2000).

Experiential, Social, and Cultural Influence on Cognition

Feuerstein (1980) hypothesized that experience and sociocultural background play superordinate roles in the development of cognitive capacities and habits. An Israeli psychologist–educator, Feuerstein became convinced that the large number of “retarded” adolescent immigrants after World War II lacked cognitive skills primarily because of poverty and socially deprived surroundings. Participants in his 2-year intervention program, which focused on acquisition of cognitive habits and strategies, demonstrated improvements in general intellectual aptitude, interpersonal conduct, self-sufficiency, and adaptation (Perkins, 1995).

Experts also suggest that basic processes of perception and cognition are influenced by culture. Nisbett and Masuda (2003) summarized a series of studies that illustrate information-processing differences in East Asian and Western cultures. They suggested that Americans tended to focus their attention on objects and object attributes, but Japanese subjects tended to focus on the field, background, relationship, or context of the objects. Consider the impact that culture also has on self-awareness. Prigatano, Ogano, and Amakusa (1997) suggested that, because incompetence in personal care is a sign of disgrace in Japan, Japanese patients with TBI tended to overestimate their abilities in this realm. On the other hand, because Japanese generally view high estimations of social and interpersonal skills as impolite, Japanese patients with TBI tended to underestimate their abilities in this realm.

Task and Environment as Contextual Mediators of Cognition

People bring their neurobiological, emotional, experiential, social, and cultural predispositions to all information processing, but performance at a given moment is mediated by characteristics of the task and environmental contexts. In her Dynamic Interactional Model of Cognition, Toglia (2005) suggested that, in addition to a person's neurological capacity, personal context, self-awareness, and processing strategies, his or her cognitive functioning is also influenced by the activity and environment. Task variables that influence cognition include complexity, arrangement, and movement demands (Toglia, 1998). Here is an example of task–cognition interplay. When a task is familiar, the thinker requires relatively little attention to recognize a problem type and determine a hypothesis and plan of action (Mayer, 1992). A familiar task or problem prompts the individual to retrieve a large number of interconnected units of knowledge, both related facts and previous solutions (Mayer, 1992). Tasks that optimally challenge an individual's cognitive capacities and abilities and engage his or her interest elicit an individual's peak cognitive performance (Csikszentmihalyi, 1990).

The environment similarly affects cognition. Contextual cues in the environment enhance recall of similar tasks or previously effective techniques or solutions. The stimulus–arousal properties of the environment also influence cognitive function. Lighting and noise can focus attention or, as is often the case for persons with brain injury, provide distractions that derail thinking.

In summary, cognition consists of specific but interrelated capacities and abilities that are influenced by neurobiological, affective, experiential–sociocultural variables and task and environmental contexts. This discussion, although not exhaustive, highlights the complexity, if not the mystery, of cognitive function, which is an appreciation necessary for assessing cognitive capacities and abilities in occupational therapy. In judging the cognitive status of another person, teasing out performance confounders is as important as selecting and correctly administering the assessment tool. Whereas assigning and summing scores on standardized instruments requires the attentiveness of a trained technician, observing and interpreting performance during assessment requires the insight of a professional.

THE PROCESS OF COGNITIVE ASSESSMENT

Occupational therapists in clinical practice assess cognition for three primary reasons:

1. To establish a baseline against which to measure change

2. To inform intervention and discharge planning
3. To identify those who would benefit from more detailed neuropsychological evaluation

As previously discussed, many persons requiring the attention of medical and rehabilitation professionals have cognitive deficits that interfere with function. Cognitive changes can be temporary, relatively static, or progressive. Occupational therapists use a combination of static and dynamic assessments to get a comprehensive picture of the client. Static assessments are standardized evaluations that provide a snapshot of the client's functioning at a specific period of time (Kolakowsky, 1998). Dynamic assessments focus on client performance at two or more points in time (Kolakowsky, 1998) and examine learning potential and the client's ability to transfer or generalize new skills (Toglia, 2005). Rather than adhering to a strict standardized administration, dynamic assessments allow clinicians to manipulate person, environment, and activity variables to ascertain how those variables might be modified to optimize the client's level of functioning (Polatajko, Mandich, & Martini, 2000; Toglia, 2005). Static assessments typically result in a numeric score that enables the clinician to characterize the nature and extent of cognitive impairment before, during, and after intervention. Dynamic assessments help occupational therapists determine what problems to address and to select specific intervention strategies.

Occupational therapists exchange information about their findings with the family and other rehabilitation professionals so that the rehabilitation team together can create a comprehensive picture of the client's function. For example, language is inextricably linked to almost every aspect of cognitive function. Occupational therapists review the results of speech and language assessment to understand the language capacities and abilities of a given patient and the influence of any impairment on cognitive assessment. Neuropsychology is informed by occupational therapists' observations of cognitive function in the context of daily life tasks and life roles. Neuropsychologists use a variety of standardized tests to diagnose localized deficits and differentiate between neurological and psychiatric symptoms. A full neuropsychological evaluation, which typically entails 2–8 hours of tests, guides decision making prior to major rehabilitation transitions (return to work or moving from supervised to independent living or vice versa) and establishes the permanence of cognitive impairments for legal purposes. Because neuropsychological evaluation is so expensive, occupational therapists often assess cognition on behalf of the team during acute rehabilitation, when cognitive capacities and abilities are in a period of rapid change.

Clinicians select the most appropriate cognitive assessment methods and tools based on the objectives of assessment and specific needs and characteristics of the client.

Occupational therapists use two complementary approaches to assessing cognition: (1) assessing function to make inferences about cognitive capacities and abilities and (2) assessing cognitive capacities and abilities to make inferences about function.

Methods and Tools for Assessing Function to Make Inferences about Cognition

Occupational therapists begin any new assessment by identifying the client's goals and priorities as well as his or her roles and performance in occupations (American Occupational Therapy Association, 2002). Assessment of cognition is part of that process. Informal and formal functional assessments provide opportunities to make hypotheses about cognitive strengths and weaknesses, allowing the clinician to identify domains warranting further evaluation. For example, during an activities of daily living (ADL) or homemaking evaluation, occupational therapists observe attention to task by counting episodes of distractions, memory for instructions, and evidence of organization and planning. Of course, informal functional assessments of cognition are highly subjective and easily influenced by the clinician's definition of "normal" and his or her acumen in using the observable (behavior) to make inferences about internal cognitive processes. This method of cognitive assessment, however, is preferable for patients who cannot understand verbal or written instructions, as with communication deficits or speaking another language.

Three standardized functional assessments help clinicians simultaneously examine function and cognition: the *Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE)* (Arnadottir, 1990), the *Rabideau Kitchen Evaluation-Revised* (Neistadt, 1992), and the *Kitchen Task Assessment* (Baum & Edwards, 1993).

Arnadottir OT-ADL Neurobehavioral Evaluation

The *A-ONE* evaluates performance of ADL and examines the effect of neurobehavioral dysfunction on task performance. There are two parts of the instrument; part 2 is considered optional. During part 1, the occupational therapist observes the patient performing dressing, hygiene, transfer and mobility, feeding, and communication tasks and completes the *Functional Independence Scale* by assigning a numerical score (0–4) for each aspect of the various tasks. For example, a score is assigned to each of the activities of dressing (donning shirt, pants, socks, and shoes; fastening clothing). While observing the patient's performance of each component, the therapist also rates the patient in terms of presence of neurobehavioral impairments, again using a 0–4 scale. For example, the patient is scored on each of the following possible neurobehavioral impairments

specified for the task of dressing: motor apraxia, ideational apraxia, unilateral body neglect, somatoagnosia, spatial relations, unilateral spatial neglect, abnormal tone, perseveration, and organization and sequencing. The scores on the *Functional Independence* and *Neurobehavioral* scales are not additive but used to establish patterns of performance and impairment. Occupational therapists may use the results of part 1 to localize cerebral dysfunction based on functional performance (part 2). Part 1 of the *A-ONE*, which takes approximately 25 minutes to administer, was standardized on patients with cortical central nervous system dysfunction. Its author recommends that therapists attend a training seminar before using the tool (Arnadottir, 1990).

Rabideau Kitchen Evaluation-Revised

The *Rabideau Kitchen Evaluation-Revised (RKE-R)* requires that persons with brain injury synthesize an array of cognitive capacities and abilities in the context of preparing a simple meal, a cold sandwich with two fillings and a hot beverage. Each of the 40 component activities is rated on a 0–3 scale indicating level of assistance or cueing required, and the total time for completion is recorded. Neistadt (1994) recommended that therapists use scores on the *RKE-R* to determine where to begin with a treatment protocol designed to improve meal preparation skills but suggested that this test may not be sensitive enough to use with persons who have subtle cognitive or perceptual deficits (Neistadt, 1992).

Kitchen Task Assessment

The *Kitchen Task Assessment (KTA)* measures the cognitive support necessary for the patient to prepare cooked pudding. Specific neurobehavioral components, such as initiation, organization, and safety, are scored on a 0–3 scale, reflecting the degree of cueing or physical assistance required for that aspect of the task. This test was standardized on patients with Alzheimer's disease.

Work Simulations

Work simulations are another method for assessing cognition through functional activity. Nadeau and Buckheit (1995) recommended a three-phase *Work Simulation Model* for outpatients with TBI as a means to observe executive functions. In the set-up phase, after patients are provided with a workspace and scheduled work time, they make a list of supplies they need for the job. Before beginning the simulation phase, patients predict their performance on projects that are somewhat similar to work tasks they would have done before the injury. In the post-simulation phase, patients rate actual performance and compare self-ratings to that of the therapist. Dougherty and Radomski

Figure 9-3 Messy cupboard.

(1993) described a similar assessment of work behaviors in which following directions, accuracy, and vigilance are rated in the context of four tasks: balancing a checkbook and using a calculator, the Yellow Pages, and transportation schedules.

Dynamic Investigative Approach

Finally, therapists can convert any task (such as organizing the messy cupboard in Fig. 9-3) to an opportunity for cognitive assessment by using a dynamic investigative approach (Toglia, 1989). Therapists deliberately manipulate performance variables related to task, environment, strategies, and cueing to determine in what conditions the patient performs at his or her best (Dougherty & Radomski, 1993). *Dynamic Interactional Assessment (DIA)* (Toglia, 1998) is a formal example of a dynamic investigative approach. *DIA* consists of awareness questioning, cueing and task grading, and strategy investigation (Toglia, 1998). During awareness questioning, patients answer increasingly specific questions that tap their intellectual awareness of potential problems. They also predict their performance before beginning the assessment task. Graded verbal cues are offered as needed once the patient begins work, and parameters of the task are changed, if necessary, to buoy the

patient's performance. During task performance, the therapist seeks to understand what strategies or approaches the patient uses by asking strategy questions. Toglia incorporates *DIA* into a number of the standardized assessment tools she developed, including the *Contextual Memory Test* (Toglia, 1993) and the *Toglia Category Assessment* (Toglia, 1994).

When using methods and tools for assessing function to make inferences about cognition, occupational therapists generally seek to determine what the patient can do given various supports and conditions. These less structured approaches to evaluation allow for observation of metaprocesses and qualitative aspects of performance that are not easily captured using more structured methods. Because of their foundation in function, such methods capitalize on the unique expertise of occupational therapists. Hajek, Gagnon, and Ruderman (1997), however, suggested that functional assessments may not be sufficient for identifying cognitive disability and that rehabilitation outcome would be better predicted if the results of functional assessment were coupled with a detailed assessment of specific cognitive capacities and abilities.

Methods and Tools for Assessing Cognitive Capacities and Abilities to Make Inferences about Function

Based on the results of assessing performance of tasks and activities, clinicians generate hypotheses as to what specific barriers or impairments interfere with a patient's optimal occupational function. Tools and methods that assess specific cognitive capacities and abilities are then used to verify these hypotheses and establish a baseline against which to measure improvement. Many instruments have demonstrated reliability and validity, and standardized scoring criteria greatly reduce therapist bias. Assessments of specific cognitive capacities and abilities, however, may be predicated on a serious theoretical fallacy—the notion that these constructs can be separated from one another. Based on the inter-relatedness of various aspects of human cognition, one questions whether, for example, memory can be assessed apart from attention. Assessment Table 9-1 provides examples of various measures of specific cognitive capacities and abilities, including a cognitive screen and three microbatteries. A cognitive screen takes less than 15 minutes to administer and provides the clinician with a general sense of a patient's cognitive status but little information about what specific areas may be impaired. A microbattery may take up to 45 minutes to administer and consists of a number of subtests, typically associated with an array of cognitive capacities and abilities.

Assessment Table 9-1

Summary of Assessments of Cognition

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Selected Tools for Assessing Cognitive Capacities and Abilities to Make Inferences about Function						
<i>Galveston Orientation and Amnesia Test (GOAT)</i> (Levin, O'Donnell, & Grossman, 1979)	A widely used measure of orientation to person, place, time, and memory for events preceding and following injury. 10 questions with weighted error points deducted from a total of 100 points.	10–15 minutes.	Performance on the GOAT strongly related to aspects of the <i>Glasgow Coma Scale</i> (for eye opening, $\chi^2 = 21.09$, $p < 0.00001$; for verbal responding, $\chi^2 = 19.53$, $p < 0.000001$).	Good inter-rater reliability (Kendall τ coefficient = 0.99, $p < 0.001$).	Well suited to track fluctuations in confusional period after traumatic brain injury (TBI).	Strength: Brief test that evaluates PTA and RA (see Definition 9-1). Weakness: Designed for use after TBI and may be difficult to use with other populations of rehabilitation patients.
<i>Orientation Log (O-Log)</i> (Jackson, Novack, & Dowler, 1998)	10-item scale that is designed for repeated administration that evaluates orientation to place, time, and situation in terms of cueing needed for correct responses. Range of scores = 0–30.	~ 5 minutes.	Significant correlation with the GOAT ($r = 0.901$, $p < 0.001$) (Novack et al., 2000).	Good inter-rater reliability for total O-Log score (Spearman Rho = 0.993).	No psychometric data available regarding the test's sensitivity. As the patient receives points for responding to cues, however, the test may be sensitive to progress.	Strength: Applicable to a wide range of rehabilitation patients. Weakness: Less well known than GOAT.

<p><i>Test of Everyday Attention (TEA)</i> (Robertson et al., 1996)</p>	<p>Test of sustained, selective, and divided attention based on 8 ecologically plausible subtests such as Map and Telephone Search (selective attention), Elevator Counting and Lottery (sustained attention), and Telephone Dual Task (divided attention).</p>	<p>45–60 minutes.</p>	<p>Concurrent validity: moderate to moderately strong correlation between TEA subtests and other measures of attention ($r = 0.42-0.63$). Discriminant validity: Statistically significant differences between older healthy controls and older stroke patients on all subtests ($p < 0.001$) and on 5 of 8 subtests with younger paired subjects.</p>	<p>Test-retest reliability (across parallel forms of the test) is strong across subtests of the parallel versions ($r = 0.66-0.90$).</p>	<p>There are 3 parallel forms of the TEA to prevent patients from learning the test with repeated administration.</p>	<p>Strengths: Development of TEA was based on investigations for functional-neuroanatomical specialization of attention. Subtests have ecological validity for clients. Weaknesses: Not appropriate for patients with significant visual problems; rather lengthy assessment of one dimension of cognitive function.</p>
<p><i>Rivermead Behavioral Memory Test (RBMT)</i> (Wilson, Cockburn, & Baddeley, 1985)</p>	<p>Assesses memory skills necessary for everyday life including remembering names, faces, routes, and appointments.</p>	<p>30–45 minutes.</p>	<p>Wilson et al. (1989) found statistically significant differences between persons with brain injury and healthy controls on all RBMT subtests ($p < 0.001$).</p>	<p>Inter-rater reliability: 100% agreement when 40 subjects with brain injury were scored separately but simultaneously by 2 raters (Wilson et al., 1989).</p>	<p>There are 4 parallel forms of the RBMT to prevent patients from learning the test with repeated administration.</p>	<p>Strengths: Subtests are similar to everyday tasks; useful in the characterization of memory disorders for a wide range of diagnostic groups (Lezak et al., 2004). Weakness: Requires intact visual and verbal skills.</p>
<p><i>Contextual Memory Test</i> (Toglia, 1993)</p>	<p>Dynamic assessment of recall, awareness of memory capacity, and memory strategy use in which client tries to remember 20 objects related to 1 of 2 themes (ADL routine or restaurant).</p>	<p>30–40 minutes.</p>	<p>Concurrent validity: strongly correlated with the RBMT ($r = 0.80-0.84$).</p>	<p>Reliability for parallel forms of test ($r = 0.73-0.81$). Test-retest reliability for persons with brain injury ($r = 0.85-0.94$).</p>	<p>Not established.</p>	<p>Strength: One assessment that provides information about memory and information about meta-memory. Weakness: Potential for cultural bias—associated pictures (Josman & Hartman-Maier, 2000).</p>

Assessment Table 9-1

Summary of Assessments of Cognition (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Selected Tools for Assessing Cognitive Capacities and Abilities to Make Inferences about Function						
<i>Toglia's Category Assessment (TCA)</i> (Toglia, 1994)	Dynamic assessment related to concept formation and ability to switch conceptual sets. 18 plastic utensils in 3 colors are sorted according to size, color, and type.	10–25 minutes to administer TCA and DR together.	Concurrent validity: positive significant correlation with the <i>Risk Object Classification</i> test, a static measure of categorization ($r = 0.51, p < 0.01$). Failed to detect significant differences between persons with schizophrenia and brain injury (Josman, 1998).	Inter-rater reliability of 0.87 (Josman, 1998).	Not established.	Strength: Involves use of familiar, functional objects to assess abstract concept. Weakness: Less predictive of IADL performance than DR test for persons with brain injury (Goverover & Hinojosa, 2002).
<i>Toglia's Deductive Reasoning Test (DR)</i> (Toglia, 1994)	TCA subtest designed to assess deductive reasoning. The client is asked to determine which utensil the examiner is thinking about by asking the fewest possible yes or no questions. Scores range from 1 (cannot obtain the right answer with maximum cues and task modification) to 7 (correct answer with 5 questions) for each of 3 trials.	10–25 minutes to administer TCA and DR together.	Adequate discriminant validity: significant differences in scores for persons with brain injury as compared to healthy controls ($F [1, 91] = 52.68, p < .001$) (Goverover & Hinojosa, 2004).	Interclass correlation coefficient computed to determine inter-rater reliability was statistically significant based on interclass correlation coefficient reliability test ($F [30] = 352.28, p < .001$) (Goverover & Hinojosa, 2004).	No information.	Strength: Score on DR test was found to be predictive of IADL performance in persons with brain injury (Goverover & Hinojosa, 2002). Weakness: Focuses on only one dimension of cognitive function.

<p><i>Tinkertoy Test (TTT)</i> (Lezak, 1982; Lezak et al., 2004)</p>	<p>Unstructured assessment of executive functions in which the patient is provided with 50 specific Tinkertoy pieces and given 2 instructions: “Make whatever you want with these” and “You will have at least 5 minutes and as much more time as you wish to make something.” The patient’s approach is observed, and the final construction is assigned a numerical score based on its complexity and sophistication, including mobility and symmetry (0–12 points).</p>	<p>At least 5 minutes.</p>	<p>Mixed findings. Bayless, Vamey, and Roberts (1989) found statistically different <i>TTT</i> scores between 2 groups: healthy controls and employed persons 2 years post TBI versus unemployed persons who were 2 years post TBI. Spikman, Deelman, and van Zomeren (2000), however, found that <i>TTT</i> scores were not statistically different when comparing the scores of persons with TBI and healthy controls.</p>	<p>Moderately strong to strong inter-rater reliability on 3 of 7 subscores (three-dimensional ICC = 0.95, $p = 0.00$; name ICC = 0.71, $p = 0.00$; moving parts ICC = 0.78, $p = 0.00$) (Koss et al., 1998). (Note: inter-rater agreement was not evaluated on the other 4 subscores.)</p>	<p>No information.</p>	<p>Strength: Unstructured nature allows for observations related to executive functioning. Weakness: Adult patients may perceive constructional task involving Tinkertoys as childish or insulting.</p>
<p><i>Patient Competency Rating Scale (PCRS)</i> (Prigatano et al., 1986)</p>	<p>The patient is asked to answer 30 questions related to everyday tasks, rating how easy or difficult each is (can’t do, very difficult, some difficulty, fairly easy, can do with ease). A person familiar with the patient’s abilities (family or staff) also rates the patient’s proficiency with the 30 tasks. The magnitude of differences between self-ratings and those of the relative or staff quantifies the patient’s awareness of deficits. Average perceived behavioral competency is calculated by computing the mean rating of competency across all 30 items.</p>	<p>15–20 minutes.</p>	<p>Moderate correlation between scores on the <i>PCRS</i> and the <i>Awareness Questionnaire</i> for patients (Spearman correlation coefficient = 0.50, $p < 0.01$) and informant (Spearman correlation coefficient = 0.62, $p < 0.01$) (Sherer, Hart, & Nick, 2003).</p>	<p>Strong inter-rater reliability (average $r = 0.92$) (Fordyce & Roueche, 1986). Strong 1-week test-retest reliability for total scores (ICC = 0.85 for persons 3 months post TBI; ICC = 0.95 for staff) (Fleming & Strong, 1999).</p>	<p>The original instrument has been modified for use with patients on an acute rehab unit (Borgaro & Prigatano, 2003).</p>	<p>Strengths: Formal methods of ascertaining discrepancies between patient, staff, and family perceptions of competence; could be used as a vehicle for discussion of incongruities. Weakness: It is necessary to be familiar with the patient to judge the accuracy of his or her self-ratings.</p>

Assessment Table 9-1

Summary of Assessments of Cognition (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Selected Tools for Assessing Cognitive Capacities and Abilities to Make Inferences about Function						
<i>Self-Awareness of Deficits Interview (SADI)</i> (Fleming, Strong, & Ashton, 1996)	Tool designed to obtain both qualitative and quantitative data on status of self-awareness. The patient is asked about self-awareness of deficits, self-awareness of functional limitations because of deficits, and ability to set realistic goals. A therapist familiar with the patient's level of functioning assigns a score in each realm (0–3, with 0 representing full awareness).	10 minutes.	SADI moderately correlated with the <i>Dysexecutive Questionnaire (DEX)</i> ($r = 0.40, p < 0.05$). Regression analyses indicated that SADI scores were significantly predicted by a set of executive functioning measures ($p < 0.01, R^2 = 0.31$) (Bogod, Mateer, & MacDonald, 2003).	Strong inter-rater reliability (ICC = 0.82). Strong test–retest reliability (ICC = 0.94) (Simmond & Fleming, 2003).	No information.	Strength: Brief semi-structured interview with questions that are relevant to treatment planning. Weakness: Potential for bias because clinician judges the extent to which patient responses reflect level of self-awareness disorder.
<i>Mini-Mental State Examination (MMSE)</i> (Folstein, Folstein, McHugh, 1975).	Screening tool involving a therapist-administered interview comprised of 11 questions related to orientation, attention, learning, calculation, abstraction, information, construction, and delayed recall. Scores of 0–30 with scores of 24 or below suggestive of possible cognitive disorder (Tombaugh & McIntyre, 1992).	5–10 minutes.	Concurrent validity: MMSE score is highly correlated with <i>Weschler Adult Intelligence Scale</i> (for Verbal IQ, Pearson $r = 0.776, p < 0.0001$; for Performance IQ, Pearson $r = 0.660, p < 0.001$).	24-hour test–retest reliability, Pearson $r = 0.887$. Inter-rater reliability, Pearson $r = 0.827$.	Concerns about sensitivity of MMSE with scores < 24 (Kukull et al., 1994). Improved sensitivity with the MMSE (Teng & Chui, 1987) and in combination with draw a clock (Suhr & Grace, 1999; Watson, Arfken, & Birge, 1993).	Strengths: Widely used and understood by many rehabilitation and medical disciplines; brief screen that is helpful in determining need for more in-depth cognitive assessment (Zwecker et al., 2002). Weaknesses: Bias toward verbal items and, therefore, insensitive to damage in right hemisphere; poor sensitivity to mild cognitive deficits.

<p><i>Loewenstein Occupational Therapy Cognitive Assessment (LOTCA)</i> (Katz et al., 1989)</p>	<p>Microbattery consisting of 20 subtests in four areas: orientation, perception, visuospatial operations, and thinking operations.</p>	<p>30–45 minutes.</p>	<p>All subtests, except identification of objects, differentiated between patients with craniocerebral injury (CCI) and healthy controls and stroke patients and healthy controls using Wilcoxon two-sample tests ($p < 0.0001$).</p>	<p>Strong inter-rater reliability (Spearman's rank correlation coefficient ranged from 0.82–0.97 for various subtests).</p>	<p>Katz et al. (1989) observed improved test scores between admission and after 2 months for TBI and stroke patients.</p>	<p>Strength: Provides a snapshot of a number of cognitive capacities in a relatively short amount of time. Weaknesses: Does not pick up subtle cognitive deficiencies on persons with mild injuries; does not include measure of memory.</p>
<p><i>Cognitive Assessment of Minnesota (CAM)</i> (Rustad et al., 1993)</p>	<p>Microbattery consisting of 17 subtests including attention, memory, orientation, neglect, following directions, money and math skills, planning and abstract reasoning, and problem solving.</p>	<p>45 minutes.</p>	<p>Concurrent validity: moderate correlation of CAM total score with the <i>Porteus Maze Test Quotient</i> ($r = 0.5016$, $p = 0.048$) and <i>MMSE</i> ($r = 0.4355$, $p = 0.046$).</p>	<p>A paired t-test comparing total CAM scores given by 2 raters indicated no statistically significant differences (suggesting adequate inter-rater reliability).</p>	<p>Discriminant analysis: results of the discriminant model indicate that 95.48% were correctly classified as having or not having cognitive impairment.</p>	<p>Strengths: Provides an overview of cognitive functioning; performance is reported in a profile format indicating presence or extent of impairment. Weakness: Possible ceiling effect for mild or subtle cognitive deficits; little literature on its use in rehabilitation.</p>
<p><i>Cognistat (Neurobehavioral Cognitive Status Examination)</i> (Kiernan et al., 1987)</p>	<p>Microbattery that comprises 10 subtests in the areas of orientation*, attention, comprehension*, repetition*, naming*, construction, memory, calculation, similarities, and judgment.</p>	<p>20–25 minutes.</p>	<p>Discriminant analysis: Wilcoxon analysis suggested that 4 of the subtests (see*) discriminated between elderly persons with stroke and healthy independent elderly (Katz, Elazar, & Itzkovich, 1996); statistically significant mean scores for healthy controls, persons with Alzheimer's type dementia, and neurosurgical patients on 9 of 10 subtests (Katz et al., 1997).</p>	<p>No information.</p>	<p>Found to be more sensitive than <i>MMSE</i> with neurosurgical patients (Schwamm et al., 1987).</p>	<p>Strengths: Scores are presented in a profile of performance in each domain (average, mild, moderate, and severe impairment); normative data available for healthy elderly persons (Eisenstein et al., 2002). Weaknesses: Some test items (construction subtest) may be too difficult for both stroke patients and healthy elderly persons (Osman et al., 1992); not appropriate for geriatric or psychiatric patients (Engelhart, Eisenstein, & Meininger, 1994).</p>

Assessment Table 9-1

Summary of Assessments of Cognition (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Selected Tools for Assessing Function to Make Inferences about Cognition						
<i>Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE)</i> (Arnadottir, 1990)	Two parts to the instrument. Part 1 involves observing ADL performance and completing the (1) <i>Functional Independence Scale</i> and (2) <i>Neurobehavioral Specific Impairment Subscale</i> . Part 2 is optional, enabling the clinician to cross link the neurobehavioral impairment to the most likely lesion site.	25 minutes.	Content validity established through expert input. Concurrent validity: compared scores of 50 persons with stroke and 79 healthy controls. Significant Mann-Whitney <i>U</i> test suggests <i>A-ONE</i> discriminates between groups for all items of the <i>Functional Independence Scale</i> and all but 6 items of the <i>Neurobehavioral Subscale</i> .	Inter-rater reliability: <i>Functional Independence Scale</i> , kappa = 0.83); <i>Neurobehavioral Specific Impairment Subscale</i> (kappa = 0.86). Test-retest reliability within 1 week ($r_s = 0.85$).	No information.	Strength: Standardized methods for combining assessment of ADL with assessment of cognition so that therapists can assess both areas at the same time. Weakness: Neurobehavioral subscale does not include assessment in key cognitive capacities such as memory and attention.
<i>Rabideau Kitchen Evaluation-Revised (RKE-R)</i> (Neistradt, 1992)	Observational tool designed to assess the functional sequencing of adults with TBI in the context of preparing a sandwich and hot beverage (score range of 0–120).	30–45 minutes.	Criterion-related validity demonstrated by statistically significant association between scores on the <i>RKE-R</i> and the Block Design subtest of the <i>Wechsler Adult Intelligence Scale-Revised</i> ($r = -0.60$, $p = 0.0002$).	Inter-rater agreement of 86% for the total score, with agreement on individual component steps ranging from 46–100%.	Not established.	Strength: Standardized tool for determining where to begin a meal preparation intervention protocol. Weakness: May not be sensitive enough to use with persons with subtle cognitive deficits.

<p><i>Executive Function Route-Finding Task (EFRT)</i> (Boyd & Sautter, 1993)</p>	<p>Patient is asked to find an unfamiliar location within the rehabilitation or health care setting as efficiently as possible. The therapist accompanies and observes the patient but may not answer questions about how to get there. Performance is rated in a number of domains including task understanding, information seeking, retaining directions, and error detection and correction, on-task behavior.</p>	<p>5–20 minutes (depending upon distance of unfamiliar location and patient's proficiency with route finding).</p>	<p>In a study involving persons with TBI, EFRT score was moderately correlated with Perceptual Organization ($r = 0.50, p < 0.05$) and Verbal Comprehension ($r = 0.44, p < 0.05$) subtest scores of the <i>Wechsler Adult Intelligence Scale-Revised</i>. Spikman, Deelman, and van Zomeren (2000) found that scores on the EFRT were statistically different in two domains when comparing the scores of persons with TBI and healthy controls (Judgment of Route, $p < 0.01$; Frequency of Cues, $p < 0.005$).</p>	<p>Good inter-rater reliability (Pearson $r = 0.94, p < 0.001$).</p>	<p>No information.</p>	<p>Strengths: Unstructured nature allows for observations related to executive functioning; ecologically valid assessment task. Weakness: No information about sensitivity or predictiveness relative to ADL and IADL functioning.</p>
<p><i>Kitchen Task Assessment (KTA)</i> (Baum & Edwards, 1993)</p>	<p>Measures cognitive support necessary for patient to prepare cooked pudding (neurobehavioral components are scored on a 0–3 scale, with total scores ranging from 0–18).</p>	<p>30–45 minutes.</p>	<p>Moderate to moderately strong correlation between KTA and 5 neuropsychological tests and 2 dementia rating scales (-0.46 to $-0.68, p < 0.001$).</p>	<p>Strong inter-rater reliability (0.853); strong internal consistency (correlation coefficients among subtests ranged from 0.72–0.84).</p>	<p>KTA scores are sensitive to stages of senile dementia of the Alzheimer's type ($p < 0.0001$).</p>	<p>Strength: Involves familiar, multistep functional task. Weakness: KTA was standardized on persons with dementia, and its appropriateness for other populations has not been established.</p>

Assessment Table 9-1

Summary of Assessments of Cognition (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Observed Tasks of Daily Living—Revised (OTDL-R)</i> (Diehl et al., 2005)</p>	<p>An assessment of everyday problem solving in which the patient performs 9 tasks related to medication use, telephone use, and financial management.</p>	<p>25–30 minutes.</p>	<p>OTDL-R scores were associated with measure of executive functioning (moderate correlation with the <i>Toglia Category Assessment</i>, $r = 0.506$, and moderately strong correlation with the <i>Deductive Reasoning Test</i>, $r = 0.796$) (Goverover & Hinojosa, 2002). OTDL-R scores were significantly different among 4 groups (community dwelling older adults, older adults living in nursing homes, individuals with schizophrenia, and individuals with brain injury) ($p < 0.001$) (Goverover & Josman, 2004).</p>	<p>Internal consistency for the total measure (Chronbach's $\alpha = 0.82$).</p>	<p>Not established.</p>	<p>Strength: Measure of everyday cognition that can be administered at bedside. Weakness: Does not provide a comprehensive picture of cognitive function, especially related to unstructured situations.</p>

CASE

EXAMPLE

Assessing Cognitive Function

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information</p> <p>D.B. is a 26-year-old single male who sustained a TBI as a result of a pedestrian–auto accident. Upon admission to the emergency room, he had a Glasgow Coma Scale score of 6, and records indicate that he was in a coma for approximately 10 days. In addition to the brain injury, D.B. sustained fractures in both legs, a tibia-fibula fracture on the right and fracture of the femur on the left. D.B. participated in inpatient rehabilitation for 3 weeks.</p> <p>D.B. graduated from college with a degree in law enforcement and worked in a rural community as a police officer at the time of his injury. His former girlfriend broke off the relationship approximately 1 month ago.</p> <p>Unable to return to his own apartment because of concerns about safety, D.B. was discharged from the inpatient rehabilitation unit to his brother's home. At approximately 3 months post TBI, D.B. was referred to outpatient occupational therapy to assess readiness for independent living. The occupational therapist focuses the assessment on D.B.'s ability to assume self-maintenance roles and identification of cognitive deficits interfering with role and task performance.</p>	<p>Understand the patient's diagnosis or condition</p> <p>Know the person</p> <p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>“D.B. had a severe brain injury and will likely have significant, long-term cognitive impairments. He sounds like someone who is used to being active and mobility restrictions may be confusing and frustrating. I wonder how he is getting around now that he is 3 months post injury.”</p> <p>“I know that I have certain stereotyped expectations of cops. I expect him to be sort of rigid and reluctant to take instructions from women. I know that I may be wrong about that. I wonder if D.B.'s girlfriend couldn't handle the changes related to the TBI or if there were longstanding issues that led to the recent breakup. Either way, D.B. must feel sad and isolated.”</p> <p>“I wonder what transpired during the past 2 months at the brother's home. How much of a role is the brother willing to play in this transition?”</p> <p>“Given his diagnosis and history, I presume that D.B.'s cognitive impairments are the biggest barriers to potential for independent living.”</p>
<p>Assessment Process</p> <p>The therapist selected the following evaluation tools: <i>Canadian Occupational Performance Measure (COPM)</i> to obtain information about the client's perceived problems and priorities; <i>Kohlman Evaluation of Living Skills (KELS)</i>; <i>Cognitive Assessment of Minnesota (CAM)</i> to obtain a general picture of cognitive capabilities; and systematic observation of the client's response to the presentation of homework.</p>	<p>Consider evaluation approach and methods</p>	<p>“Because he hasn't been assessed in occupational therapy for over 2 months, I want to get a full picture of his occupational functioning. The <i>COPM</i> will tell me about his priorities and give me a snapshot of his awareness of deficits. The <i>KELS</i> will give me a chance to observe him in a number of IADL-related tasks. <i>CAM</i> will give me a sense of his cognitive strengths and weaknesses and be useful in benchmarking cognitive change. His response to homework will help me observe his use of compensatory cognitive strategies.”</p>

Assessment Results

Based on an interview using the COPM, D.B. indicated that his ability to function independently was limited because of lower extremity fractures. He was dissatisfied with his inability to drive; the slowness with which he donned lower extremity clothing; his low stamina when walking outside the home; and lack of avocational outlets because of mobility limitations. When queried about known dependence on family members to take medications and his lack of initiation of self-maintenance tasks, D.B. quickly dismissed these reports as awkwardness associated with being a guest in their home.

D.B. needed assistance to perform two activities in the Money Management component of the *KELS* (use of banking forms, payment of bills). He seemed capable to carrying out basic arithmetic operations but made transcription errors that he did not detect or correct on his own. In areas of Self-Care and Safety and Health, he demonstrated adequate awareness of and responses to personal and household hazards.

On the *CAM*, D.B.'s scores in the areas of recall/recognition, problem solving, and abstract thinking ranked in the moderate to severe categories of impairment. Performance ranked within normal limits for such domains as orientation, following directions, immediate memory, temporal awareness, auditory memory and sequencing, and simple math and money skills.

During each of his two outpatient evaluation sessions, the therapist gave D.B. oral instructions specific to three homework assignments to complete at home, all of which he agreed to do but did not make note of. He completed none of them. He seemed motivated throughout the assessment and did not appear distracted by pain or emotional distress during his sessions.

Interpret observations

“D.B. seems to be quite aware about concrete changes in his mobility but less aware of possible cognitive changes related to initiation and memory of medications. I wonder how much family members are helping to prevent any errors in daily life that might otherwise give him feedback about his cognitive changes.”

“Simply because D.B. ‘passed’ the Self-Care and Health and Safety components of the *KELS* doesn’t mean I should set aside any concerns. This is a fairly structured test, and he might perform quite differently in a situation that required initiation and problem solving. I’ll want to look at this further over time.”

“D.B.’s performance on the *CAM* doesn’t surprise me all that much given the severity of his TBI. He seems to have a number of cognitive strengths that I think will really help him participate in the therapy process.”

“I’m guessing that D.B. has not had to take responsibility for keeping track of information in recent months; no doubt his brother has done that for him. I bet he hasn’t had much experience with his memory changes and doesn’t appreciate that he needs to compensate for these changes. He seems to be a really good candidate for outpatient rehabilitation at this point.”

Occupational Therapy Problem List

1. Decreased initiation of ADL and IADL
2. Decreased productivity due to poor stamina and limited repertoire of appropriate avocational outlets
3. Memory inefficiency and inadequate repertoire of memory compensation strategies
4. Decreased awareness of cognitive deficits interfering with compensatory strategy use

Synthesize results

“Overall, D.B. seems to have rather superficial awareness of his limitations; he acknowledges physical but not cognitive changes. His brother’s report of D.B.’s need for supervision with medications and prompts for ADL and IADL seem consistent with what I saw on his performance of the *CAM*. I don’t really feel like I have a good handle on his problem-solving capabilities because most of the evaluations were very structured in nature. I’ll want to incorporate opportunities for dynamic assessment into the treatment plan. I need to talk a little more with D.B.’s brother about the role he’d like to play in the therapy program. Maybe he needs a break and wants the team to take a more dominant role for a while.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Effects of Environment on Cognitive Function**

During his inpatient rehabilitation, D.B. was observed to have decreased attentional capacities, especially with complex tasks. How might this problem be evident during the occupational therapy homemaking assessment? What factors in the environment might exaggerate these problems? What factors might minimize them?

SUMMARY REVIEW QUESTIONS

1. Analyze bill paying and grocery shopping in terms of the specific cognitive capacities and abilities required.
2. Compare the advantages and disadvantages of the two approaches to cognitive assessment described in this chapter.
3. Describe each variable that influences a person's ability to think. How would you expect these variables to affect cognitive assessment of an elderly illiterate client? How would you expect these variables to affect cognitive assessment of a college student?
4. Explain the occupational therapist's contribution to the rehabilitation team in the realm of cognitive assessment. Specifically, outline the ways in which occupational therapy complements the assessments of other professionals and the unique elements of occupational therapy.

CHAPTER 10

Assessing Context: Personal, Social, and Cultural

Mary Vining Radomski

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the components of personal, social, and cultural context that influence occupational therapy assessment and guide treatment planning.
2. Employ methods for quantifying the influence of various contextual factors on performance.
3. Recognize the role of contextual factors in the development of conditional reasoning in clinical practice.
4. Examine his or her own contextual fabric—the personal, social, and cultural factors that shape the therapist's everyday experiences.

Glossary

Context—The whole situation, background, or environment that is relevant to a particular event or personality (Webster’s New World Dictionary, 1994).

Culture—The norms, values, and behavior patterns that serve as guidelines for people’s interactions with others and their environments (Krefting, 1991).

Cultural context—Stable and dynamic norms, values, and behaviors associated with the community or societal environments in which occupational functioning occurs.

Ethnicity—Membership by virtue solely of one’s birth in a racial, religious, national, or linguistic group (McGruder, 1998). In and of itself, ethnicity does not predict cultural identity.

Personal context—A person’s internal environment, derived

from stable and dynamic factors such as sex, age, mood, and cultural identity.

Social context—The social environment consisting of stable and dynamic factors such as premorbid roles, social network, and support resources.

Social network—An interactive web of people who provide each other with helpfulness and protection. Social networks typically vary in terms of reciprocity, complexity, intensity, and density (Heaney & Israel, 1997).

Social support—The aid and assistance (emotional, instrumental, information, and appraisal) exchanged through a social network (Heaney & Israel, 1997).

Spirituality—Beliefs and practices that give a person transcendent meaning in life (Puchalski, 1996).

Much as a phrase, punch line, or couplet can be understood only in the larger **context** of a story, joke, or poem, a client’s performance during occupational therapy assessment can be interpreted only in light of the broader context of his or her life and background. For example, lack of eye contact during an initial interview can easily be misinterpreted as lack of interest or motivation unless the therapist appreciates the contribution of cultural background—that avoiding eye contact is a way of showing respect in some **cultures**, including the Vietnamese culture (Farrales, 1996). Difficulty selecting clothing during a dressing assessment may be erroneously attributed to a patient’s poor decision-making skills unless the therapist appreciates the contribution of social role experiences—that for 50 years, the patient’s wife set out his clothing each morning.

The term *context* refers to the whole situation, background, or environment that is relevant to a particular event or personality; it has its roots in the Latin word *contexere*, to weave together (Webster’s New World Dictionary, 1994). Occupational therapists appreciate that a person’s function at any moment is shaped by a tapestry of contextual factors, and not solely by his or her capacities, acquired skills, and abilities. Without deliberate attention to these personal, social, cultural, and physical mediators of performance, therapists may misunderstand what they observe during assessment and risk assigning erroneous labels of dysfunction.

This chapter describes the personal, social, and cultural contextual factors that help or hinder performance during occupational therapy assessment. (Chapter 11 focuses on assessing contextual factors associated with the built or physical environment.) After summarizing the role of context in human functioning, this chapter discusses specific examples of personal, social, and cultural context in terms

of their potential for influencing occupational therapy assessment and intervention. Using these examples, readers are encouraged to reflect on other contextual factors not discussed herein. The role of context in occupational function cannot be exhaustively explored in one chapter; whole texts and careers have been devoted to each of these complex constructs. This overview, however, has one superordinate aim: to inspire therapists to try to interpret clients’ performance in the broader context of their background, changing circumstances, and envisioned futures.

CONTEXT AND OCCUPATIONAL FUNCTION

Occupational function is always embedded in context, with physical, cultural, social, and personal factors shaping its form (Nelson, 1988). Figure 10-1 depicts the interweaving of personal, social, cultural, and physical context that creates the parameters of a given occupational experience. Consider how minor changes in any dimension change the tapestry: a middle-aged homemaker preparing eggs and toast for her children before they leave for school versus a middle-aged homemaker preparing the same breakfast as part of an occupational therapy assessment.

The important role of context in occupational function is described by a number of models and frameworks from occupational therapy, rehabilitation, and health fields. Each of the models or frameworks summarized in Table 10-1 emphasizes the dynamic relationship between a person; his or her cultural, social, and physical contexts; and the continuum of function to disability relative to chosen roles and tasks.

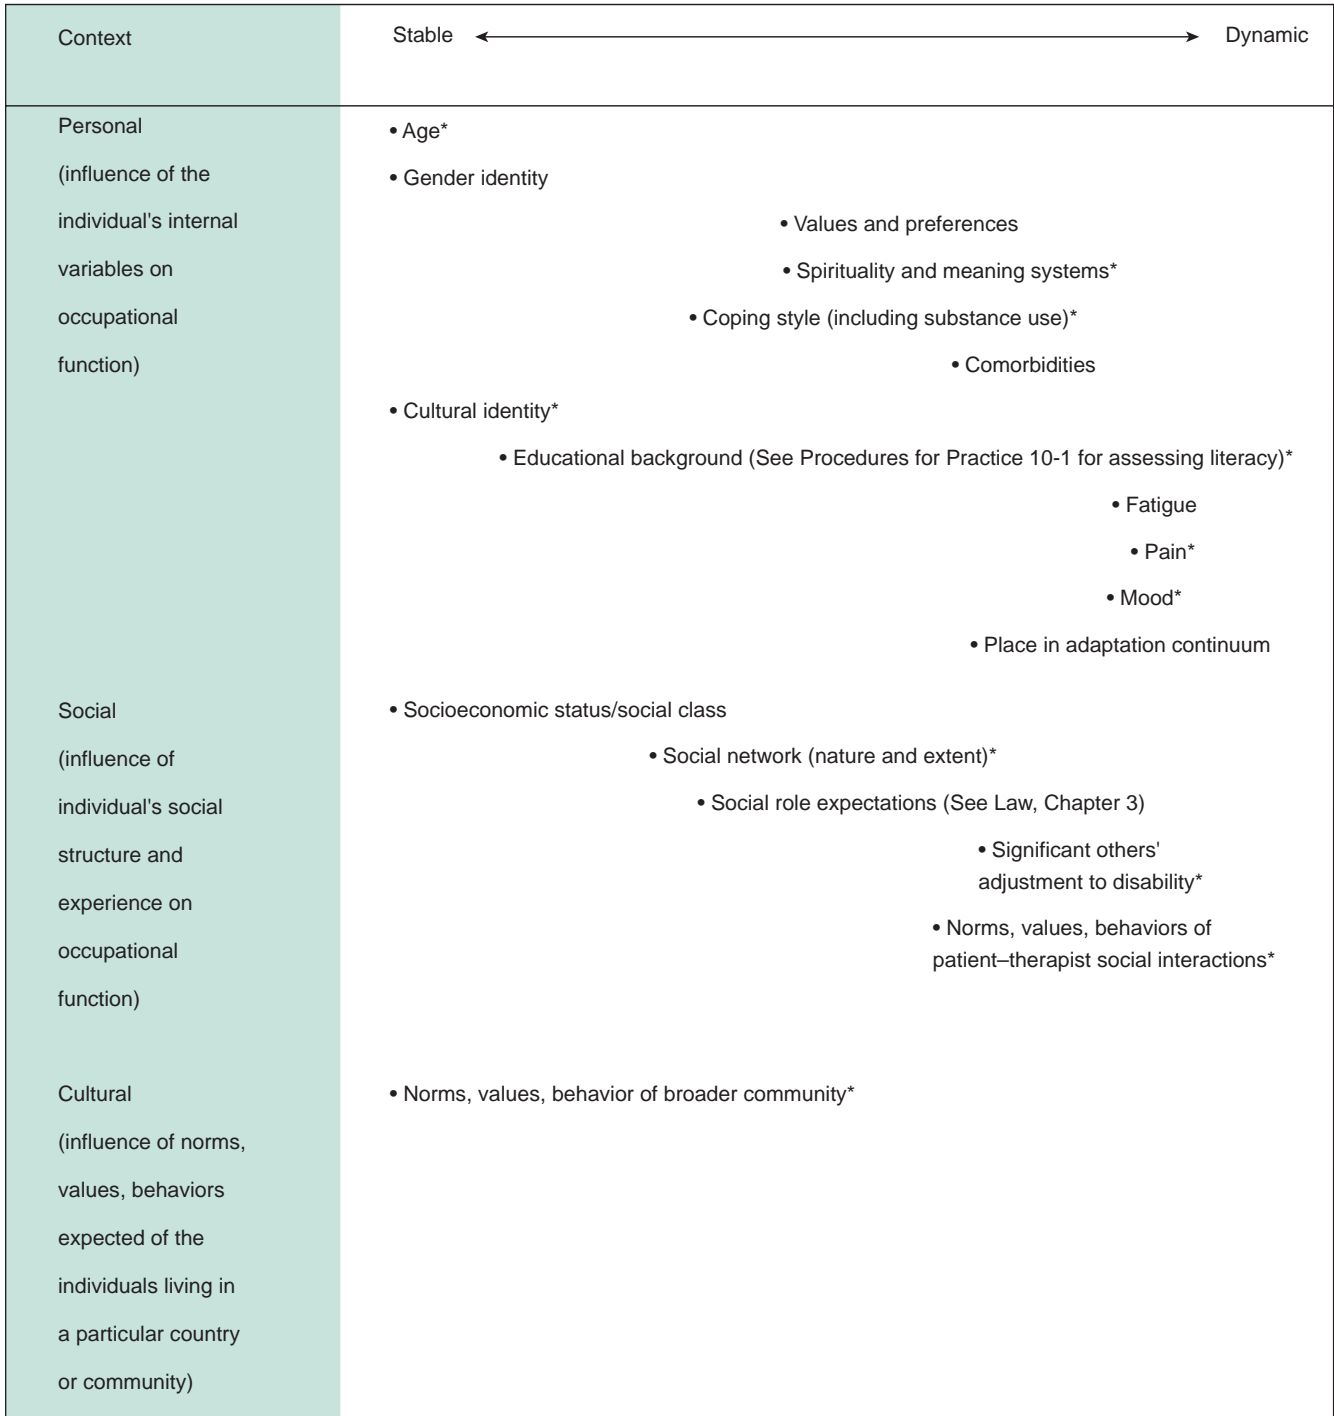

Figure 10-1 Interwoven tapestry of personal, social, cultural, and physical contextual factors.

The aforementioned models universally downplay the contribution of physical impairments and elevate the role of context in the explanation of human functioning and disablement but use slightly different terminology. In this chapter, contextual factors are presumed to be peripheral or unrelated to clients’ primary diagnoses or disabling conditions (World Health Organization, 2001) but central to the broad realms within which people carry out their lives.

- **Personal context** reflects an individual’s internal environment derived from his or her gender, values, beliefs, cultural background, or state of mind.
- **Social context** refers to factors in the human environment (roles, resources, and structure) that enable or deter the person’s occupational function.
- **Cultural context** has to do with the norms, values, and behaviors related to the community or society in which the occupational function occurs.

The convenience of describing personal, social, and cultural contextual factors as separate and distinct entities

Table 10-1. Selected Models or Frameworks that Specifically Include Context as an Element in Human Function	
Models and Frameworks	Synopsis of Role of Context in Occupation and/or Human Function
Ecology of Human Performance (Dunn, Brown, & McGuigan, 1994)	The interaction between a person and the environment affects his or her behavior and performance. Human performance can be understood only through the “lens” of context, which includes temporal (age, development, health status), physical, cultural, and social features that operate external to a person. In essence, the inter-relationship between person and context determines which tasks fall within the individual’s performance range.
Person-Environment-Occupation Model of Occupational Performance (Law et al., 1996)	Occupational function is the result of the transactive relationship “between people, their occupations and roles, and the environments in which they live, work, and play” (p. 9). This model emphasizes the interdependence of person and environment (defined as those contexts and situations which occur outside the individual such as cultural, socioeconomic, institutional, and social considerations). It also recognizes the temporal or changing nature of person, environment, occupation characteristics, and their inter-relationships.
Occupational Therapy Intervention Process Model (Fisher, 1998)	Occupational performance occurs as a “transaction between the person and the environment as he or she enacts a task” (p. 514). Therapists must be aware of the client’s performance context (comprised of temporal, environmental, cultural, societal, social, role, motivational, capacity, and task dimensions) to understand, evaluate, and interpret a person’s occupational performance.
International Classification of Functioning, Disability, and Health (World Health Organization, 2001)	“A person’s functioning and disability are conceived as a dynamic interaction between health conditions and contextual factors” (p. 10). Contextual factors include personal and environmental factors. Personal factors are internal influences of functioning that are not part of a health condition or functional state such as gender, age, social background, fitness, lifestyle, and habits. Environmental factors, external influences on functioning, include features of the physical, social, and attitudinal world.
Occupational Therapy Practice Framework (American Occupational Therapy Association, 2002)	The overarching outcome of occupational therapy is to advance clients’ engagement in occupation to support life participation in the context of their unique situations. As such, “context” (cultural, physical, social, personal, spiritual, temporal, virtual) is included in the domain of occupational therapy. Context is viewed as affecting occupational performance as well as an underlying influence on the process of service delivery.

* These factors are discussed in this chapter.

Figure 10-2 Examples of interrelated personal, social, and cultural contextual factors.

believes their complexity, inter-relatedness, and interactive influences (Fig. 10-2). Krefling (1991) described the pervasive influence of culture on community, families (norms, values, and behaviors related to social context), and individuals (such as distinctive food preferences, humor, definition of personal space; in this chapter, considered to be a part of personal context). Likewise, personal context may influence

social and cultural context. For example, a person's spiritual beliefs often shape his or her **social network**, preferred roles, and definitions of acceptable behavior.

Personal, social, and cultural contextual factors can be examined on a continuum of highly stable to highly dynamic. The relatively stable factors, such as age, gender identity, and premorbid coping style, tend to pervade

most tasks and situations and are not easily changed in occupational therapy. For example, a patient's educational background may affect how the therapist provides home instruction but is unlikely to be a focus of intervention (Procedures for Practice 10-1). On the other hand, the more dynamic contextual factors are transient and situational and more responsive to environment, task, and therapy than stable contextual factors. The headache that interferes with an individual's concentration today will likely be better tomorrow. The spouse's ability to use resources and encourage his or her loved one's independence changes as both patient and spouse adapt to the sequelae of stroke.

Importance of Personal, Social, and Cultural Context to Assessment

Personal, social, and cultural contexts influence occupational therapy assessment and treatment in at least three ways. First, contextual factors mediate (help or hinder) performance on traditional occupational therapy assessments, skewing the results and muddying their interpretation. For example, Mr. J.'s difficulty attending to instructions during a homemaking assessment might be interpreted as solely a cognitive impairment related to his right cerebrovascular accident if the therapist did not know he was awake much of the previous night as nurses addressed his roommate's dete-

PROCEDURES FOR PRACTICE 10-1

Assessing Literacy

Occupational therapists use written materials in assessment and treatment. Clients with low literacy may try to hide their difficulties with reading, compromising the assessment and the value of written home instructions (Parikh et al., 1996). Use of a reading screen allows the clinician to identify patients who need simplified, audiotaped, or pictorial education materials.

The *Rapid Estimate of Adult Literacy in Medicine (REALM)* (Murphy et al., 1993) is a reading recognition test that takes 2–3 minutes to administer and score. It contains three columns of health-related words of increasing difficulty, with 66 words in all. The client is asked to start at the top of list 1 and read the words aloud until he or she completes the three lists or is unable to read additional words. He or she is allowed 5 seconds to pronounce each word. The clinician takes note of all words pronounced correctly; this number becomes the raw score that is converted to grade range estimates. Murphy et al. (1993) suggested that patients who score below the 9th-grade level need adapted education materials.

REALM Grade Estimate

Raw Score	Estimated Grade Range and Practical Meaning
0–18	Third grade and below These patients may not be able to read most educational materials and probably cannot even understand simple prescription labels. Repeated oral instructions will be needed to enhance compliance; the doctor cannot simply write a prescription or give standard levels of instruction and expect compliance. Materials, including simple video and audio tapes, may be helpful if a health care worker is present during their use and is available to answer questions. Repeated oral instructions will be the key to establishing long-term compliance.
19–44	Fourth to sixth grade Tremendous potential for improvement exists in this group. They should respond well to direct instruction by health care providers and should be able to read and comprehend materials written on elementary school levels. Appropriately written materials may still require one-on-one counseling for adequate understanding.
45–60	Seventh to eighth grade These patients will certainly benefit from appropriately written materials, but material (both oral and written) should not be too simple (e.g., first grade) or too complex. Material written for a fourth- to sixth-grade level may be appropriate.
61–66	Ninth grade and above These readers can understand much high school-level material presented to them; therefore, current educational brochures may be effective. These individuals should also be able to converse with their physicians about matters of lifestyle.

riorating medical condition. Second, contextual factors may be facilitators or barriers to function and therefore targets of occupational therapy intervention. Consider the influence of social context on occupational therapy goals. Despite adequate strength and technical skills, Mrs. S. remains dependent in lower extremity dressing after her total hip replacement because her husband, fearful that she may overexert, insists on assisting with dressing. The home health therapist, who brings his or her own biases regarding the goal of independence, ultimately collaborates with Mr. and Mrs. S. regarding their expectations of therapy. Should they choose to work toward complete independence in self-care, the therapist helps Mr. S. become comfortable with Mrs. S. dressing herself and helps Mrs. S. improve her skills. Finally, throughout the assessment, occupational therapists trawl for glimpses of what clients find meaningful—lures to hook them into therapy. Each dimension of context holds such possibilities as goals are set and intervention is planned.

Conditional Reasoning

Awareness of interwoven contextual factors is a foundation for what Mattingly and Fleming (1994) describe as conditional reasoning: viewing the client as a complex composite of premorbid characteristics and preferences, condition-specific limitations, and future potentialities.

“Therapists try to understand what is meaningful to the patients, and to their perceptions of themselves and others in the physical and social contexts in which they experience their lives. To do this, therapists need an ability to imagine the clients, both as they were before the illness, and as they could be in the future. They also need to be able to enlist the patients in imagining a possible future for themselves” (Mattingly & Fleming, 1994, p. 197).

Conditional reasoning enables the therapist to appreciate the wholeness of the client and his or her situation. Although it is more often employed by experienced therapists than novices (Mattingly & Fleming, 1994), one may presume that desire to learn may expedite the acquisition of this mindset.

Looking in the Mirror: Therapist as Contextually Influenced Being

Appreciation for the influence of personal, social, and cultural context requires that therapists acquire a complex combination of knowledge, attitudes, and skills. The goal is to shift from viewing how a client can fit into the therapist’s world to examining how the therapist can understand and fit into the client’s world (St. Clair & McKenry, 1999). To accomplish this shift, therapists must acknowledge and inventory the personal, social, and cultural factors that influence their own function. As I become aware of my own beliefs and biases, social background, and culturally based expecta-

tions, I will be able to appreciate their influence on collaborations with patients and coworkers (Odawara, 2005).

In summary, clinicians need not obsess about correctly labeling or pigeonholing each and every contextual factor. Rather, therapists aim to tease out various contributions to clients’ performance during assessment so as to inform intervention planning by asking whether this person’s present performance is influenced by the following:

- Personal, social, or cultural factors that obscure identification of strengths or weaknesses in occupational function
- Longstanding personal, social, or cultural factors that are unlikely to change as a result of therapy
- Personal, social, or cultural factors that are transient or situational; factors that may be affected by occupational therapy intervention
- The therapist’s personal, social, or cultural contextual factors

PERSONAL CONTEXT

“Life is suddenly reduced to a one dimension picture, known as physical function, and continually referred to as ‘outcome.’ The typical outcome process ignores . . . emotional and interpersonal needs and skills. Within those parameters lies the answer to true recovery . . . I refuse to have an ‘outcome.’ I do have a life!” (Cannon, 1994, p. 3)

Personal context refers to the intrapersonal environment that shapes an individual’s experience. These factors play a role in determining the client’s unique response to the onset of illness or impairment and contribute to his or her ability to adapt (National Center for Medical Rehabilitation and Research, 1993). Some aspects of a person’s internal environment, such as age and longstanding beliefs, are stable; others, such as pain, mood, and adaptation to illness or injury (see Chapter 35), may be constantly in flux.

Personal Demographics: Age

A person’s age influences his or her occupational functioning in three primary ways: (1) age-related changes in capacities and abilities; (2) developmental shifts in goals, values, and priorities; and (3) the individual’s generation-based worldview.

Table 10-2 summarizes typical changes in capacities and abilities associated with normal aging. In tandem with physiological changes in capacities, Royeen (1995) hypothesized that people undergo “occupational shifts” (p. 11) during the life cycle that lead to major changes in patterns

Table 10-2. Age-Related Changes in Physical and Cognitive Capacities and Abilities

Age Group	Physical Development	Cognitive Development
20s	<ul style="list-style-type: none"> Fully developed body shape and proportions (except weight and body mass, which fluctuate throughout a person's life) Peak muscle strength achieved Fully mature reproductive systems, with both sexes experiencing involuntary cyclic alterations in sex hormone production 	<ul style="list-style-type: none"> Peak brain cell development (although the final number of neurons and supportive cells that a person possesses is determined by the end of the first year of life) Memory capacity peaks with the brain's greatest mass Gradual shrinkage of brain cells at around age 30, but because of the vast number of unused brain cells, these changes do not impact function
30s and 40s	<ul style="list-style-type: none"> Gradual slowing of body functions (dependent on diet, exercise, stress, genetic predisposition, and presence of disease) Without regular exercise, gradual loss of muscle size and strength and bone mass and density Decreasing elasticity in cardiorespiratory system, resulting in gradually decreasing respiratory capacity and increasing blood pressure Beginnings of hearing loss (first limited to high pitches) Beginnings of presbyopia (affecting near vision), which necessitates reading glasses or bifocals 	<ul style="list-style-type: none"> Continued gradual brain shrinkage but increasing life experiences result in high mental acumen
50s and 60s	<ul style="list-style-type: none"> Physical changes of previous decades continue at a faster rate and to a greater extent Fewer calories are required (necessitating changes in intake and/or activities to maintain weight) Changes in amounts and patterns of hormone production affecting metabolism, energy, sexuality, and reproduction 	<ul style="list-style-type: none"> Continued brain shrinkage offset by reservoir of life experience, wisdom, and judgment
70s and older	<ul style="list-style-type: none"> Loss of vestibular function in inner ears, resulting in decreased balance Steady deterioration of vision and hearing Loss of cartilage and connective tissue, leading to decreased range of motion, pain, and postural changes Reduced appetite due to inactive taste buds and changes in digestion Changes in metabolism, making it more difficult to adapt to changing temperatures 	<ul style="list-style-type: none"> Decreasing memory capacity Decreasing abilities in areas of abstract reasoning and novel problem solving Enriched perspectives based on lifelong learning and integrated experiences

Summarized from Freiberg, 1987.

of activity. She posited that early adulthood is characterized by establishing worker roles while realigning social roles to adjust to marriage and parenthood. In middle adulthood, people maintain work and leisure roles but may undergo sudden occupational shifts related to caregiving roles of parents, children, and grandchildren. During maturity (45 years to retirement), people continue their work and leisure roles, but occupational shifts arise from death of family members, loss of provider status, and adjustments in life goals. Persons in old age must adjust to changes in role performance commensurate with deterioration of physical and mental capacities.

Finally, a person's age location in history may influence his or her personality and beliefs (Lancaster & Stillman, 2002; Strauss & Howe, 1991). Although clinicians avoid jumping to conclusions about patients based on age, consider the ways in which generational identity may influence participation in occupational therapy for five contemporary generational groups in the United States:

- G. I. elders (born 1901–1924) strive for public harmony and cooperative social discipline and subscribe to a philosophy that optimism and hard work guarantee goal achievement.

- Silent midlifers (born 1925–1942) appreciate a variety of mindsets, virtues, and flaws and subscribe to a philosophy that promotes compromise and consensus as means to happy endings.
- Boomer adults (born 1943–1960) view their own opinions and perspectives as morally correct and subscribe to a philosophy suggesting that adherence to moral ideals leads to satisfying experience.
- Generation Xers (born 1961–1981) typically identify the need for personal determinism and subscribe to a philosophy that elevates the acquisition of money to personal survival in response to perceived uncertainties in their economic future.
- Millennials (born 1981–2000), who tend to be practical and techno-savvy, have a unique appreciation for diversity—variety in people, environments, and activities. They are accustomed to participant-oriented decision making and expect to work in collaboration with others in their endeavors (Lancaster & Stillman, 2002).

Of course, generalizations about patterns of aging may or may not apply to specific individuals, and therapists are cautioned against age-related patient biases (Rybarczyk et al., 2001). Human function over time is influenced by an array of factors, such as lifetime habits related to diet and exercise, stress, genetic predispositions, and sociocultural background (Freiberg, 1987). Catastrophic loss of function, as with illness or disability, takes place against a backdrop of other age-related changes, developmental tasks, and worldviews. For example, a person's adaptation to a spinal cord injury may occur as he or she is also adapting to a new marriage or career. An elderly patient's efforts to relearn motor skills and standing balance may be complicated by declines in capacities associated with age and beliefs that, if a person works hard enough, he or she will always achieve goals. A client who has lived and aged with a long-standing disability will likely have different health concerns and vulnerabilities than a young person with a new injury (Amsters et al., 2005).

Coping Strategies and Beliefs

Premorbid coping styles and long-term spiritual beliefs and meaning systems influence peoples' reactions to catastrophic injury and chronic illness.

Coping Style

The ways that people typically face stressful circumstances affect whether they seek health-related services and the extent to which they follow professionals' advice (Lerman & Glanz, 1997). Coping styles are relatively stable characteristics of a person and are thought to mediate the effects of stress on function (Lerman & Glanz, 1997). (Procedures for Practice 10-2 describes assessment of substance use, a maladaptive coping style.)

Lerman and Glanz (1997) summarized two aspects of coping. Consider how each of them contributes to or derails occupational therapy assessment and treatment when they are part of the client or therapist's longstanding coping style.

- Optimism is the tendency to have positive rather than negative expectations for outcomes. Optimism is associated with relatively few physical symptoms during stress, and it predicts psychological adjustment. Optimists tend to use active coping strategies, such as planning, problem solving, and acceptance rather than avoidance.
- Locus of control is a general belief about one's ability to control relevant life circumstances and events. People with an internal locus of control are likely to take

PROCEDURES FOR PRACTICE 10-2

Assessing Possible Substance Abuse

Alcohol use is a risk factor for spinal cord and brain injury (Bogner et al., 2001; Kolakowsky-Hayner et al., 1999). Kolakowsky-Hayner et al. found alarmingly high rates of pre-injury heavy drinking among patients who were treated in a Level I trauma center and subsequently in rehabilitation (57% of patients admitted with spinal cord injury, 42% of patients admitted with traumatic brain injury). Pre-injury substance abuse has been associated with worse rehabilitation outcomes (Bogner et al., 2001; Moyers & Stoffel, 1999) and predicts post-injury substance abuse (Kolakowsky-Hayner et al., 1999). Despite the implications for rehabilitation, health care providers are often reluctant to ask patients about substance use because of time constraints, lack of knowledge, and reluctance to intervene (Taj, Devera-Sales, & Vinson, 1998).

An occupational therapist who suspects that a patient is a substance abuser has an ethical obligation (Moyers & Stoffel, 1999) to perform a screening test and, if indicated, refer the patient for further assessment and intervention. Here are two screening methods.

- Ask a pointed question. Taj, Devera-Sales, and Vinson (1998) were able to identify 74% of at-risk or problem drinkers when physicians incorporated a simple question into their routine examinations (“On any single occasion during the past 3 months, have you had more than 5 drinks containing alcohol?”). They presented the alcohol screening question between two other general health questions (“In the past 3 months, have you used tobacco?” and “Do you regularly wear your seat belt when riding in the car?”) (p. 329).
- Use a mnemonic when interviewing clients about suspected alcohol abuse. The CAGE *Questionnaire* (Ewing, 1984) asks 4 questions related to patients' perceptions of need to **cut** down, **annoyance** with criticism, **guilt** about drinking, and need for a drink as an **eye-opener** first thing in the morning.

responsibility for change, while those with an external locus of control tend to expect other people or factors ultimately to determine a particular outcome. The assumption that one can affect one's circumstances leads to active coping and goal-directed activity that influence outcome.

Spirituality

Spirituality refers to the beliefs and practices about the world and one's place in it that give a person transcendent meaning in life (Egan & Swedersky, 2003; Puchalski, 1996). These beliefs may be expressed as a religious faith or directed toward nature, family, or community. It reflects a person's overriding system of meaning that influences use of time, choice of actions, and perceptions of purpose. As such, spirituality is central to a person's occupational function (Christiansen, 1997). In a survey of 270 registered occupational therapists in the United States, 84% of the respondents viewed spirituality as an important dimension of health and rehabilitation, but fewer than 40% of the respondents thought their patients' spiritual needs were within their scope of practice (Engquist et al., 1997). Even therapists who believe that spirituality has a role in occupational therapy practice express concerns about their lack of experience or education in addressing clients' spiritual concerns (Collins, Paul, & West-Frasier, 2001).

Therapists who do incorporate spirituality into their practice do so by dealing with clients' religious concerns, encouraging patients' core sense of self, and addressing or confronting patients' experience of suffering (Egan & Swedersky, 2003). In a survey of 112 occupational therapists, over 63% of the respondents reported that they had occasionally or frequently discussed the fear of death and dying, meaning or purpose of illness, or faith, belief, or religion with their patients (Collins, Paul, & West-Frasier, 2001). These connections with clients become opportunities for the therapist's development as well (Egan & Swedersky, 2003).

Riley et al. (1998) suggested that knowledge of a client's spiritual beliefs informs treatment planning and intervention and "is clearly too important a variable to be neglected in the rehabilitation process" (p. 263). Procedures for Practice 10-3 suggests ways to discuss coping, spiritual belief, and meaning systems with patients.

Cultural Background and Identity

Culture is an information-based system that provides guidelines for peoples' interactions with others and their environments (Baumeister, 2005; Krefting, 1991). Although socialization teaches these guidelines for values, beliefs, and behavior patterns, culture is emergent, dynamic, and interactional (Bonder, Martin, & Miracle, 2004). Culture is not biologically inherited or determined by geography or **ethnicity** (Krefting, 1991). Ethnicity is defined as

"membership, conveyed by birth, in a racial, religious, national, or linguistic group" (McGruder, 1998, p. 55). It may have implications in economic, social, and political realms, but contributes little to a therapist's appreciation of a patient's personal context. Furthermore, clinicians are cautioned about the reliability and accuracy of ethnic designations in hospital records (Stansbury et al., 2004). Because there is as much variation within ethnic groups as between them (McGruder, 1998), a person's ethnic background is not a reliable gauge of his or her cultural identity.

The influence of culture on a person's experience is hard to state precisely. Although cultural rules are learned, they are also graded, flexible, task- and environment-specific, and often self-selected. For example, the degree to which immigrants have assimilated the customs and patterns of behavior of their new country or region is determined by how recently they emigrated, the primary language spoken at home, and the amount of contact with their homeland (Krefting, 1991). People adopt the culture of specific subgroups and environments; the expectations for behavior of a clinician in an occupational therapy clinic are different from expectations for a broker working at the New York Stock Exchange. The dynamic influence of culture on human experience requires that clinicians resist attempts to characterize or stereotype clients based on ethnic or geographical background. Rather, occupational therapists attempt to recognize and then step outside of their own cultural backgrounds and biases to appreciate and accept the culturally based customs, values, and beliefs of each client (Procedures for Practice 10-4).

Many occupational therapy evaluation tools are based on norms developed for a white middle-class population (Krefting, 1991; Paul, 1995). Culturally reflective clinicians assess the cultural validity of their standardized assessment tools (Krefting, 1991) and select criterion-referenced and norm-referenced tests appropriate for the person's background (Paul, 1995). Paul described the challenges of devising culturally unbiased tests that include only items that reflect knowledge, experiences, and skills common to all cultures. He recommended the use of culture-specific evaluation tools, which include items relevant to a specific cultural group, when available. Practically speaking, it is impossible to locate culture-specific tools for all of the diverse cultural groups in North America. Therefore, therapists must make every effort to attempt to understand a client's individual cultural background before interpreting performance on the most appropriate standardized tests.

Pain

Pain, acute and chronic, interferes with occupational function and quality of life for many people receiving occupational therapy services (Ehde et al., 2003). People with spinal cord injury who use manual wheelchairs report upper

PROCEDURES FOR PRACTICE 10-3

Assessing Patients' Coping, Spiritual Beliefs, and Meaning Systems

People typically share personal information with those they trust. Therefore, to explore patients' beliefs and meaning systems, therapists invest in establishing therapeutic rapport (see Chapter 15). Without the rapport that comes with time and consistency of care providers, patients may perceive questions about their spirituality, for example, as intrusive or offensive. Therapists who are aware of their own coping strategies and belief systems will be best able to comfortably discuss these issues with their patients.

In general, discussions of these very personal and potentially sensitive matters begin at a superficial level and progress to deeper, more personal levels as dictated by the patient and therapist's comfort with each other and the subject matter. Here are examples of this progression.

- Ask the client to provide an hour-by-hour account of a typical day prior to the injury or onset of illness (Radomski, 1995). How a person is used to spending his or her time richly defines his or her valued activities and priorities.
- Take a brief life history, asking the patient to give you an overview of his or her life course, including past goals and obstacles (Kleinman, 1988). People often use stories or narratives to make connections and meaning attributions between a series of life events (Mattingly, 1991).
- Ask the patient about his or her explanatory model of the illness or disability. Kleinman (1988) suggested that faced with illness, disability, or suffering, people attempt to construct models to explain the whys of their experiences. They make attributions about causation and outcome that are more likely to be based on personal beliefs and culture than on facts or medical information. For example, patients may feel responsible for permanent impairments because they didn't try hard enough in rehabilitation to overcome them (Luborsky, 1997). If the person views onset of illness or disability as God's punishment for a past sin or mistake, he or she may not feel empowered to invest in rehabilitation efforts. Only as patients' explanatory models are acknowledged may they be negotiated with the therapist or health care team (Kleinman, 1988).
- Cox and Waller (1991, p. 86) suggested that clinicians ask patients about past experiences in which their coping skills were taxed:
 1. When you're discouraged and feeling despondent, what keeps you going?
 2. Where have you found strength in the past?
 3. What have you done in the past when you've lost someone or something important?
 4. What do you think the message in this is for you?
- Puchalski and Romer (2000) recommended an acronym for aspects of a spiritual assessment (*F*, Faith; *I*, Importance and influence; *C*, Community; and *A*, Address).
 - F. What things do you believe in that give meaning to your life?
 - I. How have your beliefs influenced your behavior during this illness? What roles do your beliefs play in regaining your health?
 - C. Are you a part of a spiritual or religious community? Is this a support to you and how?
 - A. How would you like me, your health care provider, to address these issues in your health care?

extremity pain, with the most severe pain occurring while pushing the wheelchair up an incline and during sleep (Curtis et al., 1999). Dalyan, Cardenas, and Gerard (1999) found that upper extremity pain was associated with lower employment rates and greater disability for outpatients with spinal cord injury. Finally, many stroke patients have upper extremity pain as well, typically beginning 2 weeks after the onset of stroke (Chantraine et al., 1999). In addition to its contribution to disability and to decreased quality of life, pain is linked to depression (Dalyan, Cardenas, & Gerard, 1999) and inefficiencies in information processing (Luoto et al., 1999).

Pain is a highly personal experience (Dudgeon et al., 2002); an individual's pain in the present is influenced by

his or her recollections of past pain, expectations of pain, and perceptions regarding its cause (Smith, Gracely, & Safer, 1998). Many people with disabilities are used to living with pain, differentiating between usual pain and unexpected pain (Dudgeon et al., 2006). Because many recipients of occupational therapy services may be reluctant to mention their concerns about pain to therapists (Dudgeon et al., 2002), therapists take responsibility to routinely ask and/or assess.

Million et al. (1982) described two categories of pain assessment techniques: (1) those that assess the patient's subjective experience with pain and limitations in activities and (2) those that quantify physical signs, such as moving during a physical examination and biochemical

PROCEDURES FOR PRACTICE 10-4

Cultural Assessment

Experts advise against using cultural cookbooks to gain insights about culturally based habits and behaviors of various ethnic groups, as they can lead to stereotyping individual patients (Krefting, 1991; Lipson, 1996). Instead, therapists consider the unique influence of culture on each individual's experience by carefully attending to nuances of body language, word choice, and gestures and adopting an attitude of curiosity about each client's situation and background (Bonder, Martin, & Miracle, 2004).

Lipson (1996, p. 3) suggested the following questions as key elements of a cultural assessment of any patient. Occupational therapists may get the answers to these questions in the medical record or talk directly with patients or loved ones.

- Where was the person born? If an immigrant, how long has the patient lived in this country?
- What is the patient's ethnic affiliation, and how strong is the patient's ethnic identity?
- Who are the client's major support people, family members, or friends? Does he or she live in an ethnic community?
- What are the primary and secondary languages and the speaking and reading ability?
- How would you characterize the nonverbal communication style?
- What is the person's religion, its importance in daily life, and current practices?
- What are his or her food preferences and prohibitions?
- What is the person's economic situation, and is the income adequate to meet the needs of the patient and family?
- What are the health and illness beliefs and practices?
- What are the customs and beliefs around such transitions as birth, illness, and death?

changes during activity. Beyond observing function and behavior, the former methods seem most appropriate for occupational therapists. Two commonly used subjective measures of pain are described: the *McGill Pain Questionnaire—Short Form (MPQ-SF)* (Melzack, 1987) and the *Visual Analog Scale (VAS)* (Huskiison, 1974; Million et al., 1982).

McGill Pain Questionnaire—Short Form

The *MPQ-SF*, adapted from the *McGill Pain Questionnaire* (Melzack, 1975), is widely used to measure pain and response to pain interventions (Melzack, 1987). The tool

has three components. First, patients are asked to rate descriptors from two categories that best describe the characteristics of their pain. These 15 descriptors are rated on a 0 to 3 intensity scale and then summed. The following are examples: throbbing, shooting, cramping, and sickening. The patients also complete two indices of the overall intensity of their pain (*Present Pain Index* and *VAS*).

Visual Analog Scale

The *VAS* is a self-administered measure of pain intensity. Patients are asked to indicate the severity of their pain by marking a point on a 10-cm line on which the end points are labeled "Pain as bad as it could be" or "No pain" (Huskiison, 1974). The rating is converted to a score by measuring the distance of the mark from the origin of the scale. Million et al. (1982) suggested that asking patients to provide one global rating of pain demands that they provide a singular estimate of their pain experience across time and situation, when in reality, pain varies with time and activity. Therefore, they developed 15 questions related to severity of pain associated with various activities, each accompanied by a *VAS*. Each question is answered as the patient marks the *VAS* based on the continuum of symptoms or limitations. The ends of each scale are described with extreme answers to the question. Here are two examples:

- Does your back pain interfere with your freedom to walk? (Complete freedom to walk—completely unable to walk)
- To what extent does your pain interfere with your work? (No interference at all—totally incapable of work) (Million et al., 1982, pp. 211-212).

Because it is brief, reliable, and valid, the *VAS* is often used to screen inpatients and outpatients for acute pain-related concerns, in compliance with hospital accreditation requirements (Joint Commission on Accreditation of Healthcare Organizations, 2005). The *VAS* will likely not provide adequate information to inform occupational therapy assessment or intervention for persons with chronic or variable pain.

Questionnaires and numerical or *VAS* scales should be the catalysts for, rather than replacements of, more in-depth conversations with clients about their experience with pain. A one-time rating of pain often does not represent the variability of pain that some clients experience (Zelman et al., 2004). Occupational therapists will be best equipped to interpret occupational assessment findings if they go beyond obtaining a snapshot of a client's static pain. Conversations to explore the extent to which pain levels are manageable or tolerable will be a prelude to problem solving about the kinds of strategies that might help (Zelman et al., 2004).

Mood

Many people who receive occupational therapy services have mood disorders, such as depression and anxiety (Arruda, Stern, & Sommerville, 1999). Almost one third of geriatric rehabilitation inpatients are thought to be depressed (Cully et al., 2005). Persons with spinal cord injury, traumatic brain injury (Kreuter et al., 1998), and Parkinson’s disease (Meara, Michelmore, & Hobson, 1999) tend to be more depressed than the general population. Early identification and treatment of mood disorders is important, as depression and anxiety appear to interfere with attention and concentration during assessment (Eysenck & Keane, 1990) and negatively influence outcome of intervention (Lai et al., 2002). Although occupational therapists do not diagnose mood disorders, they have numerous opportunities to observe behavior. According to Scherer and Cushman (1997), certain patterns of behavior may indicate psychological distress and warrant referral to a psychologist or psychiatrist for further assessment and treatment.

Depression

People feeling transitory sadness and discouragement or normal grief may display signs that are similar to those of depression, but will differ in terms of persistence of symptoms and their effect on self-esteem (Gorman, Sultman, & Luna-Raines, 1989). That is, sadness and normal grief resolve with time and generally do not lead to lowered self-esteem, as suggested by the following signs of possible clinical depression (Gorman, Sultman, & Luna-Raines, 1989; Scherer & Cushman, 1997):

- Significant declines in functioning lasting 2 weeks or more
- Feelings of worthlessness, inadequacy, self-doubt
- Diminished interest in virtually all activities, even formerly enjoyable activities
- Depressed or irritable mood most of the time
- Vegetative disturbances: lethargy; insomnia or excessive sleep; change of appetite with weight change of more than 5%; periods of excessive activity or slowness almost every day
- Very poor concentration
- Withdrawal from social interaction
- Recurrent thoughts of death or suicide

Anxiety

Anxiety is defined as a “subjectively painful warning of impending danger, real or imagined, that motivates the individual to take corrective action to relieve the unpleasant feelings and is experienced both psychologically and physiologically” (Gorman, Sultman, & Luna-Raines, 1989, p. 51).

Anxiety is different from fear. Anxiety is characterized by a diffuse feeling of dread, whereas fear is a reaction to a specific temporary external danger (Gorman, Sultman, & Luna-Raines, 1989). Here are some signs of possible anxiety disorder (Gorman, Sultman, & Luna-Raines, 1989; Scherer & Cushman, 1997) that may prompt referral to a psychiatrist or psychologist:

- Panic attack (choking feeling, nausea, dizziness, palpitations or chest pain, fear of dying or losing control)
- Distorted, unrealistic fears or perceptions of a situation or object
- Disruption of normal routines or daily activities associated with irrational fears

Despite their best intentions, occupational therapists often have difficulty recognizing these disorders. Therefore, occupational therapists are advised to use standardized screens to identify patients in need of psychological or psychiatric services (Ruchinskis, 2002). The *Hospital Anxiety and Depression Scale* (Zigmond & Snaith, 1983) and the *Beck Depression Index-FastScreen for Medical Patients* (Beck, Steer, & Brown, 2000) are good examples.

SOCIAL CONTEXT

“In the acute stages of an illness, it’s easy to be a good friend—exhausting but rewarding to nurse a loved one back to health. But her health never returned and chronic care takes tenacious strength when you’re also battling grief. I often feel unequal to the challenge.” (Osborne, 1998, p. 46)

Social context, including the person’s social resources, roles, and preferences, influences occupational pursuits, satisfaction, health, and well-being (Helliwell & Putnam, 2004). For example, some people select tasks and activities that put them in contact with a social network; others select occupations that allow them to avoid social interaction, as in the case of individual preferences for hobbies or careers. Social networks may facilitate an individual’s chosen occupations through emotional support, assistance, or instruction; unfortunately, some social relationships interfere with a person’s optimal function. Only if occupational therapists are aware of the social context in which occupational function occurs can they orchestrate intervention that will outlive their own involvement in a client’s recovery and adaptation.

Social Network and Support

The characteristics of a person’s social network are relatively stable social contextual factors that influence his or her identity, opportunities, and function. Langford et al.

(1997) suggested that a social network is an interactive web of people who provide each other with help and protection; that is, they give and receive **social support**. Social networks vary in terms of the following characteristics: reciprocity (extent to which resources and support are both given and received); intensity (extent to which social relationships offer emotional closeness); complexity (extent to which social relationships serve many functions); and density (extent to which network members know and interact with each other) (Heaney & Israel, 1997).

Social support is defined as aid and assistance exchanged through social relationships and interactions (Heaney & Israel, 1997). The four types of social support are: (1) emotional (expressions of empathy, love, trust, and caring); (2) instrumental (tangible aid and service); (3) information (including advice and suggestions); and (4) appraisal (feedback and affirmation) (Heaney & Israel).

During the assessment, occupational therapists first try to identify the composition and characteristics of the client's social network (i.e., who these individuals are and the nature of their relationships). Occupational therapists must step outside of their own biases and expectations to appreciate that patients' social networks take many forms, including traditional nuclear families, same-sex partners, friendships, and acquaintances. Such biases remain prevalent, insidious, and hurtful. For example, despite our profession's stance on nondiscrimination and inclusion (American Occupational Therapy Association, 2004), Jackson (2000) described many occupational therapy clinics as noninclusive environments in which a heterosexist perspective pervades conversations, humor, and assumptions.

Second, therapists attempt to determine the types of support that individuals in the social network are willing and able to provide. For example, longstanding intimate ties typically provide emotional support and long-term assistance, while neighbors and friends most often provide short-term instrumental and informational support (Heaney & Israel, 1997). Key players in the social network assume as much or as little responsibility as they are able, and the patient–family unit becomes the primary recipient of occupational therapy services (Brown, Humphry, & Taylor, 1997). Therapists can learn a lot about patients' social networks and resources by simply talking with them. An alternative method of assessing a patient's social network and resources is the *Norbeck Social Support Questionnaire* (Norbeck, Lindsey, & Carrieri, 1981). It is a standardized, self-administered questionnaire consisting of nine items and taking about 10 minutes to complete. Patients list individuals in their personal network and specify the nature of these relationships. Patients then indicate the extent to which each person listed provides emotional, appraisal, and instrumental support.

Finally, occupational therapists appreciate that some social relationships are harmful to patients. Accredited

hospitals and rehabilitation facilities are mandated to have policies in place to respond to patients considered to be vulnerable adults or potential victims of intimate partner violence (Joint Commission on Accreditation of Healthcare Organizations, 2005). Therapists must familiarize themselves with employers' policies and procedures that describe how to report, document, and respond to cases of suspected maltreatment. For example, at Mercy and Unity Hospitals in suburban Minneapolis, physical and occupational therapists are expected to screen all outpatients for family violence (Fig. 10-3) (J. L. Miller, personal communication, February 3, 2006).

Caregiver Adaptation: A Dynamic Social Factor

Longstanding intimate ties in the patient's social network (hereafter also referred to as family) are critical to patients' ability to adapt to chronic illness and disability. Families influence outcome of services because they provide a context for individual change and because they represent continuity in patients' lives (Brown, Humphry, & Taylor, 1997). The ability of significant others to provide needed support, however, is dictated in part by their own emotional and physical health and place in the adaptation process (Grant et al., 2000). Many relatives of persons with traumatic brain injury (Webster, Daisley, & King, 1999), stroke (Grant et al., 2000), and Alzheimer's disease (Pruchno & Potashnik, 1989), for example, experience significant levels of subjective burden and mood disorders as well as role changes in work, leisure, and social life (Frosch et al., 1997). To contribute to patients' long-term quality of life, occupational therapists assess family members' adaptation needs on an ongoing basis.

All of the personal, social, and cultural contextual factors described in Figure 10-2 can be applied to the significant other's occupational functioning as caregiver. That is, a spouse's ability to learn and reinforce new techniques and strategies is affected by his or her own health concerns and distractions, age and generation, sex, mood, cultural background, makeup of the social network, and culture of the community (Murray, Manktelow, & Clifford, 2000). Furthermore, caregivers' goals and perceptions of need from health providers change as they adapt to the patient's illness or injury.

Corbin and Strauss (1988) described the work of adapting to chronic disability over time as “a set of tasks performed by an individual or couple, alone or in conjunction with others, to carry out a plan of action designed to manage one or more aspects of the illness” (p. 9). This work consists of not only adjustments to self-maintenance tasks and roles but also the work involved in redefining one's identity. Corbin and Strauss used the term *illness trajectory* to refer to the sequence of physiological changes associated with an illness, injury, or disorder and the adaptive work demanded of a patient and family that accompanies each

Family Violence Screening and Response Tool

What to do: RADAR mnemonic *

Routinely ask. Inquiring about family violence can be an intervention. You're signaling that violence is inappropriate; you may be helping to end the isolation.

Affirm and support patients who acknowledge abuse.

Document objective findings; patient statements in quotes.

Address your patient's safety.

Refer the patient to people skilled in family violence and safety planning.

When do you screen?

- Patient must always be alone. The exception is with infants or nonverbal toddlers.
- Screen all adults—both males and females.

When do you introduce the screening?

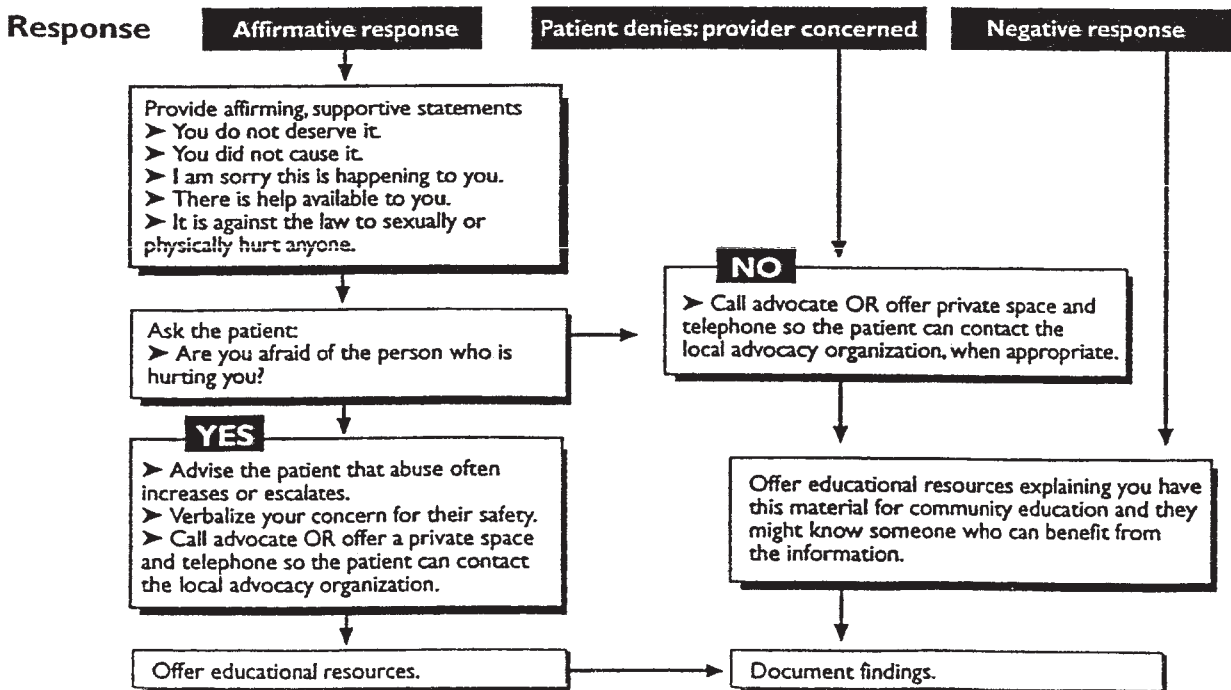

An introductory statement will lead you into asking the screening questions. This statement gives the patient the following messages:

- Violence in the home is a major health care issue;
- I care about you;
- All patients are asked these questions; and
- This is a safe place.

STATE: *We at (name clinic/hospital) are concerned about the violence that is impacting the health of many of our patients, so we routinely ask everyone the following confidential questions.*

Screening Questions

- Have you ever been hit, kicked, pushed, or otherwise hurt or mistreated by someone important to you?
- Is someone important to you yelling at you, threatening you, or otherwise trying to control your life?

* Alpert, E.J. (1999). *Partner Violence: A Guide for Physicians and Other Health Care Professionals (3rd Edition)* – Use Your “RADAR”. Waltham, MA: Massachusetts Medical Society.

Figure 10-3 Family Violence Screening and Response Tool. (Reprinted with permission from Allina Health System, Minneapolis, MN.)

phase. They further suggested that most trajectories have five types of phases, distinctly ordered according to various diagnoses and individual courses: acute, comeback, stable, unstable, and downward.

- *Acute phase.* The patient requires immediate medical attention and focuses on physiological stabilization and recovery. Patient and family may wonder how life will change because of the illness, injury, or disorder.
- *Comeback phase.* The patient is in the midst of physical and emotional recovery and focuses on getting physically well and regaining functional abilities. Patient and family may ask questions such as these: Will I (he or she) come back? How long will it take before I (he or she) peak? “In the comeback trajectory, the present is seen as overbearing, and the future is put on hold while one awaits answers to the foregoing questions” (Corbin & Strauss, 1988, p. 46).
- *Stable phase.* The patient undergoes very few changes in course of illness or functional abilities, as in the remission phase of multiple sclerosis or permanent spinal cord injury. Patient and family focus on maintaining stable health while wondering how long the phase will last and what can be done to extend it.
- *Unstable phase.* The patient has periodic but erratic downturns in function or exacerbations of illness (as might come, for example, with bladder infection). Unstable phases hamper normal living, and people in this phase ask questions like these: How long until we get this under control? How much longer can I (or we) go on like this?
- *Downward phase.* The patient slowly or rapidly loses health and function. With increasing incapacity, the patient and family view the present as temporary and the future as unknown. They are concerned with questions such as these: How fast and how far? When will it end? What can we do to slow it down?

Although there are no standardized methods for determining a person’s phase in an illness trajectory, sensitivity to each person’s changing path in this journey is prerequisite to creating a treatment plan that meshes with patient and family real-time needs and priorities. A family-centered approach allows the therapist to capitalize on the family’s priorities and contributions to the patient’s recovery and adaptation. This mindset, however, requires that therapists “follow the family’s lead rather than impose professional decisions” (Brown, Humphry, & Taylor, 1997, p. 598).

Patient–Therapist Social Interactions

Occupational therapy assessment is not a neutral process (Luborsky, 1997). Gans (1998) suggests, “Part of the way the patient behaves with you is a function of the way you are with the patient. This effect may comprise 75%, 25%, or

2% of what goes on between you and the patient, but it is there” (p. 4). Social convention and cultural norms organize the patient’s self-report of problems and symptoms and the therapist’s response to these concerns (Luborsky, 1997). The therapist is endowed with power to shape the interaction by selecting certain questions and omitting others (Luborsky, 1995), to judge or evaluate the responses of the patient, and even to determine whose expectations and “reality” are correct (Abberley, 1995).

Occupational therapists monitor the extent to which their own needs infiltrate social interactions with patients. Perhaps to meet self-imposed expectations around outcome, Abberley (1995) suggested that some occupational therapists unwittingly define the client as the problem and themselves as the solution, with failure of intervention always attributed to the patient and success always credited to the clinician’s efforts. Gans (1998) believes that a primary source of clinician gratification should stem from “the privilege of participating intimately in another person’s life” (p. 5). He further suggests that, when the work no longer feels like a privilege, one should try to figure out why (e.g., volume of caseload, private life that is distracting or burdensome, burnt out, or ethically questionable employer expectations that corrode integrity).

Clinicians also examine their expectations of their own supportive roles in patients’ lives. They recognize that professional helpers are typically not able to provide support over long periods. They realize that professional–lay relationships are not characterized by reciprocity typical of social networks and often entail invisible but palpable power differentials that interfere with the provision of genuine emotional support (Heaney & Israel, 1997). In essence, they realize that, as professionals, they should not attempt to assume a long-term role in the social network but rather work with the patient and family to create permanent social links that meet their needs.

CULTURAL CONTEXT OF THE LARGER SOCIETY AND COMMUNITY

“I used to dream about being in a world where being disabled was no big deal, where no one considered it a tragedy. No one thought you were inspiring or felt sorry for you . . . I imagined what a relief it would be to be seen every day as perfectly ordinary.” (Tollifson, 1997, p. 105)

The dominant culture influences the ease with which a person with a disability feels accepted and integrated into the community. Luborsky (1994) suggested that culturally based requirements for status of full adult person in Europe and North America, such as self-sufficiency,

activity, and upright posture, are often at odds with full participation for persons with disabilities. Adapted equipment may be rejected because of its appearance and acceptability in public rather than its functional value (Luborsky, 1994, 1997). Patients and family may respond to embarrassment or guilt over disability by attempting to keep the disability private and denying help from friends or neighbors (Armstrong & Fitzgerald, 1996). Loss of social status is further compounded when insidious cultural beliefs hold persons with disabilities responsible for their impairments. “At a deep level there is a bias that either they are culpable for the cause of the impairment, or for not working harder at rehabilitation to be able to ‘overcome’ the odds regardless of how realistic that is” (Luborsky, 1994, p. 251). As abhorrent and illogical as such notions are, patients, families, and occupational therapists are not immune to the subtle but pervasive influences of the sociocultural context in which they live.

Occupational therapists are challenged to check many of their own assumptions about people with disabilities. For example, Kielhofner (2005) reminds us that the person-first terminology that therapists are urged to use is objectionable to some disability activists and scholars who suggest that the term “disabled person” more accurately reflects his or her true minority status. Many people resent the notion that their impairments reflect some sort of personal tragedy (Wakefield, 2005; Watson, 2002) and, instead, view their disability with pride as a part of their identity (Eddey & Robey, 2005). Even the concept of rehabilitation and remediation of impairments can be interpreted as an effort to remove a flaw or a negative characteristic, a round-about way of suggesting abnormality or imperfection (Kielhofner, 2005).

GENERAL COMMENTS ON ASSESSING PERSONAL, SOCIAL, AND CULTURAL CONTEXT

If nothing else, the discussion of assessing personal, social, and cultural context underscores that occupational therapists ought to not get too comfortable with their findings, scores, or impressions and learn to tolerate the ambiguity of “it just depends.” The imposing influence of contextual variables serves to keep us humble and on guard against jumping to the wrong conclusions about assessment findings and our clients.

Occupational therapists struggle to balance their pre-eminent concerns for service to patients with very real

demands for efficiency and productivity. Clinicians typically devote 30 minutes to 3 hours assessing each patient; the short lengths of stay in acute settings allow less time; inpatient rehabilitation settings (with possibly longer stays) allow somewhat more. How does one have time to assess the web of personal, social, and cultural contextual factors on top of all pertinent areas of occupational function (roles, tasks, activities, abilities and skills, and capacities)? Here are some general guidelines:

- Review the assessments of other professionals. Many patients who are referred to occupational therapy are also assessed by social workers, psychologists, speech-language pathologists, physical therapists, physicians, therapeutic recreation specialists, chaplains, and/or nurses. Reviewing the assessments of team members greatly adds to the occupational therapist’s ability to understand a patient’s personal, social, and cultural context without using limited assessment time to do so.
- Use specific tools (many discussed in this chapter) to measure contextual factors that appear to bias or confound performance during assessment or that are expected to be targets of occupational therapy intervention (to establish a baseline).
- Take advantage of informal conversations with patients. Luborsky (1997) pointed out the value of attending to patients’ informal remarks made during structured assessments. He described how a patient’s comments during transitions between various standardized tools provide insights not captured by the tools themselves. He further stated that patients’ informal remarks “can be essential to gaining an understanding of the way subjects make sense of the assessment; to providing us with important information on the validity of the assessment tool; and to identifying important areas for clinical intervention” (p. 12).

It is advisable to use each and every moment with patients to try to understand who they are, where they come from, and how they are interpreting their experience in therapy. Gans (1998) links this investment to patient outcome: “our ongoing, relentless determination to understand the uniqueness of each patient is what the patient, to the degree he or she can, experiences as love . . . [and] patients who feel cared about and valued make the most gains in therapy” (p. 5). It is unrealistic to expect therapists to unravel the mysteries of a client’s contextual fabric during an arbitrarily defined assessment period. The richness of conversations that relate to personal, social, and cultural context grows as the therapeutic relationship deepens and continues to inform the intervention process.

CASE

EXAMPLE

Appreciating Context During Assessment

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information Mrs. N., a 30-year-old wife and mother of three young children, was referred to outpatient occupational therapy for assessment and treatment approximately 6 months after a suspected brain injury. She was injured when a shelf at a convenience store broke and its contents fell on her head. After the accident, Mrs. N. frequently complained of headaches, fatigue, and dizziness accompanied by dramatic decrease in her activity level and was observed to be forgetful, even unsafe (e.g., leaving stove burners turned on, losing track of her children, forgetting to take medication). With a high school education, Mrs. N. worked full time as a teaching assistant at a day care center but was unable to return to work following her injury. As a recent immigrant from Saudi Arabia, Mrs. N. spoke very little English. (She speaks and writes in Arabic.) The consulting neuropsychologist opted not to perform a battery of standardized cognitive assessments because of concerns about communication, cultural biases of the tests themselves, and possible religious discomfort associated with spending hours of assessment time with the neuropsychologist, a man. Therefore, assessment and observations in occupational therapy were particularly important in establishing her rehabilitation needs.</p>	<p>Understand the patient’s diagnosis or condition</p> <p>Know the person</p> <p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>“Mrs. N.’s complaints and presentation are certainly consistent with a brain injury. It appears that she did not seek medical attention immediately after the accident and that she has never received any rehabilitation services. These symptoms must be frightening for her.”</p> <p>“It is going to be challenging for me to try to get to know Mrs. N. and to provide the kind of encouragement and support that I feel is so important to my approach with patients, given our language barriers.”</p> <p>“I realize that I need an assessment strategy that is different from what I am used to. It would not make much sense for me to rely on scores from standardized tests. I will also be sensitive to the fact that it’s possible that some of what Mrs. N. says to me may be lost in translation.”</p> <p>“My guess is that some of Mrs. N.’s problems can be attributed to brain injury but I wonder what effect anxiety and/or depression may have on her overall functioning.”</p>
<p>Assessment Process Mrs. N. appeared to doze in the waiting room prior to her initial occupational therapy session. She was cooperative and soft spoken; she was able to respond in English to approximately 30% of the questions. She stayed awake for most of each of the three 1-hour assessment sessions. Mr. N., also a native of Saudi Arabia, served as translator but often dominated interactions with details of his own stress related to his wife’s status. He appeared to be on the verge of tears on at least two occasions as he described his inability to work full time because of his wife’s need for supervision, assistance, and transportation to medical appointments.</p>	<p>Consider evaluation approach and methods</p>	<p>“I think that I can learn the most about Mrs. N.’s functioning with a dynamic assessment approach—observing her response to various demands and challenges that I set up.”</p>

Patient's and Husband's Report of Abilities and Limitations

Through her husband, Mrs. N. indicated that she was primarily concerned about her memory and endurance and that her ultimate goals were to completely resume her roles as mother, homemaker, and worker. (At the time of her assessment, Mr. N. prepared all of the family meals, and their oldest daughter, age 9, did most of the household chores.) Through her husband, Mrs. N. indicated that she had very little activity or routine in her day. She woke anywhere between 8:00 AM and noon. After rising, she sat for approximately half an hour, avoiding movement so as to avoid dizziness. She did not prepare meals for herself, eating only a cookie with tea instead of breakfast or lunch. She typically spent her afternoons napping, sitting alone at the window, or watching television. She fell asleep at approximately 9:00 PM, but her husband reported that he regularly found her crying in the middle of the night. Her inactivity contrasted dramatically with reports of her pre-morbid status: working full time, attending language and driving classes, managing all household tasks, caring for her children, and socializing with friends. With the patient's permission, the therapist also contacted Mrs. N.'s American-born, English-speaking sister-in-law, who confirmed the dramatic decline in Mrs. N.'s activity level and abilities, Mr. N.'s understandable stress given these changes, and her own willingness to serve as a resource.

Observations of Cognitive Function

Mrs. N. performed the *Contextual Memory Test* (CMT) (Toglia, 1993), a test of immediate and delayed recall of 20 pictures associated with morning hygiene. Her performance on this test suggested moderate memory deficits but adequate awareness of these limitations. Her husband translated instructions to a 10-step task to which she jotted notes. After a 25-minute delay and interference activities, she was able to use her own notes to carry out the task with 70% accuracy. She appeared to make errors because she did not carefully review her notes and approached two steps in what appeared to be a hasty and impulsive manner.

Observations of Performance of Functional Tasks

The therapist requested that Mrs. N. select a familiar stove-top meal to prepare in occupational therapy and asked her to bring necessary supplies and ingredients to one of her assessment sessions. Mr. N. reportedly reminded Mrs. N. to do so. As instructed by the therapist, Mrs. N. made an obvious effort to remember to turn off the stove burner once she finished preparing her dish. She sat next to the stove throughout the task, but having removed the pan from the stove to serve the food, she did not return to turn off the burner (which was left on for 5 minutes, until the therapist turned it off). She appeared well organized in her approach to the task, removing all ingredients and supplies from the cupboard ahead of time and cleaning up as she proceeded. Despite these efforts, she forgot to add one of the ingredients she had set out on the table and asked the therapist whether she had added another.

“Descriptions of Mrs. N.'s pre-morbid activities and her self-reports of long-term goals contradict my assumptions about Muslim women from the Middle East. Prior to meeting Mrs. N., I expected that Mrs. N.'s narrow sphere of activities would center exclusively on her home and children. Mrs. N.'s pre-morbid engagement in work outside of her home and language and driving lessons and her goals to return to these roles reminds me of the importance of trying to understand each patient as an individual rather than drawing conclusions based on cultural or ethnic stereotypes.”

“It is helpful to get a snapshot of Mrs. N.'s functioning through her husband and her sister-in-law. I feel fairly confident that I'm following all that Mr. N. is telling me, as his sister-in-law tells me much the same thing.”

“I know that I am supposed to follow the CMT's administration protocol, but under these circumstances, I just can't. However, the picture format of this test might give me a sense of her ability to learn new information. I appreciate that the veracity of assessment findings are in question, as all responses were reported through her husband.”

Interpret observations

“I thought it would be a good idea to have Mrs. N. prepare a familiar dish so as to remove at least one novelty variable. I am impressed that she is willing to try every activity that I propose and that says a lot to me about her motivation to use therapy to improve her functioning.”

Mrs. N. frequently requested rest during occupational therapy sessions that entailed physical activity. She generally tolerated approximately 5 minutes of standing or walking before requesting to sit and rest because of fatigue and dizziness. During one of the three sessions, Mrs. N. complained of headache and intermittently rested her head on the table.

Analysis of Results

Mrs. N.’s performance of functional tasks in occupational therapy seemed consistent with the kinds of problems reported at home by Mrs. N., her husband, and her sister-in-law. Specifically, Mrs. N.’s performance on pencil-and-paper and kitchen tasks were marked by forgetfulness, absent-mindedness, and poor endurance. Furthermore, given her dramatic decline in activity, reports of frequent crying, and decreased appetite, the therapist was concerned about depression. Given his own stress, the therapist questioned whether Mr. N. would be able to maintain all of the roles he had assumed since his wife’s injury.

The following recommendations were suggested as pre-requisite to commencing occupational therapy treatment:

- Referral to a woman psychologist for further evaluation and treatment of possible mood disorder.
- Referral to a neurologist specializing in balance disorders (she had never had this complaint exhaustively evaluated).
- Schedule a family conference with Mrs. N.’s sister-in-law, brother-in-law, and attorney to make arrangements to assist Mr. N. at home, enabling him to put in more hours at work.
- Work with the hospital patient representative to provide a translator for future occupational therapy sessions.
- Schedule an occupational therapy home safety evaluation.

“I requested an interpreter from the Patient Representative but it has taken a little longer than I would like to find someone. Our policies and procedures recommend against using a family member as an interpreter and I can see that logic. Mr. N. has his own stresses and maybe his own agenda. He needs to be freed up to take care of his other responsibilities, and I think it would be beneficial for Mrs. N. to participate in occupational therapy sessions on her own.”

“I am concerned that Mrs. N. may not make substantive progress towards her goals if she is depressed, and so I recommended that she see a psychologist or psychiatrist before beginning occupational therapy intervention. Similarly, her complaints about dizziness have never been medically evaluated, and we need to find out what is going on. Given what Mr. and Mrs. N. have told me and what I’ve seen of Mrs. N.’s performance, I am very concerned about her safety at home. I am not confident in offering any definitive suggestions until I observe her in her own environment.”

Occupational Therapy Problem List

1. Decreased memory and concentration capabilities and inadequate strategies to compensate for these problems.
2. Deconditioning associated with prolonged inactivity complicated by poor nutrition.
3. Lack of structure or routine for daily activities and inability to judge independently which tasks were within her competence level.

Synthesize results

“I have addressed similar issues with other clients, and I am confident I can help Mrs. N. address these problems as well.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Adapting Assessment to Contextual Factors

The occupational therapist working with Mrs. N. used only one standardized assessment tool because of concerns related to language barriers and cultural biases. How might the assessment have been different if Mrs. N. had presented the same symptoms and complaints but was born in Pittsburgh and spoke English all of her life?

Assessment Table 10-1

Assessing Personal, Social, and Cultural Contexts

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<i>Rapid Estimate of Adult Literacy in Medicine (REALM)</i> (Murphy et al., 1993)	Reading recognition test that allows clinicians to estimate patients' reading skills.	2–3 minutes.	Concurrent validity: significant correlation ($p < 0.0001$) between REALM and standardized measures of reading, including the <i>Peabody Individual Achievement Test–Revised</i> ($r = 0.97$), <i>Wide Range Achievement Test–Revised</i> ($r = 0.88$), and <i>Slosson Oral Reading Test–Revised</i> ($r = 0.96$) (Davis et al., 1993).	Excellent test–retest reliability ($r = 0.99$, $p < 0.0001$).	No information.	Strengths: Brief; minimal training needed Weakness: Assesses literacy in English only
<i>CAGE Questionnaire</i> (Ewing, 1984)	Involves asking 4 questions to persons seeking medical services to identify possible alcohol abuse.	5–10 minutes.	Convergent validity for 4 CAGE questions with alcohol-related items of the <i>Army's Health Risk Appraisal</i> ranged from: Φ coefficient 0.1713–0.3496 (moderately weak). Criterion validity: persons with cut-off score of 2 were at 3.5 times greater risk for military discharge due to alcoholism (Bell et al., 2003).	Good test–retest reliability (2–30 days) for 4 questions (r ranged from 0.73–0.83) (Bell et al., 2003).	In a study of individuals with traumatic brain injury, specificity and sensitivity of CAGE were high (86% and 91%, respectively) (Ashman et al., 2004).	Strength: Appropriate for use with clinical populations Weaknesses: Poor sensitivity when modified to detect drug abuse or when used to determine pre-injury substance abuse (Ashman et al., 2004); CAGE was shown to be unable to discriminate between heavy drinkers and non-heavy drinkers in the general population (Bisson, Nadeau, & Demers, 1999).

Assessment Table 10-1

Assessing Personal, Social, and Cultural Contexts (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Visual Analog Scale (VAS)</i> to measure pain (Huskisson, 1974)</p>	<p>Presented as a 10-cm line, anchored with “no pain” on one end of the continuum and “worst imaginable pain” on the other end. Patient marks a line to indicate pain intensity, which is measured in millimeters (with zero at the “no pain” anchor).</p>	<p>Approximately 2 minutes.</p>	<p>High correlation between VAS and numerical rating scale for pain ($r = 0.94$; 95% CI, 0.93–0.95) (Bijur Latimer, & Gallagher, 2003).</p>	<p>High reliability (intraclass correlation coefficient for paired VAS scores = 0.97; 95% CI, 0.96–0.98) (Bijur, Silver, & Gallagher, 2001).</p>	<p>Statistically significant differences between changes in VAS scores (in mm) by verbal descriptors of pain ($F = 79.4$, $p < 0.001$) (Gallagher et al., 2002; Pizzi et al. 2005).</p>	<p>Strengths: Brief screening tool; widely used and understood by patients and professionals. Weaknesses: Limited research regarding reliability and validity with rehabilitation populations; may not be reliable measure of pain in patients with cognitive impairments (Williamson & Hoggart, 2005); not an appropriate tool for analyzing differences in pain across individuals (Kane et al., 2005).</p>

<p><i>McGill Pain Questionnaire (MPQ-SF)</i> (Melzack, 1987)</p>	<p>Self-report tool designed to measure pain and response to intervention that has 3-part dimensions: <i>SF</i> (word identification), <i>Pain Intensity Index (PII)</i>, and <i>VAS</i>.</p>	<p>2–5 minutes.</p>	<p>Moderately strong to strong correlation between subscales of <i>SF</i> and long form (Melzack, 1975) for 4 diagnostic groups ($r = 0.65-0.88, p < .001$). Persons with disability use many but not all of the pain descriptors included in the <i>MPQ-SF</i> when verbally describing their pain experience (Dudgeon et al., 2005).</p>	<p>Strong inter-rater reliability (intra-class correlation coefficient of 0.98 when <i>MPQ-SF</i> was readministered within 5 minutes by a second therapist) (Gridley & van den Dolder, 2001).</p>	<p>Responsive to pain-related intervention. Statistically significant differences before and after intervention with 3 diagnostic groups on 3 components of test (<i>SF</i>, $p < 0.001$, <i>PII</i>, $p < 0.001$, <i>VAS</i>, $p < 0.001$) (Melzack, 1987).</p>	<p>Strengths: Brief, measures quality of the pain in addition to intensity. Weaknesses: Melzack (1975) cautions that simply asking the patient to fill out the questions by him or herself may yield unreliable information and suggests that the clinician read each subset of questions/instructions to the patient. Patient must be able to read.</p>
<p><i>The Hospital Anxiety and Depression Scale (HADS)</i> (Zigmond & Snaith, 1983)</p>	<p>Self-administered questionnaire designed to detect depression and anxiety in a medical outpatient clinic setting. Comprised of 16 questions related to psychological rather than somatic complaints.</p>	<p>Less than 20 minutes.</p>	<p>Moderate correlation between patient self-ratings on <i>HADS</i> and psychiatric interview assessment for anxiety ($r = 0.54, p < 0.05$); moderately strong for depression ($r = 0.79, p < 0.01$).</p>	<p>Good internal consistency (Cronbach's $\alpha = 0.83$ for anxiety subscale and 0.84 for depression subscale) (Pallant & Bailey, 2005).</p>	<p>Good sensitivity and specificity for separate subscales with cut-off score of ≥ 8 (<i>HADS</i>-anxiety: sensitivity, 0.89; specificity, 0.88; <i>HADS</i>-depression: sensitivity, 0.80; specificity, 0.88) (Olsson, Mykletun, & Dahl, 2005).</p>	<p>Strengths: Brief screen, such that patient could complete while waiting for appointment; has been translated into Arabic, Dutch, French, German, Hebrew, Swedish, Italian, and Spanish; appropriate for wide range of medical diagnoses. Weaknesses: Patients must be able to read to complete the <i>HAD</i>; use of total score not adequately sensitive in identifying cases of psychiatric illness (Poole & Morgan, 2006).</p>

Assessment Table 10-1

Assessing Personal, Social, and Cultural Contexts (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<i>Beck Depression Index (BDI) – FastScreen for Medical Patients</i> (Beck, Steer, & Brown, 2000)	Self-report tool that screens for depression in adults and adolescents. Comprised of 7 items extracted from the 21 item <i>Beck Depression Inventory–II</i> .	Less than 5 minutes to complete.	Construct validity: moderately strong correlation between <i>BDI-FastScreen</i> and <i>HADS</i> ($r = 0.62$, $p < 0.001$).	Good internal consistency (alphas of the <i>BDI-FastScreen</i> for family practice, internal medicine, and pediatric patients were 0.85, 0.85, and 0.88, respectively) (Beck, Steer, & Brown, 2000).	<i>BDI-FastScreen</i> cut-off score of ≥ 4 had 100% sensitivity and 84% specificity rates (Scheinthal et al., 2001).	Strengths: Very brief with good psychometric properties; responses to <i>BDI-FastScreen</i> not related to sex, ethnicity, age, or total number of medical conditions (Beck, Steer, & Brown, 2000). Weaknesses: Does not specifically inform occupational therapy intervention planning; serves only to identify persons in need of referral for more in-depth psychiatric assessment.
<i>Norbeck Social Support Questionnaire (NSSQ)</i> (Norbeck, Lindsey, & Carrieri, 1981)	Self-administered questionnaire consisting of 9 items. Patients list individuals in their personal network and specify the nature of their relationship. Measures 3 functional types of social support (affect, affirmation, and aid).	Approximately 10 minutes.	Results of factor analysis support a 3-factor model (affect, affirmation, aid) ($\chi^2 = 8.42$, $df = 6$, $p = 0.208$) (Gigliotti, 2002). (Note: A significant chi-square test suggests that variables are not independent. In this study, the results were <i>not</i> significant.)	High degree of test-retest reliability (0.85–0.92). High internal consistency within 3 types of support (0.89–0.97) (Norbeck, Lindsey, & Carrieri, 1981).	No information.	Strengths: Based on conceptual definitions of social support proposed by Kahn (1979); instrument may provide useful structure for interviewing clients about the nature of their social support. Weakness: Specific subscale scores may be more relevant to research than practice.

SUMMARY REVIEW QUESTIONS

1. Consider your morning self-care routine—the activities you performed today to get ready to leave for school or work. List the personal, social, and contextual factors that influenced your performance. If someone who did not know you judged your performance, what aspects might they consider unusual? What aspects might he or she consider normal for someone of your age and background?
2. Review Figure 10-2 and write a paragraph describing the possible influences on occupational functioning of one of the contextual factors not discussed in this chapter. For example, how might social class or gender help or hinder performance?
3. Outline circumstances in which you would use standardized instruments to assess contextual factors and those in which you would use more informal methods.
4. Make a private list of your own biases. What assumptions do you have about people who are different from you in terms of age, sex, cultural and educational background, sexual orientation, and abilities (physical, cognitive, emotional)? List the steps you can take to debunk these biases and measures to minimize their effects during interactions with patients.
5. Observe the interactions of another clinician and patient during assessment. What, if any, comments made by the therapist could be attributed to his or her personal, social, and cultural context? What comments made by the patient could be attributed to his or her personal, social, and cultural context?

CHAPTER 11

Assessing Environment: Home, Community, and Workplace Access

Patricia Rigby, Mandy Lowe, Lori Letts, and Debra Stewart

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the roles and responsibilities of the occupational therapist in the evaluation of environmental access.
2. Identify factors that act as environmental barriers and supports to occupational performance.
3. Apply critical appraisal when selecting assessment instruments appropriate for use in evaluating access to home, community, and workplace.
4. Explain how legislation and building standards influence the degree of environmental access that is available for people with disabilities.

Glossary

Glossary

Accessibility—The ease with which the physical environment may be reached, entered, and used by all individuals.

Accommodations (environmental)—Removal of environmental barriers and provision of environmental supports and resources to enable a person with a disability to enjoy equal opportunity.

Barrier-free design—Design features of the built environment that remove physical barriers to full and equal accessibility for all persons with disabilities.

Environmental barrier—Any component of the environment that impedes optimal occupational functioning.

Environmental support—Any component of the environment that encourages, facilitates, or provides assistance to allow a person to achieve optimal occupational functioning.

PEO fit—The goodness of fit between personal factors (e.g., functional, social, and psychological), the characteristics

of the environment (e.g., barriers and supports), and the characteristics of the chosen occupation.

Physical environment—The natural or human-made features of the environment within which occupational functioning occurs.

Standardization—The process of making an assessment available in a manual with standard procedures for testing, scoring, and interpreting the results. Environmental assessments do not usually undergo a normative process because of the variability in environments, yet many are based on standards developed by the ANSI, government building codes, and interpretations of the ADA.

Transactive—Integrated, co-dependent (of a relationship).

Universal design—Design features of the built environment that enhance optimal function and convenience for all individuals, regardless of their ability.

The environment influences human behavior and provides the context within which all roles are performed. In occupational therapy, the environment is broadly defined as having physical, social, cultural, organizational, and institutional dimensions. These dimensions interact with each other and are difficult to tease apart; that is, they are said to be **transactive** (Law et al., 1996).

A number of occupational therapy theories specifically address the issue of environmental influences on occupational functioning (e.g., American Occupational Therapy Association [AOTA], 2002; Canadian Association of Occupational Therapists [CAOT], 1997; Dunn, Brown, & McGuigan, 1994; Law et al., 1996). These vary slightly in terminology and approach, but all agree on the importance of environmental considerations in the practice of occupational therapy (Rigby & Letts, 2003). Central to these theories is the notion that **environmental barriers** to occupational performance for people with disabilities can be modified or eliminated more easily than most other negative influences. Also, the theories all emphasize that **environmental supports** promote optimal occupational performance.

The examination of occupational performance involves analysis of the goodness of fit for the person-environment-occupation (PEO) relationship (Law et al., 1996). The better the **PEO fit**, the more optimal the occupational performance. Occupational therapists are frequently called upon to determine the fit between people with disabilities, their chosen occupations, and the various environments in which they live, work, and play. In this capacity, the therapist's role is as follows:

- To identify and evaluate barriers that may challenge the competency and ability of individuals to carry out their chosen occupations and roles

- To identify and evaluate resources that will support occupational performance and occupational functioning
- To develop strategies to eliminate or ameliorate barriers
- To utilize resources and supports to improve the goodness of PEO fit

This chapter focuses on the assessment of the environment for occupational performance. Specifically, it will consider the environment that is external to the client when assessing occupational functioning: the physical, social, and institutional attributes of the environment. The assessment measures selected are those that we consider the best available and that reflect the transactive nature of the relationship between people, their chosen occupations, and the environment in which these occupations are performed.

EVALUATION OF THE ENVIRONMENT

The environment provides the context for occupational functioning. Consequently, an assessment of its attributes should be augmented with information about those who will use the environment and the functions they will carry out there. In the practice of occupational therapy, it is important to begin this process with the person.

Client-Centered Approach

The client is central to all occupational therapy services, and much has been written about the need to engage and involve clients in all stages of the occupational therapy

process (Law, 1998). The client–therapist interaction begins with an interview and assessment so that the therapist can gain an understanding of the client’s occupational profile (AOTA, 2002). This involves determining what roles and occupations the client previously had and what the client currently wants or is expected to be able to do. Clinicians find that collaborative goal setting is an important stage in establishing client-centered occupational therapy (Wressle et al., 2002).

Once the occupational profile is established, the occupational therapist then completes an analysis of occupational performance to better understand the client’s performance skills, patterns, and challenges, considering the contexts within which activities and roles will be carried out. It is at this time that environmental assessment may be deemed necessary. For example, a therapist and client could focus on community mobility and access because it is important to the client to continue participating in a volunteer role at the local public library. The therapist would consider the client’s abilities by assessing his or her mobility using a wheelchair in the hospital setting, assessing the client’s ability to access community transportation systems, and possibly assessing the library’s accessibility to ensure that the client could negotiate the entrances, work areas, and public washrooms.

Roles

The roles carried out by clients address purposeful activities related to self-maintenance, self-enhancement, and self-advancement. Each individual ascribes different meaning to his/her roles. Specific features of the environment can support or hinder the fulfillment of valued roles within the home, community, and workplace.

Environmental Barriers and Supports

The occupational therapist must be able to identify the key environmental barriers and supports that influence the occupational functioning of clients. In clinical practice, barriers and supports are broadly defined. This chapter, however, discusses barriers and supports in the external environment; other contextual barriers and supports are described in Chapter 10.

The International Classification of Functioning, Disability and Health (ICF) classifies environmental factors as assistive products and technology; the natural and human-made environments; supports and relationships; attitudes; and services, systems, and policies (World Health Organization, 2001). The therapist is encouraged to consider these factors during assessment. For example, physical barriers in the natural environment can prevent or impede a person with a disability from participating in daily activities, while human-made resources can improve

accessibility. Consider the challenge that stairs or rocky paths impose on a person using a wheelchair. These barriers can be removed or reduced by adding supports such as elevators or ramps to replace stairs and a ramped bridge across the rocks to allow access for a wheelchair.

Access that is discriminatory or inconvenient, such as when persons with physical disabilities must use freight elevators or ramped entrances at the back of buildings, is no longer considered a viable solution to eliminating access barriers. Improved accessibility through the use of **universal design** and **barrier-free design** is preferred. These two terms are similar but not synonymous. Universal design refers to features of the built environment that enhance optimal function and convenience for everyone, regardless of ability. Barrier-free design refers to features of the built environment that remove physical barriers to allow full and equal accessibility for all persons with disabilities. Universal design can encompass barrier-free design, but the converse is not necessarily true. For this reason, it is preferable to promote the use of universal design (Resource 11-1).

Influences on Environmental Accessibility

Various societal and cultural attitudes influence the degree to which the **physical environment** is made accessible to people with disabilities. Occupational therapy practice standards also reflect these global views. These influences manifest as national and state or provincial legislation, building standards, and professional practice requirements.

Legislation

The Americans with Disabilities Act (ADA) (1990), is a civil rights law designed to increase the integration and successful community living of people with disabilities in American society. In other countries, similar civil rights laws may prohibit discrimination toward persons with disabilities and guarantee equal rights and provisions for **accommodations** in society.

For example, the ADA mandates that a qualified person with a disability cannot be discriminated against when seeking or participating in employment. The intent of the law is to create equal opportunity and equal access to public environments, services, and transportation for persons with disabilities. The ADA is a dynamic legal document that focuses on achieving integration and independent living for people with disabilities through societal change.

The key phrase in the ADA is the obligation of society to provide reasonable accommodation to ensure that public services, facilities, transportation, employment, accommodations, and telecommunications are accessible. Reasonable accommodations ensure that no person with a disability is excluded from or denied services, segregated, or otherwise treated differently from the general population because of the absence of auxiliary aids or services.

Titles II and III of the ADA detail the steps to be taken by public and private sector services, programs, and facilities to comply with and implement the requirements of the ADA. They address the accommodations required and the availability of resources; modifications to policies, practices, and procedures; the removal of barriers; and alternative forms of services, such as accessible transit services when mainline public facilities are unavailable. Legal parameters are developed through challenge on a case-by-case basis.

These regulations were expected, over time, to eliminate barriers and improve accessibility for people with disabilities. Analysis of the impact of the ADA 10 years later is mixed. Persons with disabilities do not, as yet, perceive that the ADA has been very effective in improving accessibility (Hinton, 2003). Analysis of social policy, however, demonstrates that attitudes and practices of Americans have changed and that the ADA has improved the quality of life for persons with disabilities (Harrison, 2002). See Resources 11-1 for further information on the ADA.

Although the ADA does not mandate professional involvement in achievement of the criteria it sets forth,

occupational therapists, who are skilled in occupational analysis, environmental assessment, and determining PEO fit, are well suited to assist with meeting the requirements of the ADA. When occupational therapists were surveyed, however, they demonstrated a lack of knowledge about the ADA and reported inaction in implementing ADA provisions (Redick, McClain, & Brown, 2000). Because the ADA and similar laws are critical for improving accessibility, independence, and empowerment of persons with physical disabilities, it is imperative that occupational therapists take action to better utilize such legislation.

Building Standards

In 2004, the United States Access Board released the updated ADA-ABA (Architectural Board Act) Accessibility Guidelines for new or altered buildings, which provide the accessibility requirements for public and private facilities (United States Access Board, 2004a). The specifications in these guidelines are based upon adult and child dimensions and anthropometrics and should be applied during the design and construction or alteration of buildings and facilities covered by titles II and III of the ADA. Specifications are provided for most aspects of the built environment including space required for maneuvering wheelchairs in corridors and rooms (Figs. 11-1 and 11-2), washrooms, building entrances, and parking lots.

Figure 11-1 Position—clear space of a minimum of 30 × 48 inches (760 × 1220 mm) for either forward or parallel approach to an element. (Adapted from the ADA-ABA Accessibility Guidelines [United States Access Board, 2004a].)

Figure 11-2 Clear width of a minimum of 42 inches (1065 mm) at approach to turn, and 48 inches (1220 mm) at turn. (Adapted from the ADA-ABA Accessibility Guidelines [United States Access Board, 2004a].)

Other standards have been developed for specific environments, such as the workplace. For example, the National Institute of Occupational Safety and Health (NIOSH) publishes criteria directed at reducing the rate of workplace injuries. Occupational therapists who work in these environments must become familiar with the standards and guidelines relevant to their area of practice.

The *Americans with Disabilities Act Checklist for Readily Achievable Barrier Removal* (Adaptive Environments, 1995) was developed for owners and managers of public buildings and businesses to identify barriers in their facilities. This survey tool is based on the older ADA Accessibility Guidelines (ADAAG) (United States Access Board, 2002) and provides easy-to-use measurement guides to identify accessibility barriers and suggestions for “readily achievable” access solutions. For example, requirements for a ramped entrance to a building are shown in the checklist in Figure 11-3. The occupational therapist can assist businesses to use this tool and set priorities for achieving accessibility. It would be important and reasonably easy to cross-reference this checklist with the new ADA-ABA Accessibility Guidelines (United States Access Board, 2004a).

RAMPS

QUESTIONS	MEASUREMENT	YES	NO	POSSIBLE SOLUTIONS
Are the slopes of ramps no greater than 1:12? Slope is given as ratio of the height to the length. 1:12 means for every 12 inches along the base of the ramp, the height increases one inch. For a 1:12 maximum slope, at least one foot of ramp length is needed for each inch of height.	slope = _____			<input type="checkbox"/> Lengthen ramp to decrease slope. <input type="checkbox"/> Relocate ramp. <input type="checkbox"/> If available space is limited, reconfigure ramp to include switchbacks.
Do all ramps longer than 6 feet have railings on both sides?				<input type="checkbox"/> Add railings.
Are railings sturdy, and between 34 and 38 inches high?	height = _____			<input type="checkbox"/> Adjust height of railing if not between 30 and 38 inches. <input type="checkbox"/> Secure handrails in fixtures.
Is the width between railings or curbs at least 36 inches?	width = _____			<input type="checkbox"/> Relocate the railings. <input type="checkbox"/> Widen the ramp.
Are ramps non-slip?				<input type="checkbox"/> Add non-slip surface material.
Is there a 5-foot-long level standing at every 30-foot horizontal length of ramp, at the top and bottom of ramps and at switchbacks?	length = _____			<input type="checkbox"/> Remodel or relocate ramp.
Does the ramp rise no more than 30 inches between landings?	rise = _____			<input type="checkbox"/> Remodel or relocate ramp.

Figure 11-3 Accessible approach ramps. (Adapted from the *Americans with Disabilities Act Checklist for Readily Achievable Barrier Removal* [Adaptive Environments Center, 1995].)

Professional Practice Requirements

The practice of occupational therapy is also guided by professional regulations. Standards of practice, core competencies, and functions expected of therapists are developed at the national and state/provincial levels and provide performance evaluation criteria. These guidelines are usually generic in nature and apply to all therapists, regardless of the area, setting, or focus of practice (AOTA, 1995; CAOT, 1996). Knowledge of and ability to perform assessments of context/environment are considered to be core competencies and functions of practice for all occupational therapists (AOTA, 1995; Association of Canadian Occupational Therapy Regulatory Organizations, 2000).

ASSESSMENTS OF ENVIRONMENT

Ideally, the occupational therapist should select instruments with **standardization** that assess PEO fit to take into consideration the goodness of fit between the personal factors and characteristics of the environment and the occupation. The PEO relationship is dynamic, complex, and interwoven and, therefore, more difficult to measure than interactions that can be understood by assessing discrete components. Few measures have been developed to assess this complex PEO relationship. Thus, we have included not only those measures in this chapter, but also an array of very useful tools that measure the person–environment relationship or specific characteristics of the environment.

In this chapter, the assessments have been categorized by setting: those suitable for assessing homes (Assessment Table 11-1), the community (Assessment Table 11-2), and the workplace (Assessment Table 11-3). Key information about each assessment, including an analysis of the tool's strengths and weaknesses, was included in the tables to assist occupational therapists in identifying the most appropriate tool(s) for their purposes. The critique of each tool was guided by using the Outcomes Measures Rating Form and Guidelines (Law, 2004). Most measures included here have established psychometric properties. We have, however, included some unique measures that have good content validity and clinical utility but for which formal studies of psychometric properties are unavailable or incomplete. Each table follows its related narrative.

Assessment of Access to Home

A home assessment completed by an occupational therapist can be an important component of the occupational therapy process. Home assessments are often completed as part of a discharge planning process from rehabilitation. It is vital to ensure that clients' home environments are able to provide them with the supports they need while they

recover from or live with disabilities. The overriding purpose of a home assessment is to identify the degree of fit for the person completing his or her daily roles within the home environment and to recommend modifications to the environment to ensure optimal independence and safety. A home assessment may also provide opportunities to prevent secondary injuries resulting from home hazards or unsafe practices. Research on the effectiveness of home assessments to prevent falls in older adults demonstrated that home assessments may reduce the risk of falls, especially in people who have a history of past falls (Cumming et al., 1999). Other research has described varying patterns of home modification recommendations resulting from home assessments when comparing clients insured through public or private insurance systems, suggesting that occupational therapists tend to make recommendations that can be practically implemented considering the financial resources available to the client (Lysack & Neufeld, 2003). In a study comparing assessment results between home-based performance assessment, client and proxy report, and clinic-based performance assessment, Rogers et al. (2003) found that home-based performance assessment provides an accurate reflection of the clients' ability to manage in that setting, which cannot be replaced by self-report, caregiver proxy, or clinic-based performance assessments. See Safety Note 11-1 for considerations related to visiting a client's home.

Standardized home assessments are now available for occupational therapists to use with clients and families to identify occupational performance problems in the home. Researchers have discussed the limited use of standardized home assessments by occupational therapists (Mitchell & Unsworth, 2004) and called for the use of dynamic and criterion-referenced assessments (Rogers, Holm, & Stone, 1997). In clinical practice, where service provision needs to be justified, the use of standardized home assessments can be important to ensure that a comprehensive assessment is completed to meet the needs of the client and to justify requests for equipment and home modifications. A review of assessment tools to guide home adaptations (Rousseau et al., 2001) presented information on 16 different assessments, although 10 of these had no psychometric studies reported. While some home assessments focus almost exclusively on the physical environment (e.g., accessibility and home hazards), a number are now available that take into consideration such environmental factors as social supports provided by caregivers and the attitudes within the environment.

Home assessments typically involve the examination of PEO fit for a client within his or her home environment and recommendations related to home modifications. The *Housing Enabler* (Iwarsson & Isacson, 1996) and *EASE3* (Christenson, 2002) are both measures that address environmental factors explicitly in relationship to clients' needs and ability. Both include separate components that

SAFETY NOTE 11-1

Therapist Safety on Home Visits

Therapists are often the only health professionals involved when conducting home visits, so safety of the therapist and client need to be considered. Although a therapist may be very confident about her/his safety with the client, other occupants of the home, building, or even the neighborhood (including animals) may put the therapist at risk. Home and community settings can present risks because they are complex and often unfamiliar to the therapist. Therefore, it is always advisable for therapists to maintain vigilance about their personal safety when conducting home visits. The following points are useful to ensure that the therapist and client are safe during home visits:

- Ensure that someone knows the location and approximate times for your home visit. It is good practice when a visit is conducted outside of normal business hours to phone that person when you have completed a visit and are on your way to let him/her know that you are safe.
- Carry a mobile phone to use in case of emergency during the travel or home visit. Keep the battery charged.
- If traveling by car, ensure that it is in good repair, prepared for emergency, and has at least a half tank of gas.
- Park as close as you safely can to the client's home.
- If taking public transportation, follow safety recommendations related to its use.
- When you arrive at the home, assess the surroundings and inside the home to identify any potential hazards.
- Throughout the visit, ensure that you are aware of exits and escape routes.
- Have the client lead you to different areas of the home, including up and down stairways.
- Try to limit the amount of material that you bring into the home or have outside of a carrying bag at any time.
- If possible, wear footwear inside the home, even if that means removing outdoor footwear at the door and donning a second pair of indoor shoes.
- If you feel unsafe or uncomfortable at any time, leave the situation immediately.
- Adhere to any policies or procedures of your employer, including conducting joint visits, and report any unusual or unsafe situations immediately.

first address the client's abilities and disabilities and then examine the home environment in relation to these factors. Both tools are administered through an interview; the *Housing Enabler* also involves observation of the physical environment. To rate items on the *Safety Assessment of Function and the Environment for Rehabilitation (SAFER)*, *Home Fast*, and *Westmead*, clinicians integrate information about the client's abilities with observations about the environment. For example, in determining if an item such as toileting is a problem on the *SAFER* (or the extent to which it is a problem on the *SAFER-HOME*), the therapist must consider the client's ability to safely transfer on to and use the toilet while simultaneously considering the availability of physical supports (such as grab bars) and social supports (family caregiver assistance) and how willing the client is to make use of the supports available (see Fig. 11-4 for an example of this tool). Ideally, all of these assessments should be conducted in the client's home. In clinical settings where it is not possible to visit the home, the occupational therapist may choose to conduct an interview using the items of the *SAFER* or *EASE3* with the client and/or a family member or friend selected by the client who knows the client's home well. The interview, however, cannot be used as a substitute to determine whether or not a client can manage safely at home or what modifications may be needed. Rather, it can be used to highlight issues that clients and/or caregivers need to consider in the home. Other options include self-assessment guides to home adaptation, which can be used in collaboration with a client (e.g., *Maintaining Seniors' Independence through Home Adaptation: A Self-Assessment Guide* [Canadian Mortgage and Housing Corporation, 2003] and *A Consumer's Guide to Home Adaptation* [Adaptive Environments Center, 2002]). These tools provide practical suggestions for home adaptations in relation to functional problems, such as difficulty entering the bathtub, as shown in Figure 11-5. The therapist could help the client to select solutions that best fit his or her situation. See overview of home assessments in Assessment Table 11-1.

Housing options can also be reviewed with home assessments to determine the best fit for the client. Options are numerous and most communities have innovative, barrier-free housing with access to attendant care and other support services, meals, and recreation. Many seniors and persons with severe physical disabilities choose to live in these housing projects since they can more easily achieve independence within a supportive system. Transitional housing programs also assist clients to develop independent living skills and to develop knowledge of available resources. The occupational therapist can use assessment tools such as the *Housing Enabler* (Iwarsson & Isacson, 1996) and *EASE3* (Christenson, 2002) for such purposes.

Assessment and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Home Falls and Accidents Screening Tool (HOME FAST)</i> (Mackenzie, Byles, & Higginbotham, 2000).</p> <p>The appendix of the article includes all items of the HOME FAST along with definitions.</p>	<p>Assessment of the home hazards that may contribute to falls and, therefore, fall prevention interventions.</p> <p>Scoring level: Nominal (items are scored as a hazard, not a hazard, or not applicable).</p> <p>Scores range from 0–25 (indicating the number of items for which hazards are identified).</p>	20–30 minutes.	<p>Content: Based on compilation of items from the literature, field testing with 83 older adults, and review of content and field testing data by an expert panel to reduce the number of items (Mackenzie, Byles, & Higginbotham, 2000).</p> <p>Content was further examined through a cross-national validation (Australia, Canada, and United Kingdom) that asked occupational therapists, physiotherapists, and nurses to respond to a survey regarding the content and weighting of HOME FAST items (Mackenzie, Byles, & Higginbotham, 2002a).</p> <p>Convergent: Not established. No gold standard exists.</p> <p>Construct: Initial evidence suggests that the HOME FAST may be useful in identifying relative risk for falls associated with exposure to home hazards, based on 99% confidence intervals</p>	<p>Inter-rater: Evaluated (n = 40) using kappa for individual items and weighted kappa for the total number of hazards. The overall weighted kappa was 0.56 (considered fair to good agreement); kappas for individual items indicated that 4 items had excellent reliability, 20 had fair to good reliability, and one item (hazardous outside paths) had poor reliability (Mackenzie, Byles, & Higginbotham, 2002b).</p> <p>Test-retest: Not established.</p>	Not established.	<p>Strengths: Can be quickly administered as a screening assessment. Research has been conducted in various countries. Initial psychometric research is positive.</p> <p>Weakness: Further examination of construct and predictive validity would strengthen our understanding of the measure.</p>

<p><i>Life EASE 3.2 Basic and 3.2 Deluxe</i> www.lifease.com/lifease-home.html Author: Margaret Christenson (mchristenson@lifease.com)</p>	<p>Computer-based questionnaire to assess personal needs and abilities as well as potential home environment problems. Based on these data, program recommends solutions.</p> <p>Scoring level: Basic scoring is nominal (yes/no) rating whether or not the person can perform the functional activity; deluxe version involves a 5-point Likert scale for each item related to the person's ability to function. An individualized environmental checklist is then created based on the functional abilities of the person.</p> <p>Range of scores: no summary score is provided.</p>	<p>Varies depending on extent of activity limitations and number of rooms in the home.</p>	<p>(MacKenzie, Byles, & Higginbotham, 2000). Further research in this area is required with larger sample sizes and with longitudinal information rather than cross-sectional data.</p>	<p>Content: Excellent item selection including: comprehensive assessment of physical characteristics of home; functional activities needed for doing ADL at home; and provides a wide range of design and AT products and solutions. Constantly under review.</p> <p>Convergent: Not established.</p> <p>Construct: Not established.</p>	<p>Not established.</p>	<p>Not established.</p>	<p>Strengths: Practical, comprehensive, and popular. Power Point slides for occupational therapists available through company and AOTA. Weakness: Lacks psychometric testing.</p>

Assessment Table 11-1

Access to Home (continued)

Assessment and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Safety Assessment of Function and the Environment for Rehabilitation (SAFER tool)</i> and <i>SAFER-HOME</i> (Chiu et al., 2001)</p> <p>COTA Health, 700 Lawrence Ave. West, Suite 362, Toronto, Ontario, M6A 3B4; Telephone: 416-785-9230. E-mail: info@cotahealth.ca</p> <p>Order form can be downloaded from Products at www.cotahealth.ca</p>	<p>The SAFER tool is designed to identify and describe safety concerns of individuals in their own homes and to collect information to plan interventions and recommendations to improve safety (14 sections: living situation, mobility, kitchen, fire hazards, eating, household, dressing, grooming, bathroom, medication, communication, wandering, memory aids, and general).</p> <p>The SAFER-HOME is designed to measure change in safety over time (10 domains: meal preparation, awareness of safety hazards, mobility and toileting, cognitive impairment, homemaking support, emergency communication, functional communication, personal care, family assistance, and medication).</p>	45-90 minutes.	<p>Content: For both the SAFER and the SAFER-HOME, content validity has been established through review by experts and clinicians, as well as statistical analysis of completed measures.</p> <p>Criterion: Not established (as no gold standard exists).</p> <p>Construct: SAFER: Total scores have been associated with cognitive status and independent living in houses, but not directly to ADLs or IADLs (Letts & Marsall, 1995; Letts et al., 1998).</p> <p>SAFER-HOME: Total scores were compared to functional status scores using the Functional Autonomy Measurement System (SMAF) (Hebert, Carrier, & Bilodeau, 1988). The correlation was weak, which confirmed that the SAFER-HOME is measuring more than functional abilities (Chui & Oliver, in press).</p>	<p>SAFER: Inter-rater: kappa or % agreement: acceptable to excellent for 92 items (Letts et al., 1998).</p> <p>Test-retest: kappa or % agreement: acceptable to excellent for 90 items (Letts et al., 1998).</p> <p>SAFER-HOME: Internal consistency: coefficient alpha for total scores = 0.8593; subscales ranged from 0.539-0.789 (Chui & Oliver, in press).</p>	<p>Not established: It is hypothesized that the SAFER-HOME will be more sensitive to change with its 4-point rating for each item.</p>	<p>Strengths: Comprehensive coverage of home safety. Both tools developed and tested rigorously.</p> <p>Weaknesses: Length of administration may be problematic in some clinical situations. Further research on responsiveness to change needed.</p>

<p>Scoring level: <i>SAFER</i>: Nominal for each item (problem or not a problem); <i>SAFER-HOME</i>: Ordinal (4-point rating scale [0–3]: no problem, mild problem, moderate problem, severe problem). Ranges of scores: <i>SAFER</i>: 0–97; <i>SAFER-HOME</i>: 0–279.</p>	<p>One home visit required.</p>	<p>Content: Established through content analysis of the literature and a rigorous expert review process (Clemson, Fitzgerald, & Heard, 1999). Criterion: Not established (as no gold standard exists). Construct: Not established.</p>	<p>Inter-rater: tested in a sample of 21 clients' homes; kappa values of >0.75 for 34 items; and between 0.4 and 0.75 for 31 items; kappa could not be calculated for some items (Clemson et al., 1999). Test-retest: Not established.</p>	<p>Not established.</p>	<p>Strengths: Comprehensive and systematic assessment of home hazards specific to falls in older adults. Manual is helpful and provides operational definitions for key hazards. Weaknesses: Does not address home hazards besides falls. Further evaluation of reliability, construct validity, and responsiveness to change would be helpful.</p>
<p><i>Westmead Home Safety Assessment</i> Co-ordinates Publications, a division of Co-ordinates Therapy Services Pty Ltd, P.O. Box 59, West Brunswick, Victoria 3055; Telephone: 011 61 3 93801127; Fax: 011 61 3 93874829; www.therapybookshop.com/coordinates.html</p>	<p>Assessment to identify fall hazards in the home environments of older adults. Scoring level: Nominal (dichotomized relevant or not; each relevant item is rated as a hazard or not; hazards are presented by type). Ranges of scores: No summary score.</p>	<p>One home visit required.</p>	<p>Inter-rater: tested in a sample of 21 clients' homes; kappa values of >0.75 for 34 items; and between 0.4 and 0.75 for 31 items; kappa could not be calculated for some items (Clemson et al., 1999). Test-retest: Not established.</p>	<p>Not established.</p>	<p>Strengths: Comprehensive and systematic assessment of home hazards specific to falls in older adults. Manual is helpful and provides operational definitions for key hazards. Weaknesses: Does not address home hazards besides falls. Further evaluation of reliability, construct validity, and responsiveness to change would be helpful.</p>

Do you have any difficulty stepping into or out of the bathtub?

- No** ➤ If no, go to next question
- Yes** ▼ If yes, check the adaptations below which would help you
- Install a vertical and an horizontal or angled grab bar by the tub
 - Install non-slip flooring throughout the bathroom
 - Install a non-slip surface in the bathtub
 - Install a commercial or custom-made transfer bench so that the tub can be entered from a seated position
 - Replace bathtub with a shower stall, if difficulty is severe
 - Install a separate shower stall, if difficulty is severe
 - Other (describe)

A vertical grab bar provides support when entering the tub, while an horizontal (or angled) bar helps you to complete the entrance and lower yourself onto a shower seat or to the bottom of the tub.

Figure 11-5 Using the bathroom: accessing the bathtub. (Adapted from *Maintaining Seniors' Independence through Home Adaptations: A Self-Assessment Guide*. Canadian Mortgage and Housing Corporation, 2003.)

make sure persons with a physical disability have equal access to the housing of their choice (United States Department of Housing and Urban Development [HUD], 2001). Specific accessibility requirements have been established to ensure that the design and construction of new residential buildings comply with the Fair Housing Act (e.g., buildings must have an accessible entrance on an accessible route). Occupational therapists conducting an environmental assessment of an apartment should also remember to evaluate building access, parking, halls, facilities, and fire routes to ensure that these requirements have been met. Many of the home assessments presented in this chapter offer items relevant to single family as well as multi-unit dwellings.

Assessment of Access to Community

Occupational therapists are becoming more involved in changing environments to facilitate their clients' roles within their communities. This may be particularly important toward achieving community participation and the realization of self-enhancement roles. Persons with disabilities may not be aware that community businesses and services must be made accessible to them (ADA, 1990). Occupational therapists can assume consultation or advocacy roles with groups seeking to make educational, cultural, commercial, and religious facilities accessible. The

concept of universal design is also gaining increased attention in communities, and occupational therapists can play an important role in promoting this mainstreaming approach to design (Ringaert, 2003).

The transportation needs of persons with disabilities should not be overlooked in communities (Iwarsson, 2003). Useful information about standards and devices for vehicular transportation for persons with physical disabilities can be sought from the United States Department of Transportation and the National Highway Traffic Safety Administration. Commercial transportation companies, such as airlines, buses, and trains, must also comply with accessibility standards and make reasonable accommodations according to the ADA.

The occupational therapist should be familiar with the new ADA-ABA Accessibility Guidelines to ensure community structures are in line with ADA requirements (United States Access Board, 2004a, 2004b). A new instrument for assessing urban public transport accessibility, the *Travel Chain Enabler*, has been successfully piloted by occupational therapist Suzanne Iwarsson and her colleagues in Sweden (Iwarsson, Jensen, & Stahl, 2000). The therapist can also ask the client's opinions about community access and supports by using the *Craig Hospital Inventory of Environmental Factors (CHIEF)* (Craig Hospital Research Department, 2001) and can measure a client's perceptions of environmental facilitators and obstacles to their social participation and daily occupation using the *Measure of*

Quality of the Environment (Fougeyrollas et al., 1999). The *Multidimensional Scale of Perceived Social Support* (Zimet et al., 1988) is useful for quickly identifying clients' perceptions of social supports available from their family and friends and to lead into a discussion of social resources toward enabling greater community participation. Some of these assessment instruments and their sources are presented in Assessment Table 11-2.

Assessment of Access to Workplace

Occupational therapists play an important role in enabling clients to fulfill self-advancement roles by assisting them to seek or return to work. On-site assessment of workplace accessibility is critical, as workplace environments can differ significantly (Innes & Straker, 1998). Workplace assessment is a key step in helping the occupational therapist learn how workplace factors impact work performance (Bootes & Chapparo, 2002). See Procedures for Practice 11-1 and 11-2 for suggestions related to conducting work site assessments.

Knowledge of the ADA and the supporting guidelines is critical for guiding workplace assessment. For practical assessment purposes, the occupational therapist may wish to use the guidelines together with the *Americans with Disabilities Act Checklist for Readily Achievable Barrier Removal*, as mentioned earlier in this chapter (Adaptive Environments Center, 1995). Other tools, such as the *ADA Work-Site Assessment* (Jacobs, 1999a) or the *Job Analysis during Employer Site Visit* (Jacobs, 1999b), may also be used to help the occupational therapist focus on specific environmental factors in addition to work demands that may influence work performance. Unfortunately, these checklists have incomplete psychometric validation.

Occupational therapists recognize that a range of environmental factors can affect one's ability to work. Therefore, it is also important to assess the sociocultural environment, including social supports, staff interactions, and attitudes of co-workers and supervisors (Bootes & Chapparo, 2002). Tools such as the *Life Stressors and Social Resources Inventory*, *Work Environment Scale*, *Work Experience Survey*, and *Workplace Environment Impact Scale* (refer to Assessment Table 11-3 for details) are not limited to physical access issues because they also address areas such as social environments and resources.

Persons with disabilities may also face challenges while volunteering at or attending school. Many of the tools previously discussed to address work environments or community access may be of use in these instances. Occupational therapists may also use tools such as the *Accessibility Checklist* from the North Carolina State University, Disability Services for Students (1997). This informal checklist briefly addresses physical, policy/programmatic, information, and attitudinal environments from a post-secondary school perspective.

PROCEDURES FOR PRACTICE 11-1

Preparing for a Site Visit

The occupational therapist is asked to perform a work site assessment to determine accommodations that may be necessary for successful return to work of a client. The following background information should be gathered:

- Description of job (e.g., duties, responsibilities, sequence, temporal patterns, risks, variations in complexity of tasks, essential competencies, etc.)
- Description of workstation and work site (e.g., structure, ambiance, layout, environmental hazards, location, etc.)
- Consent of employer/business/industry representatives and client (including nature of client's wishes regarding information to be shared)—often written
- Understanding worker and employer perspectives (e.g., expectations, issues, abilities, etc.)
- Arrangements for visit (including consent and preparatory planning with appropriate personnel) should be conducted well in advance of visit
- Presence of a contact person during visit (e.g., supervisor, occupational health personnel, etc.)
- Evaluation framework, including list of questions, activities, safety concerns, and so on
- Charts/assessment forms to record findings
- Consideration of contributions from second person (e.g., physiotherapist)—dependent on nature of assessment

PROCEDURES FOR PRACTICE 11-2

Supplies and Materials Required for Site Visit

Planning with employer (including a preliminary understanding of the work site) may help to determine with greater accuracy what supplies and materials may or may not be required in advance of the visit.

- Paper, pens, pencils, and clipboard
- Measuring tape and wheeled measuring device
- Stopwatch
- Force gauge dynamometer
- Personal protective equipment as appropriate (e.g., steel-toed footwear)
- Thermometer
- Digital camera (with video recording capacity), tripod
- Photo release forms
- Laptop computer (Aja, 1996; Jacobs, 1994.)

(Aja, 1996; Jacobs, 1994.)

Assessment Table 11-2

Access to Community

Assessment	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Craig Hospital Inventory of Environmental Factors (CHIEF) and CHIEF Short Form</i></p> <p>The Center for Outcome Measurement in Brain Injury (http://tbims.org/combj/chief) at Craig Hospital: (www.craighospital.org/Research/Disability/CHIEF%20Manual.pdf), (www.craighospital.org/Research/Disability/DISCHIEF.asp), (www.tbims.org/combj/chief/CHIEF.pdf)</p>	<p>Assessment of the frequency and magnitude of a broad range of environmental characteristics that act to impede accomplishment of daily activities and social roles.</p> <p>Self-administered or administered by interview.</p> <p>Full CHIEF: 25 items. Short Form: 12 items.</p>	<p>Self-administered, 10 minutes.</p> <p>Interview administered, 15 minutes.</p> <p>Short Form: 5 minutes for self-administration, 10 minutes for interview.</p>	<p>Content validity established by literature review and consultation with experts. Four advisory panels involved.</p> <p>Construct validity addressed when subscales were established: showed differences in reported frequency and magnitude of environmental barriers between groups with different impairments and activity limitations (Whiteneck, Gerhart, & Cusick, 2004; Whiteneck et al., 2004).</p>	<p>Internal consistency: moderate to high ratings for total score (0.93) and subscales (ranging from 0.76–0.81).</p> <p>Authors recommend that proxies should not be used to complete CHIEF.</p> <p>Study of test-retest reliability showed an overall ICC of 0.926 for total score, and ICCs for individual items ranged from 0.332–0.882 (Whiteneck et al., 2004).</p>	<p>No evidence.</p>	<p>Strengths: Based on ICF.</p> <p>Comprehensive inventory of environmental factors. Quick and easy to administer and score. Appropriate for both population-based or individual-focused assessment and research.</p> <p>Weaknesses: Further evaluation of psychometric properties needed. Scale for assessing magnitude of barriers has only 2 points (little vs. big problem).</p>

<p><i>Measure of Quality of the Environment (MQE)</i> (Fougeyrollas et al., 1999) Available from authors: Kathy Boschen (boschen.kathy@toronto rehab.on.ca); or Luc Noreau (Luc.Noreau@rea.ulaval.ca)</p>	<p>Measures environmental facilitators and obstacles to social participation and accomplishment of daily activities. Environment is defined broadly to include social, attitudinal, institutional, technical, and physical factors in the environment. Interview format: can be administered with client in context of home, community, or workplace.</p>	<p>Less than 30 minutes.</p>	<p>Content based conceptually on the Disability Creation Process model and input from individuals with SCI and clinicians (Fougeyrollas, Noreau, & Boschen, 2002). Construct validity has been demonstrated (Noreau, Fougeyrollas, & Boschen, 2002).</p>	<p>Moderate concordance scores across items. Good test-retest reliability (Boschen, Noreau, & Fougeyrollas, 1998).</p>	<p>No evidence.</p>	<p>Strengths: Tool is easy to administer. Some evidence of validity and reliability. Weaknesses: Not published and only available from authors; no method for summarizing and interpreting scores. Further examination of psychometric properties is recommended.</p>
<p><i>Multidimensional Scale of Perceived Social Support (MSPSS)</i> (Zimet et al., 1988)</p>	<p>Assessment of perceptions of social support from 3 sources: family, friends, and significant other. Inventory/list of 12 statements of relationships. Each item rated on 7-point Likert-type scale.</p>	<p>2–5 minutes.</p>	<p>Content validity established through factor analysis. Multiple studies established construct validity with numerous health constructs, psychopathology, suicidal behavior, anxiety, and depression. Marginalized groups demonstrate lower perceived social support.</p>	<p>Internal consistency good, with Cronbach's alpha ranging from 0.81–0.91 in multiple studies. Test-retest reliability in one study with undergraduate psychology students was good for total score (0.85) and subscales (0.72, 0.85, and 0.75) (Zimet et al., 1988). Good reliability shown in study with older adults (Stanley, Beck, & Zebb, 1998).</p>	<p>No evidence.</p>	<p>Strengths: Simple to use and score in a short time. Has been used primarily with mental health populations; appears to have utility for populations with physical disability. Weaknesses: Need to be wary of socially desirable responses. Requires evaluation of sensitivity to change and utility as an outcome measure.</p>

Assessment Table 11-3

Access to Workplace

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<i>Americans with Disabilities Act (ADA) Work-Site Assessment</i> (Jacobs, 1999a)	Used for work-site assessments based on <i>ADA Checklist</i> and short answer format.	Information not available.	Not available.	Not available.	Not available.	Strength: Observations guided by ADA. Weakness: Lacks psychometric validation.
<i>Job Analysis during Employer Site Visit</i> (Jacobs, 1999b)	Checklist to analyze a range of factors during work site visit. Factors include environmental conditions, social conditions, job tasks, physical and cognitive demands, classification of work by amount of strength required, and physical barriers.	Information not available.	Not available.	Not available.	Not available.	Strength: Structures observations. Weakness: Lacks psychometric validation.
<i>Life Stressors and Social Resources Inventory—Adult Form (LISRES-A)</i> (Moos & Moos, 1998) Psychological Assessment Resources (PAR) Inc., 16204 N. Florida Ave., Lutz, FL 33549; www.parinc.com; Telephone: 1-800-331-8378 or (813) 968-3003.	Questionnaire designed to provide an overview of an individual's life context, including life stressors (9 measures) and social resources (7 measures). Self-report or therapist administered; 200 items (uses dichotomous and Likert-type scales).	30 minutes to administer; 10–15 minutes to score.	Face and content validity addressed through descriptions of domains and placing of domains in non-overlapping dimensions. Construct validity has been demonstrated (Moos, Finney, & Moos, 2000).	Internal consistency averaged 0.82 for stressors and 0.79 for resource measures (Moos & Moos, 1998).	Not established; however, commonly used to evaluate social resource/stress reduction interventions.	Strengths: Examines both stressors and social supports in one tool. Modified ICDH format. Well standardized. Internally consistent, relatively stable tool. Weaknesses: Further research needed with broader populations. No spirituality items.

<p><i>Work Environment Scale (WES)</i> (Moos, 1994) CPP, Inc., 1055 Joaquin Rd., Suite 200, Mountain View, CA 94043; Telephone: (650) 969-8901; Toll Free: 1-800-624-1765; Fax: (650) 969-8608</p>	<p>Questionnaire to assess employees' perceptions of social environments across work settings. Self-administered questionnaire (90 items, true/false); 10 subscales (e.g., work pressure, supervisor support, and physical comfort)</p>	<p>15–20 minutes; 5–10 minutes to score.</p>	<p>Face validity established in manual; tools based on <i>Social Climate Scales</i>. Multiple studies demonstrate construct validity (e.g., Staten et al., 2003).</p>	<p>Cronbach's alpha coefficients for test-retest reliability (1 month) fall between 0.69 and 0.83 At 12 months, test-retest coefficients ranged from 0.51–0.63 Test-retest reliability: ICC > 0.70 (Moos, 1994).</p>	<p>No information found.</p>	<p>Strengths: Standardized; established psychometric properties; readily available, portable. Promotes discussion and identifies clients' views. Useful on an individual basis, with groups, or with organizations. Weaknesses: Scores alone should not provide direction for intervention. Need further study with populations with physical disability.</p>
<p><i>Work Experience Survey (WES)</i> (Roessler & Gottcent, 1994; Roessler, 1996) Available from The National Clearinghouse of Rehabilitation Training Materials http://shopping.net suite.com/s.nl/c.392723/sc.1/f</p>	<p>Interview used to identify job accommodation needs (worksite accessibility, performance of essential functions, job mastery, and job satisfaction). Based on several tools or sources of information that have been adapted and included in the WES (Roessler & Gottcent, 1994).</p>	<p>30–60 minutes.</p>	<p>Has been used across groups of clients with a range of diagnoses (e.g., MS, blindness, arthritis) and frequently cited as a valid tool, although specific psychometric data could not be located.</p>	<p>Coefficient alphas for assessing job mastery and assessing job satisfaction reported as 0.74 and 0.78, respectively, in one study (Roessler, 1996).</p>	<p>Not available.</p>	<p>Strengths: Literature cites its use in several case studies. Facilitates identification of barriers and reasonable accommodations. Assists in empowering clients to address work barriers with employers. Has been used in individuals with a variety of disabilities Weaknesses: Need to look at utility of WES in follow-up interviews. Additional psychometric data required.</p>

Assessment Table 11-3

Access to Workplace (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
<p><i>Workplace Environment Impact Scale (WEIS)</i> (Kielhofner et al., 1998). Model of Human Occupation Clearinghouse, University of Illinois at Chicago; www.moho.uic.edu/; www.moho.uic.edu/assess/weis.html</p>	<p>Semi-structured interview and rating scale. Addresses individuals' experiences and perceptions of their work environments. Designed for use with individuals with physical or psychosocial disabilities who are employed or are planning to return to work after an interruption in employment (due to injury/illness). 17 items scored on 4-point ordinal scales.</p>	<p>30–45 minutes to conduct interview (depending on interviewer's abilities and the client); 15 minutes to complete scoring.</p>	<p>Construct validity established (based on Rasch analysis in which $\text{infit Mnsq} = 1.6$ and $\text{Zstd} = 3.0$) (Kielhofner et al., 1998). Found to measure a single construct (none of 17 items fit criteria for misfit) (Corner, Kielhofner, & Lin, 1997); found to be valid across 2 distinct cultures (Kielhofner et al., 1998).</p>	<p>Rasch analysis: Item separation statistic was 2.77 (reliability of 0.88); items were consistently separated into distinct (non-overlapping) groups (Kielhofner et al., 1998). Found to lack ability to discriminate between groups, although population was found to be homogeneous (Corner, Kielhofner, & Lin, 1997).</p>	<p>Not established.</p>	<p>Strengths: Items work well to measure the construct of work environment impact. The scale is suitably matched to the clients and effectively discriminates different levels of work environment. Both language versions of the WEIS are equal and free of cultural bias. Manual includes suggested questions (www.moho.uic.edu/moho_pub_respond.php). Weakness: Need to be very familiar with interview and scale to ensure appropriate use.</p>

Through partnering with clients and employers, occupational therapists help identify environmental factors that can affect one’s ability to work. A range of strategies, such as work-station modifications and assistive technologies, can be implemented to reduce performance barriers. (See Chapter 36 for discussion of specific strategies.) Additional research is required to better understand how environmental factors affect work outcomes (Shaw & Polatajko, 2002).

Looking Ahead

Many occupational therapists rely mainly on experience, observation, and interviews when called on to evaluate the environment. While these strategies are necessary

? CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Professional Issues to Consider When Making a Work Site Assessment

During a site visit, the occupational therapist observed department store clerks performing a full range of duties. What environmental factors should be noted and evaluated? In particular, consider transportation; access to the building, offices, and public areas; workstations and work areas; and the essential tasks of the job. What methods should be used to collect data? What additional sources of information could be sought and considered to determine the degree of PEO fit present?

CASE EXAMPLE

Assessment of the Home Environment

Occupational Therapy Assessment Process

Clinical Reasoning Process

	Objectives	Example of Therapist’s Internal Dialogue
<p>Patient Information Mrs. P. is an 85-year-old woman who sustained a right-sided cerebrovascular accident (CVA) 2 months ago, resulting in left-sided hemiparesis. She was recently discharged from the rehabilitation center to an apartment that she has shared with her husband for more than 30 years. Results from the <i>Functional Independence Measure (FIM™)</i> (conducted at time of discharge) are available from the referral (see Fig. 11-6). Her total <i>FIM™</i> score improved from 70 (at time of admission) to 97 on discharge. Mr. P. and their daughter are presently doing the housekeeping and most of the meal preparation. Mr. P. would like to hire an attendant to work a few hours a day to assist with Mrs. P.’s personal care and to help with the housekeeping, but financial constraints do not allow for this. Both Mr. P. and their daughter have reported becoming increasingly frustrated and fatigued. They both say that they don’t believe that they can leave Mrs. P. alone because of their concerns about her safety and independence. Prior to her stroke, Mrs. P. prided herself on her ability to care for her husband and her home. Mrs. P. is becoming increasingly concerned about becoming too much of a burden on her family and thinks that they are being overly protective. Mrs. P. has been referred to the community occupational therapist to address concerns about her independence and safety in her home environment.</p>	Understand the patient’s diagnosis or condition	“Although Mrs. P. is still early in her recovery, I would expect that her hemiparesis and any cognitive and perceptual changes will limit her basic personal care, homemaking, and community living skills and safety. Depression is possible after stroke, so I will need to be on the lookout for any mood changes as well.”
	Know the person	“She seems like someone for whom her abilities to care for herself and her family were extremely important to her. I wonder how she is coping now. Since she may have been the person who took care of everything and everyone at home, I wonder how well her daughter and husband are managing all of this. I haven’t worked with many older people and realize that I may have some stereotyped expectations of her readiness to change; I will need to be careful as I could very well be wrong about this. However, I am a bit concerned about how willing she will be to make modifications to her home if I suggest them.”
	Appreciate the context	“I want to know more about her relationships with her husband and her daughter. How have they been affected by the changes? As Mrs. P. uses a quad cane to walk in her home, I also wonder about how well she is able to get around because apartments can be quite small. I may also want to consult with the OT who worked with Mrs. P. at the rehabilitation center for more information.”

Figure 11-6 Case example of Functional Independence Measure (FIM™) assessment. (Reprinted with permission from Uniform Data Systems, 1993.)

Develop provisional hypotheses

“Given her diagnosis, I am assuming that there may be cognitive and perceptual impairments in addition to the more obvious physical problems that will impact Mrs. P.’s occupational performance. I also think that the environment will play a big role in how independent and safe she is at home.”

Assessment Process

The therapist decided to use the *Canadian Occupational Performance Measure (COPM)* (Law et al., 1998) to identify Mrs. P.’s perceptions and priorities for therapy. The *SAFER* tool was chosen to assess Mrs. P.’s ability to safely engage in occupations in her home.

Consider evaluation approach and methods

“I would like to get a sense of her priorities and learn more about her abilities to advocate for herself and make her ideas heard. The *COPM* will be ideal for this. The *SAFER* tool will provide me with information about her home environment and safety. It allows us to discuss her abilities and challenges and to demonstrate a variety of occupations in her home. It will help me identify areas of concern and make recommendations to enhance safety and independence.”

Assessment Results

Based on the *COPM*, Mrs. P. indicated that her priorities were to bathe, prepare meals, complete housekeeping, and do the laundry. The *SAFER* tool highlighted areas of safety concern that Mrs. P. had not raised previously, including issues associated with medication use, vision, and ability to remember to turn off appliances (refer to Figure 11-4, the *SAFER* tool results for this case study).

Interpret observations

“Mrs. P. seems to have limited awareness of any cognitive, visual or perceptual changes since her stroke. However, she is very aware of physical changes. Further assessment may be helpful to explore cognitive, visual, and perceptual difficulties impacting occupational performance. I was surprised that Mrs. P. was having difficulties remembering to turn off the stove, as she doesn’t seem to have memory problems in more social situations. She is occasionally missing things on the left, so I am wondering whether she has any visual attention difficulties as well.”

Occupational Therapy Problem List

1. Decreased independence in self-care, particularly in bathing and toileting.
2. Decreased independence in IADLs including meal preparation, laundry, and housekeeping.
3. Physical barriers to independence and safety identified in home (particularly kitchen and bathroom).
4. Limited funds available for assistive devices, home modifications, and purchase of services.
5. In addition to changes in motor function since CVA, cognitive, visual, and perceptual difficulties may also be impacting safety and independence in daily occupations.

Synthesize results

“Overall, Mrs. P. seems to benefit from occupational therapy intervention. She clearly has many areas she would like to address and is very motivated to work on these areas. The safety concerns I have identified should be addressed as soon as possible. Although Mrs. P. does not seem to be as concerned about the safety concerns, she is open to addressing them if only to help her husband and daughter feel a bit better. I will need to develop a plan to address the areas where I suspect that more assessment would be beneficial. I can also use the database provided in the *EASE 3.2* software to find design modifications and AT products that can improve the accessibility of Mrs. P.’s home. I should consult with a colleague regarding options for funding. I wonder what programs Mrs. P. may qualify for that will supplement funding for equipment I may recommend. I am glad that I used the *SAFER* and the *COPM* as I can re-administer both of these tools in the future as part of my outcome evaluation.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of the Physical Environment on Performance of Meal Preparation

Mrs. P. is an 85-year-old woman with left-sided hemiparesis who can walk short distances using a cane (see Case Example). Considering the occupational therapist’s assessment findings, what would a therapist expect to observe if Mrs. P. tried to make a light meal in her apartment kitchen? What environmental factors might help or hinder her performance? How might family members help or hinder the process? What environmental modifications would you suggest to facilitate her task?

components of good practice, they cannot stand alone. The use of well-validated, standardized instruments is also necessary. Although there is limited availability of well-developed measures for assessing the environment, new instruments may soon be created to assess both barriers and resources in the environment (WHO, 2001).

SUMMARY REVIEW QUESTIONS

1. Why would an occupational therapist assess the environment?
2. List seven examples of environmental barriers that a person with mobility impairment might encounter when returning to work.
3. List seven examples of environmental supports that would allow a senior with arthritis to continue to live at home.
4. What assessments would you use to evaluate whether a client with a spinal cord injury can live independently in the community?
5. As an occupational therapist consultant to an assisted-living facility, what assistance could you offer the facility's administration regarding their plans to renovate the building?
6. What are some reasonable accommodations mandated by the ADA with which occupational therapists should be familiar?

SECTION III: Therapeutic Mechanisms

CHAPTER 12

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Define occupation.
2. Discuss the importance of occupation in people's lives.
3. Discuss occupation as a therapeutic medium.
4. Characterize occupation-as-end and occupation-as-means.
5. Discuss the therapeutic qualities of occupation: purposefulness and meaningfulness.
6. Cite evidence that supports the use of occupation as therapy.
7. Describe how therapeutic occupation is implemented in practice.

Occupation: Philosophy and Concepts

Catherine A. Trombly Latham

Glossary

Glossary

Activity analysis—A process by which properties inherent in a given activity, task, or occupation may be gauged for their ability to elicit individual motivation and to fulfill patient's needs in occupational performance and performance components (Llorens, 1993).

Constraints—Limitations imposed on purposeful movement or the completion of occupational performance. Extrinsic constraints include the physical and sociocultural environment and task demands. Intrinsic constraints include biomechanical and neuromuscular aspects of a person's body, as well as other personal contextual factors (Newell, 1986).

Habit—A usual manner of behavior (Mish, 2004).

Phase planes—Graphs of movement, with velocity of the end point on the ordinate and displacement on the abscissa. Movements using the same motor plan produce replicable phase planes, but movements using different plans produce unique phase planes.

Purposeful activity—Purposeful activity is a general class of human actions that are goal directed. A person may participate in activities to achieve an occupational goal, but these activities, on their own, do not assume a place of central importance or meaning for the person (AOTA, 2002, p. 610).

Task demands—The context (e.g., objects, surroundings, ritual, tools, materials) that evokes certain maneuvers required to accomplish the goal of the task.

OCCUPATION DEFINED

Occupation is defined by the general public as an activity in which one engages, especially one's work (Mish, 2004). Occupational therapists define *occupation* "as activities of everyday life, named, organized and given value and meaning by individuals and a culture. Occupation is everything people do to occupy themselves, including looking after themselves, enjoying life and contributing to the social and economic fabric of their communities" (American Occupational Therapy Association [AOTA], 2002; Law et al., 1997, p. 32). Occupational therapists believe that "occupation is a source of meaning and purpose, choice and control" (Hammell, 2004, p. 299). The term *occupation* applies to the integration of the person's abilities, motivations, goals, and the environment to enable role performance. Personal identity emerges from "an harmonious balance" of the many meaningful occupations in which a person engages over time (Christiansen, 1999; Unruh, 2004, p. 294). People engaged in occupation not only define their identity but also achieve a sense of competence and report a sense of satisfaction and fulfillment (AOTA, 2002). Occupational therapists work with people who have experienced a significant crisis in occupational identity (Unruh, 2004). It is the role of the occupational therapist to help the person to grieve his or her loss and to reconstruct an acceptable occupational identity.

Although the terms *occupation* and **purposeful activity** are used interchangeably by most therapists, the American Occupational Therapy Association (2002) has distinguished between the two on the basis of meaningfulness. It defines occupation as activity having unique meaning and purpose in a person's life. Occupations are central to a person's identity and competence, and they influence how one spends time and makes decisions (AOTA, 2002,

p. 610). Purposeful activity, or activity, is a general class of human actions that are goal directed. A person may participate in activities to achieve a goal, but these activities do not assume a place of central importance or meaning for the person (AOTA, 2002, p. 610). Each occupation is composed of several purposeful activities.

Purposeful activity is circumscribed; it demands particular responses within particular contexts and is used therapeutically to facilitate change in impairments and functional limitations. In this text, occupation-as-end is equated to *occupation*, and occupation-as-means is equated to *purposeful activity*.

Both occupation and purposeful activity involve interaction by a person with the environment. The temporal aspects differ. Occupation takes place over time, such as playing a game of baseball, preparing a meal, building a house, or being a friend. Purposeful activity occurs within the moment of performance, such as hitting a baseball as part of the occupation of playing a baseball game or spreading toothpaste on a toothbrush to accomplish the occupation of grooming.

Strings or sequences of occupations or activities constitute routines (AOTA, 2002). Routines give life order (Segal, 2004, p. 499). Most self-maintenance and many self-advancement and self-enhancement occupations depend on routines and **habits**, which are long practiced and automatic. Injury or disease disrupts those routines and habits, causing occupational dysfunction.

IMPORTANCE OF OCCUPATION IN PEOPLE'S LIVES

Occupational engagement contributes to the experience of a life worth living (Hammell, 2004). Engagement in

positive occupations (e.g., care of self, others, and property; creative endeavors; work) that the person has the capabilities to accomplish and chooses to accomplish regulates the rhythm of personal and community life. Such occupations absorb attention and evoke creativity, promote feelings of satisfaction with achievement, and contribute to a sense of self-esteem and self-efficacy (Fig. 12-1). These occupations are potentially therapeutic.

Time-use studies indicate that people who are mentally able to envision goals fill their time with activities and tasks (Grady, 1992; McKinnon, 1992; Pentland et al., 1999; Yerxa & Baum, 1986; Yerxa & Locker, 1990). Beyond the organization and positive feelings generated by engagement in occupation, there is evidence that social and productive occupations are independently associated with survival. A study followed 2,761 men and women in one U.S. city over 13 years. The researchers controlled all other variables that could possibly explain the survival rate and found that social activities, defined as going to church, cinema, and restaurants; taking trips; playing cards and other games; and participating in social groups and productive activities

(defined as gardening, preparing meals, and shopping), conferred survival advantages equivalent to those of fitness activities. They concluded that social and productive activities exert an independent protective effect not due exclusively to the associated physical activity (Glass et al., 1999). In an explorative study of older Swedish adults with functional impairments, researchers found that some persons continued to engage in meaningful occupation despite reduced capacities, although others failed to do so (Borell et al., 2001). Failure to do so was associated with a reduced sense of hope. In the absence of social and productive occupation (as occurs, for example, early in retirement or in the acute stage of motor disability, or immediately after a profound loss [Hoppes, 2005]), a person may experience a sense of disorganization, depression, and loss of a sense of self-worth.

Not all occupation or purposeful activity is beneficial. Attempts to engage in occupations beyond one's capabilities lead to frustration, anxiety, and depression (Rebeiro & Polgar, 1998). Engagement in negative occupation (e.g., crime, destruction) disrupts personal and community life.

Figure 12-1 Occupation-as-end. Baking brownies again under new circumstances (after spinal cord injury). **A.** Preparing the pan. **B.** Transporting to the oven. **C.** Putting the brownies into the oven.

Doing the same activity repetitively beyond the requirements of the task, as seen in obsessive-compulsive disorder (OCD), reinforces pathology. Imposition of unsuitable, negatively meaningful activities (e.g., children's games for elderly patients) fails to build a sense of self-esteem and satisfaction. These types of occupation are not therapeutic. Therapeutic occupation, a special type of occupation, is defined as the use of positive, meaningful, and purposeful activities to improve a person's occupational functioning or to improve abilities and capacities to enable improved occupational functioning.

Occupation as Therapy

Occupation is the unique therapeutic medium of occupational therapy (National Society for the Promotion of Occupational Therapy, 1917; Reilly, 1962). Long before there was scientific evidence, occupational therapists believed that occupation maintained or restored health and gave meaning and quality to one's life (Rebeiro, 1998). Even now, the evidence is meager (Rebeiro, 1998).

What about occupation maintains or restores health? That question is still debated, but one suggestion is that occupation is therapeutic when it appeals to the patient (has meaning for the patient); when it advances therapeutic goals (makes demands on the system needing improvement); and when it is carried out in the space,

time, and sociocultural conditions that it would be in real life (fulfills a purpose in the person's life) (Pierce, 1998). Another aspect of the therapeutic experience is the "just right" challenge, the optimal fit between demands of the occupation and the skills of the person (Rebeiro & Polgar, 1998). An occupation is therapeutic when it requires effort for the patient to accomplish but is possible for the patient to accomplish. By accomplishing it, the patient improves the impaired ability or capacity being challenged. By succeeding in the challenge, the patient is motivated to continue or repeat the experience (Rebeiro & Polgar, 1998). See Chapter 13 concerning selection and grading of occupation. A successful therapeutic occupation results in feelings of self-satisfaction, self-esteem, and self-efficacy.

Today, as in the past, occupational therapists help people achieve satisfying occupational lives in several ways. One way is to adapt the environment or tools and teach the person how to use these contextual adaptations or other adapted methods to accomplish activities and tasks of daily life (Clark et al., 1997; Jackson et al., 1998; Moyers, 1999). In this case, occupation is both the treatment and the end goal (occupation-as-end). The second way is to remediate impaired capacities and abilities that prevent successful performance of activities and tasks required of a patient's roles (Moyers, 1999). In this case, occupation is the means to remediate impairment (occupation-as-means) (Fig. 12-2). The occupation

A

B

Figure 12-2 Occupation-as-means. **A.** Folding towels as a means to improve sitting balance for a person with spinal cord injury. **B.** Polishing the car to gain movement control of a weak arm after a stroke.

used may actually be the same, for instance, chopping apples to make a pie. If the goal is to relearn how to make an apple pie, then we consider it occupation-as-end. If the goal is to improve strength of grasp to enable multiple other life occupations, then we consider chopping apples occupation-as-means.

Occupation-As-End

Occupation-as-end is the complex activities and tasks that comprise roles (Fig. 12-3). Learning the occupation within the customary environment is the goal. Occupation-as-end is more or less equivalent to *areas of occupation* of the Occupational Therapy Practice Framework (AOTA, 2002) and *activities and participation* of the World Health Organization's International Classification of Functioning (ICF; World Health Organization, 2001) (see Chapter 1). Occupation-as-end is a person's functional goal that he or she tries to accomplish in a given environment using what abilities and capacities he or she has and any adaptations that may be necessary (Fig. 12-4).

An explorative study of Swedish adults aged 42 to 82 years old who had suffered a stroke found that patients were frustrated in their daily occupations because they were not able to carry out their former habits due to their impairments (Wallenbert & Jonsson, 2005). They resisted making adaptations or developing new habits, however, because they feared doing so would diminish gains they could make for their physical impairments. They saw development of new habits as a symbol of dependence. The possibility of this type of thinking needs to be explored with patients who resist the benefits of engaging in occupation-as-end. Occupation-as-end may remediate impairments, but this benefit is serendipitous, and the occupation is not chosen for that purpose. Occupation-as-end achieves its therapeutic effect from the qualities of

Figure 12-3 Occupation-as-end. Relearning to make the bed after stroke.

Figure 12-4 Occupation-as-end. Relearning to vacuum after stroke.

purposefulness and meaningfulness (Definition 12-1). Purposefulness is hypothesized to organize behavior, and meaningfulness is hypothesized to motivate performance (Trombly, 1995).

Occupation-as-end is purposeful by virtue of its focus on accomplishing activities and tasks. Purposeful occupation-as-end organizes a person's behavior, day, and life (Meyer, 1922, 1977; Slagle, 1914; Yerxa & Baum, 1986; Yerxa & Locker, 1990). Although there are no studies on how occupational therapists use occupation-as-end to organize people's lives, there is some anecdotal evidence that occupation-as-end does organize people's lives. For example, an occupational therapist and a patient reported on how the patient reorganized her own life after traumatic brain injury using a synergistic mix of occupation and narration (Price-Lackey & Cashman, 1996).

Occupation-as-end is not only purposeful but also meaningful because it is the performance of activities or tasks that a person sees as important. Only meaningful occupation remains in a person's life repertoire. Meaningfulness of occupation-as-end is based on a person's values acquired from family and cultural experiences. Meaningfulness also springs from a person's sense of the importance of participating in certain occupations or performing in a particular manner, from the person's

DEFINITION 12-1
de·fin·i·tion
Therapeutic Characteristics and Effects of Occupation-As-Means and Occupation-As-End

	Occupation-As-Means	Occupation-As-End
Purposefulness	Organizes abilities and capacities, e.g., movement, cognition, perception	Organizes capacities and abilities into activities, tasks, roles
Meaningfulness	Motivates engagement in therapeutic occupation	Motivates engagement in activities, tasks, life roles
Effect	Occupation, through task demand, remediates capacities and abilities	Occupation, through adaptation or education, restores activities and tasks of life roles

estimate of his or her reward in terms of success or pleasure, and possibly from a threat of bad consequences if the occupation is not engaged in. Meaning is individual (Bruner, 1990), and although the occupational therapist can guess what may be meaningful to the patient based on the person's life history, the therapist must verify with each patient that the particular occupation *is* meaningful to that person *now* and verify that the person sees value in relearning it. The therapist cannot substitute his or her own values in selecting appropriate occupational goals for the patient.

One study has determined that individualized, meaningful occupation-as-end used preventatively resulted in significant benefits across various health, function, and quality of life domains compared with no treatment or group social activity for well elderly participants (Clark et al., 1997). Meaningfulness is not only a psychological term but also a mechanism of change. It affects neurological functioning, as was seen in a positron emission tomography (PET) study by Decety et al. (1997) who discovered that brain activation differed with the meaning of an action regardless of subjects' strategies. Meaningful actions strongly engaged the frontal and temporal regions of the left hemisphere, while meaningless action activated mainly the right occipitoparietal areas.

Few studies in occupational therapy have tested the hypothesis that meaningful occupation-as-end motivates behavior. One qualitative study of the experience of occupational engagement for persons with mental illness reports that the participants experienced a sense of competency secondary to engagement in activities they believed at first to be beyond their capabilities. They were eager to attend therapy to continue working on their projects (Reberio & Cook, 1999). Related studies indicate that life satisfaction is at least partially defined in terms of competent role performance. One can extrapolate from this indication that, if a particular role is satisfying, one would be motivated to do the tasks associated with that role. For example, in the study by Yerxa and Baum (1986) of 15 subjects with spinal cord injury and their 12 non-

disabled friends, a significant moderate correlation ($r = 0.44$) was found between satisfaction with performance in home management and overall life satisfaction. A slightly higher correlation ($r = 0.62$) was found between community skills and overall life satisfaction.

Occupation-As-Means

Occupation-as-means is the use of occupation as a treatment to improve a person's impaired capacities and abilities to enable eventual occupational functioning. Occupation-as-means refers to occupation acting as the therapeutic change agent. Various arts, crafts, games, sports, exercise routines (Figs. 12-5 and 12-6), and daily activities that are systematically selected and tailored to each individual are used as occupation-as-means (Cynkin & Robinson, 1990). The capacities and abilities that are required to complete the activity or task are improved when the person engages repeatedly in the activity or task.

Occupation-as-means is therapeutic when the activity has a purpose or goal that makes a challenging demand yet has a prospect for success. Because the central nervous system (CNS) is organized to accomplish goals (Granit, 1977), the goal or purpose seems to organize the most efficient response, given the **constraints** of person and context. Furthermore, if an activity has meaning and relevance to the individual who is to change, it motivates the will to learn and improve (Cynkin & Robinson, 1990).

Meaningfulness in the sense of occupation-as-means has an immediate aspect. Choice to participate in an activity at the moment is based on immediate motivation that is guided by currently perceived needs, feelings, and desires that may or may not be related to life goals. The meaningful aspect of occupation-as-means may be the emotional value that an interesting and creative experience offers the patient (Ayres, 1958). Or meaningfulness may stem from familiarity with the occupation, its power to arouse positive associations, the likelihood that completion of it will

elicit approval from others who are respected and admired, its value in learning a prized skill, or its potential to contribute to recovery (Cynkin & Robinson, 1990; Grady, 1992).

Thus, the therapeutic aspects of occupation used as a means to change impairments are purposefulness and meaningfulness (Definition 12-1).

Evidence that Occupation-As-Means Organizes Responses

Evidence of changes in organization of emotions, cognition, and perception secondary to engagement in occupation or activity having the therapeutic quality of purposefulness is not easily obtained. Evidence concerning the organization of movement, however, can be easily gained using instruments designed to track the spatial-temporal aspects of movement. Movement organization can be detected from the shape of the velocity profile (Georgopoulos, 1986; Kamm, Thelan, & Jensen, 1990). Different velocity profiles, which indicate differences in movement organization and CNS control, emerge for particular goals or purposes (Jeannerod, 1988; Nelson, 1983) (Fig. 12-7). Some of that evidence will be reported here.

In 1987, Marteniuk et al. demonstrated for the first time the effect of goal on the organization of movement as detected from velocity profiles. They found that five university students organized movement differently when they reached for the same object for different purposes. One goal was to pick up a 4-cm disk and place it in a slot. The other goal was to pick up the disk and throw it into a basket. They measured the reach to the disk. The distance and biomechanical demands were exactly the same under both conditions. Only intent after reach was different. The two purposes produced different velocity profiles for reaching for the disk, indicating different movement organizations.

Goal or purpose is generated from the patient's own intention, from the therapist's directions (Fisk & Goodale, 1989), or from the context, including what objects are available, the relevance of the objects, and what the objects afford the person in terms of action. We are familiar with generation of goals by the person and by the therapist, but contextual indication of goal may be unfamiliar, so studies concerning this will be reviewed.

Mathiowetz and Wade (1995) tested whether the same motor organization was elicited when 20 subjects with multiple sclerosis performed functional tasks in

Figure 12-7 Velocity profiles. The profile on the left is symmetrical and bell-shaped, which is commonly seen in planned reach to a stationary, large target. The peak of the velocity profile (end of the acceleration phase) occurs between 33% and 50% of the reach. The profile on the right is left-shifted, which is commonly seen in guided reach to a small target. The peak velocity occurs early in the reach, and the deceleration phase is extended as the person guides the hand to the target.

natural, impoverished, partial, and simulated conditions. In the natural condition, the subjects actually ate applesauce from a dish with a spoon; in the impoverished condition, they pretended to eat applesauce, with no applesauce, spoon, or dish; in the partial condition, they pretended to eat applesauce using a dish and spoon but no applesauce; in the simulated condition, they performed the feeding subtest of the *Jebsen-Taylor Hand Function Test*, which has the subject pick up kidney beans with a spoon and transfer them to a can. The different contexts transmitted the idea of different goals to the subjects. Because subjects produced unique spatial-temporal maps (**phase planes**), which are indicative of different movement organization, in each context, the researchers concluded that subjects perceived each as a unique activity having a different goal.

Trombly and Wu (1999) examined, in two conditions, the movement organization of 14 people who had had a stroke. The conditions were goal object present and goal object absent (rote exercise). In the goal object-present condition, participants were asked to reach forward to take a piece of food off the plate and bring it to the mouth. In the goal object-absent condition, they were asked to reach forward to the same place but without the food goal. Although the two conditions were biomechanically equivalent, the reach was organized differently (smoother, faster, more forceful, and more planned) when the goal object was present compared with when it was absent. These findings have been verified in other studies (Ma, Trombly, & Robinson-Podolski, 1999; Wu et al., 1998, 2000). At least in terms of motor responses, then, purposiveness, as transmitted by context, does appear to organize behavior. Of course, much more study is required to verify this and confirm it to be true for other performance skills.

Evidence that Occupation-As-Means Motivates Participation

Although the meaningfulness of occupation to a person must be determined by interview and discussion with that person, *meaningfulness* has been operationalized in occupational therapy research in four ways: (1) provide enjoyment; (2) offer a choice; (3) offer the end product to keep; and (4) enhance the context or make the context more applicable to the person's life. The response, *motivation*, is measured as the number of repetitions or length of time engaged in the occupation or the effort expended.

Fun or Enjoyment

Fun is immediately motivating. Several studies confirm that fun or enjoyment derived from play motivates attempts to perform an action or prolongs engagement in an action. King (1993) treated 146 patients in a hand clinic using either a computer game that required the person to pinch or grasp to play the game or by using pinch or grip-strengthening devices. Both treatments lasted 3 minutes. Those who participated in the game did significantly more repetitions (237.2 grips, 240.5 pinches) than those who did the exercise without the game (170.7 grips, 203.2 pinches). Hoppes (1997) studied 10 elderly women who were unable to maintain a functional standing position. They alternatively played a game of their choice or did other chosen, non-playful activities, such as reading, conversing, or folding towels, all while standing at a raised table. Although the difference in standing tolerance was only a minute and a half, it was significantly greater for playing the game (386.5 seconds) than for the other activities (294.3 seconds).

RESEARCH NOTE 12-1

Abstract: Wu, C., Trombly, C. A., Lin, K., & Tickle-Degnen, L. (2000). A kinematic study of contextual effects on reaching performance in persons with and without stroke: Influences of object availability. *Archives of Physical Medicine and Rehabilitation*, 81, 95–101.

A counterbalanced repeated-measures design was used to examine the effects of context on reaching performance in neurologically impaired and intact populations. Context was varied by the presence or absence of objects used to complete a task. Subjects were 14 people with stroke and 25 neurologically intact persons. In a motor control laboratory in a university setting, each participant was tested under two conditions: presence of the object, in which the participant reached forward with the impaired arm or corresponding arm to scoop coins off the table into the other hand; and absence of the object, in which the participant reached forward to a place where the coins would be placed if the object were present. The dependent variables were kinematic variables of movement time, total displacement, peak velocity, percentage of reach where peak velocity occurs, and movement units derived from acceleration data for the reaching part of the activity. The condition of object present elicited significantly better ($p < 0.0055$) performance of reaching movements than the condition of object absent. Better performance was defined as faster (shorter movement time), more direct (less total displacement), more planned and less guided (greater percentage of reach where peak velocity occurs), and smoother (fewer movement units). Peak velocity (forcefulness) was not significantly different between conditions ($p = 0.2791$).

Application to Practice

- Occupation provides significant performance advantage over rote exercise.
- Tasks that use real objects elicit improved organization of movement.
- Treatment in simulated contexts using simulated objects and simulated goals may not help a patient learn occupational performance for real life.

Choice

Provision of a choice presumably creates emotional value because the person is likely to choose an activity that is interesting and creative and/or arouses positive associations from the past. Zimmerer-Branum and Nelson (1995) gave 52 elderly nursing home residents a choice between a simulated basketball game chosen to encourage shoulder flexion and rote shoulder flexion exercises. After trying both, 69% chose the game for the actual treatment session. LaMore and Nelson (1993) found a significant increase in repetitions when 22 adult subjects with mental disabilities

were given a limited choice of which ceramic object to paint (26 repetitions) as compared with being told to paint a particular one (17 repetitions). Choice or perceived control was also found to result in more effective and efficient performance in both younger and older adults whether the task was familiar or novel (Dickerson & Fisher, 1997). Pride of performance may be part of the motivating force when choice is offered.

Keeping an End Product

Presumably, letting a patient make a product that he or she can keep motivates by arousing positive emotions and through the potential of gaining approval from others. Murphy et al. (1999) found that 50 college-aged subjects worked significantly longer on a craft project of their choice when they could keep the product (21.2 minutes) than when they could not (16.9 minutes). However, this was true for only two of the four activities from which the subjects could choose, and only 80% of the subjects reported being interested in keeping the end product. So it is not safe to assume that offering an opportunity to keep an end product is motivational; one must ask.

Enriched Context

Enriched or natural contexts motivate through the positive emotions associated with familiarity and arousal of positive associations with one's home, culture, or previous life. Lang, Nelson, and Bush (1992) tested the responses of 15 elderly nursing home residents under three conditions: kicking a red balloon, kicking a described imagined balloon, and exercise in which they kicked as demonstrated. A significantly greater number of repetitions was associated with really kicking the balloon (54) versus in the imagery or exercise conditions (26 and 18, respectively). This study was later replicated by DeKuiper et al. (1993) with similar results. A number of other researchers demonstrated significantly greater numbers of repetitions or duration of performance under enhanced context conditions (Bloch, Smith, & Nelson, 1989; Kircher, 1984; Miller & Nelson, 1987; Steinbeck, 1986; Thomas, Vander Wyk, & Boyer, 1999; Yoder, Nelson, & Smith, 1989).

Meaningfulness, as operationalized by fun and enjoyment, enhanced context, and possibly choice, appears to motivate continued performance, but more research is needed.

EFFECTIVENESS OF THERAPEUTIC OCCUPATION

For occupational therapists to take pride in their work, they must have confidence that the therapy they offer is effective in improving occupational functioning for their patients. Each therapist's personal experience nurtures

that belief. In this age of evidence-based health practice, however, we need to offer our patients, the payers, and the public more substantial proof of that effectiveness than our anecdotal experiences.

Evidence that Occupation Restores a Sense of Self-Efficacy or Self-Esteem

The qualitative study by Rebeiro and Cook (1998), mentioned earlier, provides the best evidence we have at this time that engagement in occupation restores a sense of self-efficacy and self-esteem. The participants were eight long-time members of an outpatient Women’s Group at a mental health facility who engaged in a cooperative occupational project—making a quilt. On interview after 25 weeks of participation, the participants reported that engagement in the occupation gave them a sense of self-confidence and competency because of their accomplishment, which they did not have before the introduction of occupation to the group.

Evidence that Occupation-As-End Restores Self-Maintenance, Self-Enhancement, and Self-Advancement Roles

Direct evidence of the effectiveness of occupation-as-end to restore life roles is sparse. One study reported successful resumption of role performance in 17 randomly selected chronically disabled community-living elders after receiving home-based occupational therapy (Levine & Gitlin, 1993). As a result of the program, participants engaged in a greater range of tasks, such as wine making, visiting relatives, attending church, and cleaning, than they did before the intervention. They became more engaged in life, as shown by their volunteerism and increased social activities. See Evidence Table 12-1 for examples of studies from which evidence concerning the effectiveness of occupation to restore role resumption can be gleaned.

Evidence that Occupation-As-Means Remediate Impairments

Studies of the effects of occupation-as-means on persons with physical impairments are few and scattered; two are described in Evidence Table 12-1.

IMPLEMENTATION OF THERAPEUTIC OCCUPATION IN PRACTICE

Lyons, Phipps, and Berro (2004) described ways of organizing one clinic to efficiently utilize occupation therapeu-

tically. The treatment areas in the clinic were rearranged to resemble a homelike environment (e.g., bedroom, living room, nursery). The therapists prepared “occupation kits,” which were large plastic boxes containing all the props necessary to engage in an occupation. Occupation kits were made for gardening, letter writing, pet care, fishing, scrapbooking, and car care, which were the most commonly named activities by their clients. Therapists in this clinic were encouraged to work with the patients in the various areas of the hospital campus and surrounding environment, the larger community, and the client’s own community (barbershop, market, place of worship) to provide meaningful occupation-based interventions in the clients’ natural contexts.

Occupation-as-end is implemented by teaching the activity or task directly, using whatever abilities the patient has, or by providing whatever adaptations are necessary to enable performance. Because occupation occurs within a person–task–environment interaction, change in any one of these variables may result in successful performance. Implementation of occupation-as-end focuses on changing the **task demands** and/or the environment, whereas occupation-as-means focuses on changing the person. Therapeutic principles for application of occupation-as-end derive from cognitive information processing and learning theories. It is the rehabilitative approach (Trombly & Scott, 1977). In this approach, occupations are analyzed to ensure that they are within the capabilities of the patient, but they are not used to bring about change in these capabilities per se. The patient learns, with the help of the therapist as teacher and adaptor of the task demands and context. In the therapeutic encounter, the therapist:

- Ensures that the task is within the person’s capabilities
- Organizes the subtasks to be learned so the person will succeed
- Provides clear instructions
- Provides feedback to promote successful outcome

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Implementing Therapeutic Occupation in Practice

One way to incorporate occupation into practice is to use “occupation kits,” as suggested by Lyons, Phipps, & Berro (2004). Occupational kits are used to implement occupation-as-means. Describe the contents of occupational kits designed for these occupations:

1. Needlework
2. Home entertainment
3. Home repair

State why each object is included (the therapeutic benefit).

Evidence Table 12-1

Selected Evidence for Occupational Therapy Practice Regarding Occupation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Occupation-as-end: Goal-specific training to achieve valued occupational goals	Experimental: long-term ADL goals valued by the participants and carers and considered amenable by the staff were worked toward via a series of written contracts that specified interim and short-term goals. Carried out in homes, day centers, and work place. Control: booklet that listed resources with those particular to the participant highlighted.	94 (75.5% male) persons with moderate to severe TBI aged 16–65 years, in acute to chronic stages of recovery. Randomized to group.	2–6 hours per week for a mean of 28 weeks for experimental group and 1 visit for control group.	Randomized controlled trial. 1A2a	Yes. Community rehabilitation after severe TBI can yield benefits that outlive the active treatment period even if offered years after injury.	35% of the experimental participants versus 20% of the control group improved on the <i>Barthel Index</i> (Mann-Whitney $U = 831, p < 0.05$). The experimental participants scored significantly better than the control on the total <i>BICKO-39</i> score (Mann-Whitney $U = 517, p < 0.05$) and self-organization (Mann-Whitney $U = 474, p < 0.05$) and psychological well-being (Mann-Whitney $U = 469, p < 0.05$) subscales. Effect sizes could not be calculated from data provided.	Powell, Heslin, & Greenwood, 2002

<p>Occupation-as-end: Training in leisure activities to regain hobby roles</p>	<p>Experimental: practice skills and use of equipment to improve participation in self-identified hobbies and interests at home. Control #1: ADL practice and perceptual drills at home. Control #2: no treatment.</p>	<p>65 persons with acute stroke (23 LCVA; 41 RCVA; 1 other); mean age = 65.9 years. Randomized to group.</p>	<p>30 minutes once a week for 12 weeks after discharge from hospital and 30 minutes every 2 weeks for the next 12 weeks.</p>	<p>Randomized controlled trial. IB2a</p>	<p>Yes. The experimental group scored significantly higher than the two control groups on the <i>Nottingham Health Profile</i>, a measure of psychological well-being.</p>	<p>Experimental > Control #1: $p = 0.0002$, $r = 0.39$; Experimental > Control #2: $p = 0.0011$, $r = 0.34$.</p>	<p>Drummond & Walker, 1996</p>
<p>Occupation-as-end: Training to resume adult roles of family member and worker</p>	<p>Three parts: (1) adaptation of computer programs, keyboard, and monitor; (2) instruction in adapted word processing and e-mailing; (3) computer-related activities designed to enhance participation in desired social roles.</p>	<p>1 male after traumatic brain injury, with obsessive compulsive disorder and ADHD since childhood, left hemiparesis, left hemianopsia, and speech deficits; living in a residential setting.</p>	<p>2-hour weekly sessions for 4 months.</p>	<p>Case study. VC3c</p>	<p>Yes. The participant was able to reestablish his roles of brother and adult son; develop and maintain an extended family of others beyond his family of origin; create a satisfying adult work role that brought greater meaning to his life.</p>	<p>No statistical analysis. Anecdotal evidence. No controls to allow one to accept with confidence that the treatment caused the outcome.</p>	<p>Gutman, 2000</p>

continued

Evidence Table 12-1

Selected Evidence for Occupational Therapy Practice Regarding Occupation (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Occupation-as-means: Game to increase arm reach	Condition #1: participant reached to a point 3 in above the center of the table placed to require full forward reach. Condition #2: participant reached the same distance to play the Simon® computer-controlled game of flashing lights and sounds.	20 (17 men; 3 women) brain-injured adults with mild to moderate spasticity of the upper extremity.	10 trials of each condition in a laboratory setting.	Non-randomized, counterbalanced design. IIC2c	Yes. The use of the game elicited significantly more range of motion of the affected upper extremity than the rote exercise. The results support the use of an occupationally embedded intervention.	$t_{(19)} = 5.77$, $p < 0.001$, $r = 0.80$.	Sietsema et al., 1993
Occupation-as-means: Game to decrease pronator spasticity and to increase supination (external rotation) ROM	Experimental: bilaterally assisted supination exercise in the context of a dice game that required the subjects to supinate to dump out the dice for a score. Control: bilaterally assisted supination exercise using the same apparatus without the game.	26 women in acute stage after stroke (11 LCVA; 15 RCVA); mean age = 68.4 years. Participants were randomly assigned in a stratified balanced way to either the experimental or control condition.	Two sets of 10 trials for each condition; different days.	Randomized controlled trial. IC2c	Yes. Those who participated in the game demonstrated significantly greater handle rotation [supination] (95.3°) than the controls (81.9°).	Mean gain of 13.4° in handle rotation by the experimental group ($p = 0.016$, $r = 0.42$)	Nelson et al., 1996

ADL, activities of daily living; TBI, traumatic brain injury; LCVA, left cerebral vascular accident; RCVA, right cerebral vascular accident; ADHD, attention deficit hyperactivity disorder; ROM, range of motion.

- Structures the practice to ensure improved performance and learning
- Makes adaptations as necessary.

To implement occupation-as-means, occupations of interest are analyzed to determine that they demand particular responses from the person and that the responses demanded are slightly more challenging than what the person can easily produce. The therapist provides the opportunity to engage in the potentially therapeutic occupation (Meyer, 1922, 1977), and as the person makes the effort and succeeds, the particular impairment the occupation-as-means was chosen to remediate is reduced. In the therapeutic encounter, the therapist:

- Ascertains the patient’s interests

- Selects occupations that reflect those interests
- Analyzes the occupations to determine which would be appropriate to achieve the patient’s goal
- Lets the patient choose from among several offered occupations
- Instructs the patient in the correct procedure for doing the activity to derive the most therapeutic benefit
- Grades the occupation to increase the challenge as the patient improves.

See the Case Example of how occupation as therapy is implemented in practice. The processes involved in using occupation therapeutically are **activity analysis**, selection and gradation, and adaptation. Guidelines for these processes are presented in Chapter 13.

CASE

EXAMPLE

Ms. C.: Using Occupation Therapeutically

Occupational Therapy Intervention Process

Patient Information

Ms. C. is a 55-year-old, right-handed woman who began inpatient rehabilitation after a left cerebral vascular accident (LCVA). She was originally from the Philippines, where she worked as a school teacher. For the past few years, she has been living in the U.S. with one of her daughters.

Evaluation:

1. *Occupational history interview.* She described her life through a series of stories, allowing her self story to become evident. Several themes of meaning and important occupations emerged: (a) theme of being a teacher, which was evident in her communication style, her previous role as teacher, and the educational play she described with her grandchildren; (b) theme of cleanliness and efficiency, which was evident through her report that she had to finish all the housework before playing with her grandchildren; and (c) theme of spirituality when she discussed the importance of daily church attendance.

Clinical Reasoning Process

Objectives

Appreciate the context

Examples of Therapist’s Internal Dialogue

“Ms. C. is a relatively young woman who has experienced a stroke affecting her dominant side. She is depressed because she fears the loss of important roles and occupations. I chose to use a narrative approach to begin the evaluation so that I can understand Ms. C. as an occupational being and she can gain hope that someone is going to help her resume her life activities. Three themes of meaning emerged as she talked—teaching, home management, and spirituality. These will become important components of the treatment planning process.”

2. *Description of a typical day* in chronological sequence revealed that her routine consisted of cooking breakfast for her granddaughters, doing housework, playing with her grandchildren, going to church in the evening, and sending text messages to her friends in the Philippines.
3. *Evaluation of impairments* revealed: (a) decreased motor control but developing volitional movement throughout her right arm; (b) decreased sensation; (c) poor muscle tone of the right side of her body, but able to stand for short periods of time; (d) impaired but improving expressive language; and (e) poor executive cognitive functioning.

Develop intervention hypotheses

“Occupation-based treatment will initiate the development of Ms. C.’s new view of herself as someone who could now continue to participate in her roles and occupations. This new vision of herself will lighten her depression and assist her in setting goals for her future. I notice that by providing Ms. C. with the opportunity to make decisions regarding her goals and preferences for treatment, she is becoming empowered and demonstrates increased motivation to participate in therapy.”

Select an intervention approach

“I will use a client-centered, occupation-based approach.”

Reflect on competence

“I have treated many patients of Ms. C.’s age with similar disability. My client-centered, occupation-based approach has been universally successful with them; therefore, I am competent to treat Ms. C.”

Recommendations

Ms. C. will attend inpatient occupational therapy for 60- to 90-minute treatment sessions, 6 times a week for 3 weeks.

Long-term goal is to return home and resume valued roles of grandmother, homemaker, and church attendee.

Consider the patient’s appraisal of performance

“I have helped Ms. C. notice that she is able to incorporate her returning motor, cognitive, and language skills directly into occupation-based treatment so that her impairments will improve as she relearns the activities and tasks of her valued roles. This pleases her.”

Consider what will occur in therapy, how often, and for how long

“Intensive therapy during her brief inpatient hospitalization is warranted. Ms. C. agrees with this plan.”

Ascertain the patient’s endorsement of plan

Summary of Short-Term Goals and Progress

Goal setting was accomplished using the *COPM (Canadian Occupational Performance Measure)*. Ms. C.’s goals included the following most valued occupations:

1. performing household chores
2. cooking
3. storytelling with her grandchildren
4. sending text messages to the Philippines
5. going to church
6. using public transportation

The initial occupation-based session with Ms. C. involved engaging in household management occupations. To prepare for engaging in these roles at home, she began cleaning, vacuuming, and doing laundry in a homelike setting within the clinic.

A subsequent intervention session was held in a simulated living room environment. Her daughter brought her two children, along with some of their storybooks. During the session, Ms. C. had difficulty maintaining the attention of the children and physically calming them down. She then used her teaching skills to explain to her grandchildren her new participation level in her role as grandmother and taught them to help hold her right hand as they played together.

One of Ms. C.’s final intervention sessions involved going on a market outing to prepare for a cooking activity. This session provided Ms. C. with opportunities to relearn how to push a grocery cart, reach for and manipulate items in the store, attend to tasks despite increased ambient noise, and practice mobility within the store.

Know the person

“We are using occupation-as-means, so by performing valued activities, Ms. C. is improving motor control by incorporating her right arm into activity completion. She is also learning how to structure her day to complete the activities she wants to include in her day. She is using the household management “occupation kit” to practice opening containers of laundry products, which promotes fine motor skills as well as prepares her for an important activity. Vacuuming is challenging her dynamic balance. Ms. C. told me that she saw her new role as an assistant in home management so, through the use of occupation-as-end, Ms. C. is beginning to form a new self-identity and vision for her future.”

Appreciate the context

“In the play session with her grandchildren, Ms. C. gained insight into the process of role resumption for this activity at home. In addition, her family was able to see her potential for participating in the children’s play.”

“The shopping session allowed Ms. C. to carry over some of the skills that she had learned in the clinic into the real world. The experience supported her continual formation of herself as an occupational being, and it provided her with hope for participation in this role.”

Next Steps

Again, using the *COPM*, these short-term goals were identified for outpatient rehabilitation:

1. clean the bottom of her bathtub
2. clean the bathroom sink
3. carry a heavy laundry basket
4. carry heavy grocery bags long distances
5. cut vegetables with her right dominant hand
6. write letters to friends in the Philippines (communication had stopped because of cost of text messaging)
7. find transportation to attend church daily
8. kneel to pray and read the Bible in church
9. volunteer in a local hospital

Anticipate present and future patient concerns

“At discharge from inpatient rehabilitation, Ms. C. believed she would be able to return to her chosen occupations, such as self-care, light household management, playing with her grandchildren, and preparing light meals. She was able to initiate and integrate the use of her right side, so she expected she could participate in her typical day when she returned home. Armed with strategies and ideas regarding how to more fully participate in her life roles and occupations, she felt that she had a good foundation to return home. However, Ms. C. found that the transition from the structure of the inpatient rehabilitation setting to home and community settings presented greater challenges to her participation than she had anticipated. She was tearful about diminished participation in occupations that held considerable meaning for her life. Outpatient occupational therapy was required, and I recommended that she be seen for 60- to 120-minute sessions, once a week for 4 weeks to facilitate the transition.”

Analyze patient’s comprehension

Decide if he or she should continue or discontinue therapy and/or return in the future

Adapted with permission from the American Occupational Therapy Association (publisher) and the authors. Lyons, A., Phipps, S. C., & Berro, M. (2004). Using occupation in the clinic. *OT PRACTICE*, 9, 11–15.

SUMMARY REVIEW QUESTIONS

1. Define occupation and purposeful activity.
2. State some reasons why occupation is important in a person's life.
3. Define occupation-as-end.
4. Define occupation-as-means.
5. Therapeutic occupation is both purposeful and meaningful. What effects do these qualities produce?
6. List two examples of evidence that occupation is therapeutic.

ACKNOWLEDGMENTS

I thank my former students Dr. Steven Cope, Dr. Susan Fasoli, Janice Ferguson, Yvonne Fuller, Dr. Hui-Ing Ma, Dr. Susan Murphy, Julie Pope, Natalia Ramsbey, Ellen Rosenberg, Dr. Pimjai Sudsawad, Dr. Pei-Luen Tsai, and Dr. Ching-Yi Wu for their assistance and conversations about occupation. I am also especially indebted to the occupational therapists and patients of the Sister Kenny Institute in Minneapolis, MN, for allowing me to photograph them or for facilitating the photography. Specifically, I thank Cindy Bemis, Arlan Berg, Michelle Brown, M.Ed., OTR/L, Larry Chaney, Anthony Drong, Larry Larkin, Robb Miller, OTR/L, Mary Radomski, M.A., OTR/L, Jennifer Theis, M.S., OTR/L, and Sharon E. Gowdy Wagener, OTR/L.

CHAPTER 13

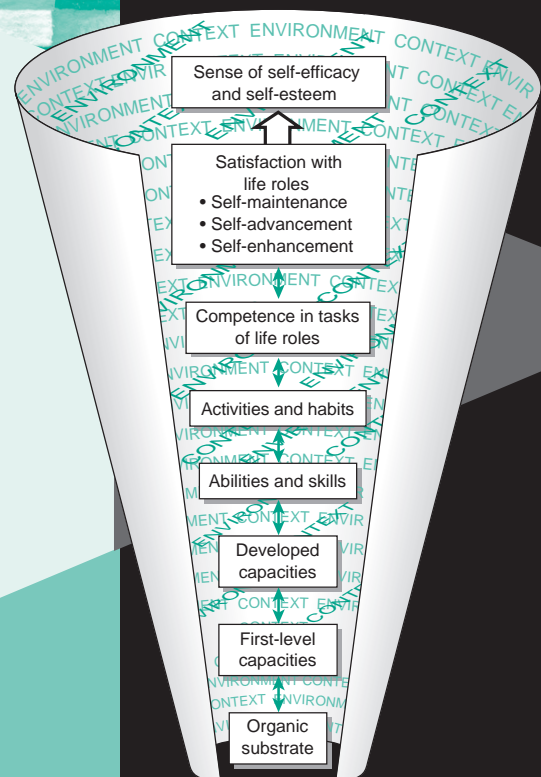

Occupation as Therapy: Selection, Gradation, Analysis, and Adaptation

Catherine A. Trombly Latham

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Select occupation-as-means to achieve particular goals.
2. Grade occupations to challenge the person's abilities to improve performance.
3. Analyze occupations to determine their value for remediation of impaired abilities and capacities.
4. Analyze occupations to determine whether they are within the capabilities of a particular person.
5. Adapt occupations to increase their therapeutic value or to bring them within the capability of a person.

Glossary

Activity analysis—A process by which properties inherent in a given activity, task, or occupation may be gauged for their ability to elicit individual motivation and to fulfill patients' needs in occupational performance and performance components (Llorens, 1993).

Closed task—A closed task involves the least interaction with environment (Gentile, 1987). A closed task is one in which the task demands remain constant and for which habits can develop so that little conscious control is required once learned.

Constraints—Limitations imposed on purposeful movement or the completion of occupational performance. Extrinsic constraints include the physical and sociocultural environment and task demands. Intrinsic constraints include biomechanical and neuromuscular aspects of a person's body, as well as other personal contextual factors (Newell, 1986).

Electromyographic—Pertaining to recording the electrical activity produced by a contracting muscle. When a muscle is at rest, no electrical activity is recorded. As the muscle contracts, the electrical activity increases proportionately.

Kinematic—Spatial and temporal description of movement measured by optoelectric or videographic instruments that allows detection of strategies for the organization of movement (Georgopoulos, 1986; Jeannerod, 1988).

MET (metabolic equivalent)—The amount of energy expended when a person is engaged in activity. At rest in a semi-reclined position and with the extremities supported (basal state), that amount is 3.5 mL of oxygen per minute per kilogram of body weight (1 MET). Energy expenditure of activities is rated in terms of multiples of METs.

Occupation-as-end—Activities and tasks that constitute the roles of a given individual (Trombly, 1995).

Occupation-as-means—Activities and tasks chosen to remediate deficient abilities or capacities (Trombly, 1995).

Open task—Task with most interaction between the performer and environment (Gentile, 1987). An open task is one for which the environment and/or objects may vary during performance and between trials. Open tasks require attention and vigilance.

Task analysis—Similar to activity analysis; term used primarily in relation to work assessment (ergonomics). Analysis of the dynamic relationship among a person, a selected task or occupation, and a specific context or environment (Watson & Wilson, 2003).

Task demands—The context (e.g., objects, surroundings, ritual) that evokes certain maneuvers required to accomplish the goal of the task.

As described in the previous chapter, occupation is the therapeutic medium of occupational therapy with the goal of facilitating participation in life (American Occupational Therapy Association [AOTA], 2002). The therapist must select the appropriate occupation for the patient to remediate deficit abilities or capacities (**occupation-as-means**) or to enable independent performance of valued occupations (**occupation-as-end**). To be able to *select* an appropriate occupation, the therapist must be able to *analyze* activities. To improve subnormal abilities and capacities, the occupation must challenge those abilities and capacities and continue to do so as the patient improves. The therapist controls the challenge by *grading* the activity along particular therapeutic continua and/or by *adapting* the methodology. To enable performance of occupation-as-end, when the patient's impairments prevent usual engagement in the occupation, therapists adapt activities, tools, or context/environment. This chapter instructs on how to select, analyze, grade, and adapt occupation.

are available and are of interest to the patient (occupation-as-means).

Selection of Occupation-As-End

Occupations-as-end are activities and tasks that constitute the patient's life roles. The patient and therapist identify key tasks and activities that would enable the patient to engage in the role. Through activity analysis, the therapist matches the particular patient's capabilities to the demand level of each activity. The comparison between **task demands** within the usual environment and the patient's capabilities determines whether the patient will be able to do the activity independently, with adaptation, or not at all. A person feels best when engaging in activity if his or her skills match the situational challenges posed by the activity and the challenge of the activity matches the person's skills—called “flow” by Csikszentmihalyi (1990; Moneta & Csikszentmihalyi, 1996).

SELECTION AND GRADATION

The therapist skilled in activity analysis can match the patient's abilities with activities and tasks the patient needs or wants to do (occupation-as-end) and select the most appropriate activity for remediation from those that

Selection and Gradation of Occupation-As-Means

An activity that is to be used to restore one or more abilities or capacities must challenge the patient's level of ability so that, through effort and/or practice, the patient improves

(see Definition 13-1). Some specific characteristics for the goals commonly addressed by occupational therapists who treat persons with physical disabilities are listed here and are summarized in Procedures for Practice 13-1. The dimensions along which the activity is to be graded are also listed. When more than one dimension is listed, the therapist should be careful to grade the changes one dimension at a time so that the patient has more of a chance at success. The best activity for remediation is one that intrinsically demands the exact response that has been determined to need improvement and that allows incremental gradations starting where the patient can be successful. Contrived methods of doing an ordinary activity to make it therapeutic may diminish the value of the activity in the eyes of the patient. Contrived methods also require the patient constantly to focus directly on the process rather than the goal of the activity, undermining the therapeutic value.

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Selecting and Adapting Occupation-As-End**

Mrs. B. is experiencing increased occupational dysfunction secondary to degenerative joint disease. One of Mrs. B.'s goals is to resume gardening. Given her abilities and capacities, as described in the Case Example in Chapter 5, what key factors must pertain to gardening activities to enable participation? How could these key factors be implemented?

**DEFINITION 13-1****Characteristics of Therapeutic Occupation**

Generally, activities should:

- Have the necessary inherent characteristics to evoke the desired response
- Allow gradation of response to progress the patient to the next higher level of function
- Be within the patient's capabilities
- Be meaningful to the person
- Be as repetitive as required to evoke the therapeutic benefit

To Retrain Sensory Awareness and/or Discrimination

The activity must provide components that offer a variety of textures, shapes, and sizes, graded from large, distinct, common shapes to small, less common shapes with less distinct differences between them. The texture of the various objects should be graded from diverse coarse materials to similar smooth materials. The patient and the therapist must also involve themselves in a teaching-relearning interactive experience in which the characteristics of the objects are discussed and correct identification by touch is rewarded.

To Decrease Hypersensitivity

The activity should involve objects or media whose textures can be graded from those that the patient perceives to be least noxious to textures perceived to be tolerably noxious. Another plan grades textures and objects from soft to hard to rough and grades the contact with the objects from touching them to rubbing them to tapping them.

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Selecting and Grading Occupation-as-Means**

Mrs. B., who is described in Chapter 5, has gardening as one of her self-enhancement goals. Currently she is experiencing weakness of her dominant upper extremity, low endurance (fatigue), and pain that interfere with achieving this goal. Although she could engage in some gardening activities using adaptations to the tools, method, and context, she could engage in more activities with less adaptation if her impairments were improved. What key factors must the occupation-as-means offer to improve these impairments? What occupation-as-means could you offer to Mrs. B. to implement this treatment? How could this activity be graded as she improves?

PROCEDURES FOR PRACTICE 13-1

Selecting and Grading Therapeutic Occupation-As-Means

Remediation Goal	Key Factors of the Activity
To retrain sensory awareness or discrimination	Offer various textures, sizes, shapes. Grade from diverse, coarse, large to similar, smooth, small.
To decrease hypersensitivity	Offer various textures and degrees of hardness or softness. Grade from acceptable to barely tolerable.
To reacquire skilled voluntary movement	Require sought-after, goal-directed response; allow feedback. Grade from simple to complex movements.
To improve coordination and dexterity	Require ROM the patient can control. Grade from slow, gross movement involving limited number of joints to fast, precise movement involving a greater number of joints.
To increase passive ROM	Provide controlled stretch or traction. Grade from lesser to greater ROM.
To increase strength	Require movement or holding against resistance. Grade from lesser to greater resistance or from slow to fast movement.
To improve cardiopulmonary endurance	Use activities rated at the patient's current MET level. Grade by increasing duration, frequency, then intensity (METs).
To improve muscular endurance	Require movement or holding against 50% or less of maximal strength. Grade by increasing repetitions or duration.
To decrease edema	Allow use of the extremity in an elevated position and require isotonic contraction.
To improve problem solving	Require performance at the outside edge of the patient's current skill. Grade from simple (one step) to complex (multiple steps) and from concrete to abstract.

To Relearn Skilled Voluntary Movement

Organization of voluntary movement depends both on the unique problem or goal and the **constraints** operating at a given time (Jordan & Newell, 2004; Newell, 1986). The activity must have a clear goal or purpose, demand the sought-after movement or movements, and offer opportunity to self-monitor success (feedback). The contextual and task constraints should support natural responses. Grading should provide increasingly more difficult motor challenges (e.g., moving the body in various directions, moving the limbs in various directions, isolated movement of particular joints, faster movement, more accurate movement in more challenging contexts, or greater number of submovements [Ma & Trombly, 2004]).

Sensorimotor learning requires practice, so opportunities for vast amounts of varied practice should be provided. The activity may provide an opportunity for practice simply through the accomplishment of the intended goal. For example, weaving requires multiple passes of the shuttle to produce the desired product and offers good practice of bilateral horizontal abduction and adduction. For other activities, the goal may be achieved quickly, so practice is sought through repetition of the whole action, as with ironing, polishing silverware, throwing a ball, and other activities of daily living. Variable practice promotes learning. Unvaried (blocked) practice improves perform-

ance within a session but does not improve long-term learning. Blocked practice is used to begin to develop a new movement or skill (see Chapter 14).

To Increase Coordination and Dexterity

The activity should allow as much range of motion (ROM) as the patient can control and allow grading from slow, gross motions to precise, fast movements involving greater ROM or action at more joints. At first, if you are grading along the continuum of increasing speed, expect accuracy to suffer. A speed-accuracy trade-off is basic to the organization of the central nervous system (CNS) (Fitts, 1954).

To Increase Active ROM

The activity must require that the part of the body being treated move to its limit repeatedly and be graded, naturally or through adaptations, to demand greater amounts of movement as the patient's limit changes.

To Increase Passive ROM or Elongate Soft Tissue Contracture

The activity must provide controlled stretch or traction to the part being treated and be held at the end of range for several seconds. *Stretch should be slow and gentle to avoid tearing the tissue.* Grade from lesser to greater ROM.

To Increase Strength

Stress to muscle tissue increases strength. Stress can be graded by increasing the velocity and/or resistance needed to complete the activity or, for very weak muscles, by increasing the number of repetitions of an isotonic contraction or the amount of time an isometric contraction is held.

To Increase Cardiopulmonary Endurance

The metabolic demand of the activity (**MET** level) should match the patient's status. The demand can be graded by increasing the duration of a task, by increasing the frequency of doing the task, by changing the muscles used in the task (smaller muscles increase metabolic demand), or by increasing the intensity (METs). The metabolic intensities (METs) of 605 physical activities, including activities of daily living and sexual activity, occupation (work), transportation, volunteering, religious activities, and sports and recreational activities, have been measured and reported (Ainsworth et al., 1993, 2000). Some MET levels are listed in Chapter 5.

To Increase Muscular Endurance

The activity must be repetitious over a controlled number of times or period. Resistance should be held to 50% or less of maximal strength.

To Decrease Edema

The activity should entail repetitive isotonic contractions of the muscles in the edematous part. An activity that requires repeated movement of the extremity into an elevated position helps to drain the fluid out of the extremity.

To Improve Perceptual Impairments or Problem-Solving Strategies

The activity should involve varied practice of information processing or perceptual processing at the outside edge of the person's capability. For example, if the person has impaired figure-ground discrimination skill, practice may start with detecting one figure from a plain background and progress through finding multiple figures on a plain background or finding one figure in more complex backgrounds until the person has developed the level of functional ability he or she requires (e.g., able to find the scissors in a kitchen "junk" drawer). Gradation is along a continuum of increasing complexity (more stimuli).

If the person has impaired problem-solving skills, practice may start with concrete problems involving objects that the person can see and touch, such as the problem of getting soup out of a can, with can, manual can opener, and electrical can opener at hand. The patient figures out

that he or she must open the can to get the soup, selects a can opener, and figures out through exploration how to use the can opener. Therapy may proceed to a higher level of abstraction by asking the person to figure out how many pills he or she needs for the week if he or she should take one (or two or more) pill(s) every day. The pill bottle, calendar, and weekly pill minder container are present. The patient may solve the problem in one of several ways: using arithmetic (unlikely, since the patient is in treatment for cognitive deficits); using a calendar, taking out the pill or pills for each day and lining them up on the calendar and counting them; or putting a pill in each compartment of the pill minder and then counting them.

Gradation is along a continuum of concrete to abstract and few objects or ideas to multiple objects or ideas. See Chapters 28 and 29 for suggestions for particular impairments.

ANALYSIS

Activity analysis, or **task analysis**, is a fundamental skill of occupational therapists. Occupational therapists analyze an activity because they want to know (1) whether the patient, given certain abilities, can be expected to do the activity or (2) whether the activity can challenge latent abilities or capacities and thereby improve these. Through activity analysis, one gains an appreciation of the activity's components and characteristics (Greene, 1990).

Activity analysis developed from industrial time-and-motion study methods. Military occupational therapists applied these methods to rehabilitation of injured soldiers during World War I (Creighton, 1992) at the suggestion of

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Activity Analysis

Analyze planting tulip bulbs in a raised garden area according to the format in Procedures for Practice 13-2 and the example in Procedures for Practice 13-3.

Context: The garden measures 10 feet by 18 inches and is 2 feet above ground level. It is surrounded by a stone wall. The dirt is well cultivated. There are no other plants in the garden at this time. No squirrels live in the vicinity, so the gardener does not have to treat the bulbs or cover the garden with wire.

The gardener sits on a rolling garden stool so that, when seated, the top of the garden is equal to the gardener's mid-chest level.

Discuss your analysis with your classmates and professor. If you disagree, determine why and clarify your analysis.

Gilbreth and Gilbreth (1920), industrial engineers who observed injured soldiers in military hospitals. Gilbreth (1911) listed these steps for analyzing a task: “(1) Reduce. . . practice to writing; (2) enumerate motions used; (3) enumerate variables which affect each motion” (p. 5). Variables considered were characteristics of the worker, the surroundings, and the motion. This method has been used by occupational therapists for many years when focusing the analysis on the activity. Other methods of occupational analyses that focus on the performance of the patient are Performance Analysis (Fisher, 1998), Ecological Task Analysis (Burton & Davis, 1996; Davis & Burton, 1991), and Dynamic Performance Analysis (Polatajko, Mandich, & Martini, 2000). These analyses require extensive training and skill. Both activity and performance analyses entail unnesting the component tasks and activities that constitute the occupation and determining what abilities, skills, and capacities are needed to do the specified activity or that may improve if the person does the activity (Mayer, Keating, & Rapp, 1986; Trombly, 1995). The activity-focused analysis is presented in this chapter because it demonstrates the process to the inexperienced activity analyst, with the expectation that therapists will continue to educate themselves concerning this important therapeutic skill.

Analyzing for the abilities and capacities required to carry out the activity presupposes that activities have reliably identifiable inherent therapeutic qualities. This belief is stated in a position paper of the American Occupational Therapy Association (1995): “Whether physical or mental in nature, the behaviors necessary for completion of tasks in daily occupations can be analyzed according to specific components related to moving, perceiving, thinking, and feeling” (p. 1015). Although tasks and activities require particular performance skills, abilities, and capacities, identification of these (activity analysis) is a high-level skill that requires practice under supervision. A survey of 120 experienced therapists indicated that there was limited consensus on which performance skills, abilities, or capacities were required by particular activities (Tsai, 1994). Neistadt et al. (1993) also reported discrepancies among therapists in identifying components of common activities. Research on activity analysis and greater emphasis on activity analysis in educational programs are needed.

Activity-Focused Analysis

Using an analytical approach, the therapist examines an activity to determine its components and the level of capability demanded. The outcome can be used to select activities for remediation or to match a particular person’s skills with the demands of the task.

All analyses should occur within some conceptual framework to give them direction, coherence, and meaning

(Mosey, 1981). For example, planting a tulip bulb in a plant pot can be analyzed from various frames of reference. The biomechanical approach prompts the therapist to examine the physical aspects, such as grasp and ROM, whereas the cognitive-perceptual approach examines the activity according to its cognitive or perceptual demands. The Model of Human Occupation might focus the therapist’s attention on how this planting activity may meet the patient’s nurturing needs and values.

Whereas biomechanical analysis observes joint ROM and estimates muscle contraction used to carry out the activity based on knowledge of anatomy and kinesiology, **electromyographic** (EMG) and **kinematic** research indicates that this type of analysis may not be wholly valid because of individual differences in muscle action and differences in movement strategies secondary to learning, maturation, injury, and perception of goal (Illyes & Kiss, 2005; Jordan & Newell, 2004; Kelly et al., 2005; Trombly & Quintana, 1983) that are not detectable by an observer without instrumentation. Each person’s CNS plans movement to accomplish the goal with the resources the person has. Reaching for a glass of milk on the table may or may not activate the anterior deltoid. If that muscle is weak, the patient may accomplish the goal by substituting other muscles or strategies, such as turning sidewise to the table to make use of the stronger middle deltoid to reach the glass. The substitutions listed in the muscle testing section of Chapter 5 are common ways people accomplish the movement goal when the prime mover is weak. The idea that doing a certain activity will always exercise a certain weak muscle may be naive. If it is essential that a particular muscle of a particular patient be contracting to a certain level of activity, as may be the case in tendon transfer rehabilitation, it is best to monitor the muscle directly using EMG biofeedback as the patient does the activity (Trombly & Cole, 1979; Trombly & Quintana, 1983).

On average, certain motions and muscle actions are more probable than others and, therefore, an analysis can be based on observation if the therapist realizes that actual performance of a particular patient must be verified and not assumed. As instrumentation to measure human movement is too complex to be used clinically at this time, by default, the traditional biomechanical activity analysis continues to be the method used by practicing therapists and is described here (Procedures for Practice 13-2 and 13-3).

The therapist begins the biomechanical analysis by stating the goal (purpose) and by identifying the task demands, that is, the constraints that will impinge on performance. Some constraints to be considered are the size and type of tools, placement of the selected tools and equipment in relation to the patient, the speed at which the activity is to be accomplished, the complexity of the task, and the context in which it will be carried out. Changes in any of these variables change the task demands and require a different analysis. The prerequisite abilities and capacities

PROCEDURES FOR PRACTICE 13-2

Activity-Focused Analysis

1. Name the activity goal.
2. Describe the task demands:
 - Task constraints: How are the person and materials positioned, especially in relation to one another?
 - Task constraints: What utensils/tools/materials are normally used to do this activity?
 - Environmental constraints: Where is this activity usually carried out?
 - Contextual constraints: Does this activity or the way it is carried out hold particular meaning for certain cultures or social roles? Is there a time factor involved in carrying out the activity?
3. What capacities and abilities are prerequisite to successful accomplishment of this activity?
4. List the steps of the activity.
5. Describe the biomechanical internal constraints for the most therapeutic or repetitive step.

Motions	ROM	Primary Muscles	Gravity Assists, Resists, No Effect	Minimal Strength Required	Type of Contraction

6. What must be stabilized to enable doing this activity, and how will that stabilization be provided?
7. For which ages is this activity appropriate?
8. What is the estimated MET level of this activity?
9. What precautions must be considered when using this activity in therapy?
10. For which short-term goal or goals is this activity appropriate?
11. How can this activity be graded to improve the following:
 - Strength
 - Active ROM
 - Passive ROM
 - Endurance
 - Coordination and dexterity
 - Edema
 - Perceptual abilities
 - Cognitive skills

for accomplishing the whole activity are identified. If these prerequisite abilities are lacking and the goal is to accomplish the activity (occupation-as-end), then the way the goal is to be accomplished would have to be modified (e.g., if the patient is blind). Alternatively, if the goal is to improve one or more of the required abilities (occupation-as-means), then the activity would be adapted to reduce the demands to just challenge the patient’s level of performance.

The first step of an activity analysis is to identify the exact activity. For example, the steps of vacuuming the carpet while standing are listed under no. 4 in Procedures for Practice 13-3. The potential repetitions of each motion are noted. Only the fourth step, pushing the vacuum cleaner back and forth, would be analyzed further if vacuuming were going to be used as occupation-as-means because it is the repetitive, therapeutic aspect of this activity. The other steps occur too infrequently to be therapeutic. Each

repetitive step is subdivided into motions. For example, pushing the vacuum back and forth involves shoulder flexion with elbow extension, shoulder extension with elbow flexion, and trunk flexion and extension, although trunk movement may be eliminated, depending on how the person moves in relation to the machine. Wrist stabilization (co-contraction) in extension and cylindrical grasp are also “motions” associated with vacuuming.

The range of each motion is estimated by observing another person or by doing the activity oneself. Each motion is further analyzed to determine which muscle or muscles are likely responsible, based on anatomical, kinesiological, and electromyographical knowledge. Examining the effect of gravity allows estimation of the minimal strength necessary to do the motion. The kind of contraction demanded for each muscle group in each motion is established by definition.

PROCEDURES FOR PRACTICE 13-3

An Example of an Activity-Focused Analysis

1. Name the goal: Vacuuming the hallway carpet using a lightweight vacuum with a 25-foot cord.
2. Describe the task demands:
 - Task constraints: How are the person and materials positioned, especially in relation to one another?
 - The vacuum cleaner is in a closet next to the area to be cleaned.
 - The electrical plug is halfway between the two ends of the hallway, 5 inches from the floor.
 - When vacuuming, the person will be directly behind the machine.
 - Task constraints: What utensils, tools, and materials are normally used to do this activity?
 - A lightweight vacuum cleaner
 - Environmental constraints: Where is this activity usually carried out?
 - The hallway is 30 feet long and 3 feet wide.
 - No furniture is in the way.
 - The carpet is a flat pile.
 - Contextual constraints: Does this activity or how it is carried out hold particular meaning for certain cultures or social roles? Is there a time factor involved in carrying out the activity?
 - The person takes pride in a clean, well-vacuumed home.
3. What capacities and abilities are prerequisite to successful accomplishment of this activity?
 - The person is not willing to switch to a lighter, nonmotorized carpet sweeper because of the feeling that it doesn't do a proper job.
 - There is no limiting time factor involved in the activity under normal circumstances.
3. What capacities and abilities are prerequisite to successful accomplishment of this activity?
 - Standing balance
 - Ability to bend over and straighten up
 - Ability to grasp
 - Ability to walk forward and backward on carpeting
 - Ability to move dominant arm against gravity and moderate resistance
 - Vision¹
4. List the steps.
 1. Get the vacuum cleaner from the closet.
 2. Unwind the cord.
 3. Plug cord into wall socket and turn vacuum cleaner on.
 4. Push the vacuum cleaner back and forth.
 5. Unplug it and wind the cord.
 6. Return the vacuum cleaner to the closet.
5. Describe the biomechanical internal constraints for pushing the vacuum back and forth (step #4).

Motions	ROM (degrees), Distances	Primary Muscles	Gravity Assists, Resists, No Effect	Minimal Strength Required	Type of Contraction
Shoulder flexion	0–75	Anterior deltoid, coracobrachialis, pectoralis major	Resists	4– to 4	Concentric
Elbow extension	90–0	Triceps	Assists	4– to 4	Concentric
Scapular protraction	1.5 in	Serratus anterior	No effect	4– to 4	Concentric
Shoulder extension	0–45	Posterior deltoid	Assists	4– to 4	Concentric
Elbow flexion	90–120	Latissimus dorsi	No effect		
Scapular retraction	1.5 in	Teres major	Resists		
Cylindrical grasp		Biceps, brachialis	Resists	4– to 4	Concentric
Wrist stabilize		Middle trapezius	No effect	4– to 4	Concentric
Trunk flexion	0–30	Finger flexors, finger extensors, interossei	No effect	4– to 4	Isometric
Trunk extension	30–0	All wrist muscles	No effect	4– to 4	Isometric
		Back extensors	Assists	3+ to 4–	Eccentric
		Back extensors	Resists	4– to 4	Concentric

¹The blind person needs to use adaptive methods for knowing which sections of the carpet have been cleaned and which have not.

PROCEDURES FOR PRACTICE 13-3 (continued)

6. What must be stabilized to enable doing this activity, and how will that stabilization be provided?
 - Nothing
7. For which ages is this activity appropriate?
 - 18+ years primarily
 - 10–17 years secondarily
8. What is the estimated MET level of this activity?
 - 2–3 METs
9. What precautions must be considered when using this activity in therapy?
 - If standing balance and bending over are not well developed, the patient must be guarded.
 - A patient who is apt to lose balance walking on carpet must be guarded.
 - A patient who has low back pain must be taught to do the activity without bending forward.
 - A patient with low endurance needs to rest periodically.
10. For which short-term goal or goals is this activity appropriate?
 - Strengthening of upper extremity musculature
 - Developing dynamic standing balance
 - Improving grip strength
 - Improving central and peripheral endurance
 - Learning proper back mechanics
11. How can this activity be graded to improve the following?
 - Strength
 - Heavier vacuum cleaner
 - Thicker carpet
 - Active ROM
 - At limit
 - Passive ROM
 - Not applicable
 - Endurance
 - Increase amount of carpeting vacuumed before resting
 - Coordination, dexterity
 - Place furniture in the area so patient has to change directions of the vacuum to go around the obstacles
 - Edema
 - Not applicable
 - Improve perceptual abilities (examples)
 - Change the color of the “dirt” on the carpet, e.g., spread bits to be vacuumed either in contrasting colors or closer to the color of the carpet (figure–ground)
 - Put objects in the way for the person to figure out how to move around them (spatial relations)
 - Improve cognitive skills
 - Not applicable

Activities selected to restore motor function must also take into account the person’s cognitive and perceptual abilities, emotional status, cultural background, and interests. Some cognitive aspects of the activity to be considered include the number and complexity of the steps involved in doing the activity, the requirements for organizing and sequencing of the steps or stimuli, and the amount of concentration and memory required. Some perceptual factors to be considered are whether the activity requires the patient to distinguish figure from ground, determine position in space, construct a two- or three-dimensional object, or follow verbal or spatial directions. Other cognitive-perceptual considerations are found in Chapters 28 and 29. Some psychosocial aspects of an activity that may be important to patients include whether the activity must be done alone or in a group, the length of time required to complete the activity, whether fine detailed work or large expansive movements are involved, how easily errors can be corrected, the value of the activity from the person’s par-

ticular cultural and social background, and the likelihood of producing a satisfying outcome.

Other methods of analysis of activities have been published. Gentile (1987) has provided a detailed taxonomy of task analysis to be used for evaluation and selection of functionally relevant activities. The taxonomy is related to the learning of motor tasks. Her taxonomy is briefly described here, although the reader should see the original material for a complete description and rationale. The taxonomy consists of 16 categories comprised of movement types and environmental regulatory constraints. The dimensions are presented separately in Definition 13-2 for the sake of clarity, but they are meant to be combined. The easiest tasks are repetitive ones done in a stationary environment with the body in a stable position, such as sitting and brushing one’s hair. Tasks are graded by changing one at a time the various parameters (e.g., environmental regulatory conditions, differences in performance between trials, body orientation, manipulation demands). The

DEFINITION 13-2
de·fin·i·tion
Examples of Tasks Described According to the Taxonomy of Gentile

Environmental Regulatory Dimension		
Environmental Regulatory Conditions During Performance	No Differences in Performance Between Trials	Differences in Performance Between Trials
Stationary: the objects, people, and/or apparatus do not move	Closed tasks Climbing stairs at home Brushing teeth Unlocking the front door Turning on the bedroom light	Tasks in which objects are different but stationary during performance: Walking on different surfaces Drinking from mugs, glasses, cups Putting on shirt, sweater
Motion: the objects, people, and/or apparatus move	Tasks in which objects move consistently over repeated encounters: Stepping onto an escalator Lifting luggage from the conveyer belt at the airport Moving through a revolving door	Open Tasks Propelling a wheelchair down a crowded hall Catching a ball Carrying a wiggling child
Movement Type Dimension		
Body Orientation	No Manipulation	Manipulation
Stability: body is positioned in one place	Body stability: Sit Stand Lean on table	Body stability plus manipulation: Hold object while standing Reach for hairbrush while sitting Keyboard sitting at computer
Transport: body is moving through space	Body transport: Walk Run Propel wheelchair	Body transport plus manipulation: Run to catch a ball Drive an automobile Dial phone while walking

Held (Eds.), *Movement science: Foundations for physical therapy in rehabilitation* (pp. 93–154). Rockville, MD: Aspen Systems.

most demanding tasks are those done in an environment that changes with the performance, with requirements that change between trials, and with the body in motion while manipulating an object, such as playing basketball.

Neistadt et al. (1993) published a model for analyzing activities in relation to cognitive and perceptual demands. Watson and Wilson (2003) published a task-analysis form based on the American Occupational Therapy Association's Occupational Therapy Practice Framework.

Some therapists keep files of activity analyses, which they adapt to particular patients, while others prefer to analyze specifically for a particular patient in a particular context. Some activity analyses have been published: Hi-Q game (Neistadt et al., 1993); macramé (Chandani & Hill, 1990); planting a small garden (Nelson, 1988); using a computer for skill development, education, and pre-

vocational training (Okoye, 1993); hand activities (Trombly & Cole, 1979); donning a sock (Greene, 1990); and bilateral inclined sanding (Spaulding & Robinson, 1984).

Performance-Focused Analysis

Using an analytic approach, the therapist observes the patient's performance of role-related occupations. Figure 13-1 and Procedures for Practice 13-4 depict analysis of role performance using the Occupational Functioning Model as the basis (Trombly, 1993). The first step is to determine whether the person is accomplishing the role as he or she wants, needs, or expects to. If not, the patient identifies the tasks and activities within the role that are

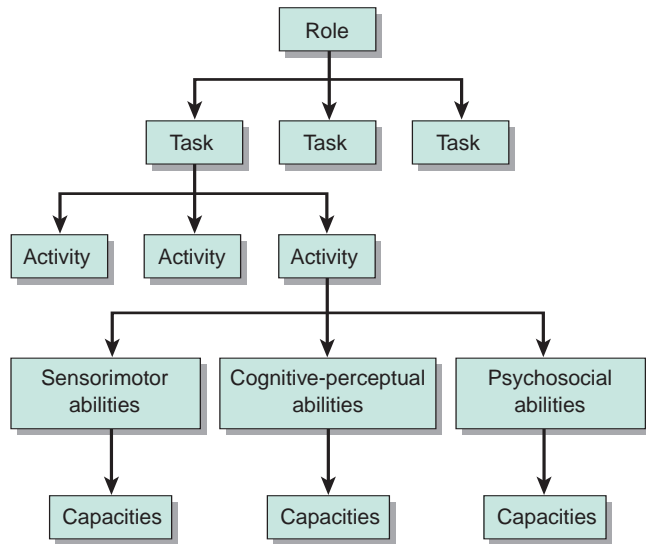

Figure 13-1 Performance-focused analysis according to the Occupational Performance Model. One role is composed of several tasks. Each task consists of several activities. Each activity depends on varying degrees of sensorimotor, cognitive-perceptual, and psychosocial abilities. Those abilities depend on supporting capacities. The performance-focused analysis examines these from the top down by observing the patient. When the patient has difficulty performing, the therapist examines the next lower levels and/or the environment as possible constraints to the performance.

not being accomplished to criterion. Observing the person's attempt gives the therapist clues about which abilities and capacities may need further evaluation and treatment. This is the assessment described in Chapter 1. It is similar to the Dynamic Performance Analysis (DPA) proposed by Polatajko, Mandich, and Martini (2000). The DPA is described as a performance-based dynamic iterative process of analysis that is carried out as the client performs an occupation. The steps are: (1) establish whole-task performer prerequisites (motivation and knowledge of the task), (2) analyze observed performance to identify where the patient demonstrates performance difficulties, and (3) establish the source of the difficulties within the relationship between client abilities and the environmental or occupational supports or demands. Analysis according to the Occupational Functioning Model is also similar to the analysis based on the Occupational Therapy Practice Framework (Watson & Wilson, 2003) but is less complicated.

The Performance Analysis proposed by Fisher (1998) involves observational evaluation of the “transaction between the client and the environment as the client performs a task that is familiar, meaningful, purposeful and relevant” (p. 517). To do this, Fisher uses a standardized performance analysis, the *Assessment of Motor and Process Skills (AMPS)* (Fisher, 1997; Merritt & Fisher, 2003), although it can also be done by informal observation. The

quality of performance, not the person's underlying capacities, is graded, although the capacities are considered when interpreting the outcome and planning treatment.

The Ecological Task Analysis (ETA) is based on ideas of the dynamical systems theory of movement and Gibson's (1977) theory of affordances (Burton & Davis, 1996; Davis and Burton, 1991). This analysis examines the interacting constraints (limitations and enablers) of performer, environment, and task as the occupation is undertaken. The ETA is based on the premise that there are many solutions to a particular task, determined by the unique interaction of performer and environment with the goal or intent of the action. The steps are as follows. (1) The therapist selects and establishes the task goal, structures the physical and social environments, and provides verbal and other cues to allow for an understanding of the task goal by the patient. (2) The patient practices the task, with the therapist allowing the patient to choose movement solutions. (3) The therapist manipulates the performer, environment, or task variables to find the optimal performance. The therapist identifies specific contexts in which the person can always (sometimes, never) accomplish the task and discovers by perturbation (e.g. increase speed, force, or other potentially controlling variable) the importance of performer or environmental variables on the performance of the task or movement. (4) The therapist provides direct instructions of other possibilities of movement solutions. See Chapter 22 for application of this analysis and teaching process.

PROCEDURES FOR PRACTICE 13-4

Performance-Focused Analysis According to the Occupational Functioning Model

1. Name the role.
2. List the tasks the person identifies as important to this role.
3. List the activities the person identifies as part of a key task.
4. Observe the person performing one of the activities.
5. If the person is able to perform the activity, observe another of the activities. When the person is unable to do an activity, one of two directions can be taken:
 - Teach the person adapted methods to accomplish the activity
 - Remediate impaired abilities and capacities to enable performance
5. If remediation is chosen, analyze what ability limitations are interfering with performance.
7. After identifying particular ability limitations, measure those abilities to confirm the limitation.
8. If the ability is significantly limited, analyze what deficit capacities are causing that limitation.
9. Measure those capacities. Treat when verified.

ADAPTATION

Activity adaptation is the process of modifying an activity of daily living, craft, game, sport, or other occupation to enable performance, accomplish a therapeutic goal, or prevent cumulative trauma injury (Definition 13-3). Although we may like to think that occupational therapists devised this process, actually Gilbreth devised it in the early 1900s (Creighton, 1992, 1993). He proposed adapting activity to suit the anatomy of workers to make work more efficient (Gilbreth, 1911).

There are four reasons to adapt an activity in the treatment of the physically disabled. One is to modify the activity to make it therapeutic when ordinarily it would not be so. Many examples of this can be seen in occupational therapy clinics. For example, in wall checkers, the board is mounted on the wall and has pegs at each square to hold the checkers. Tic-tac-toe can be adapted similarly by drawing the grid on the wall and using Velcro-backed Xs and Os or Xs and Os drawn on sticky notes (Fig. 13-2).

The second reason for adaptation is to graduate the exercise offered by the activity along therapeutic continua to accomplish goals. Grading of activity for this purpose is an original principle of occupational therapy (Creighton, 1993). For example, to increase coordination, the activity must be graded along a continuum from gross, coarse movement to fine, accurate movement. Checkers and other board games lend themselves easily to such gradations. For example, checkerboards or cribbage boards and the pieces can be changed in size so that the aficionado can continue a favorite game while continuing to benefit therapeutically (Fig. 13-3, A & B).

The third reason for adapting activities is to enable a person with physical impairments to do an activity or task he or she would be unable to do otherwise. For example, after having a stroke that causes paresis of one upper limb, a patient can learn a new method of putting on a shirt that requires only one hand. Or the environment in which a

Figure 13-2 Therapist and patient playing tic-tac-toe in an adapted way that requires reaching up.

favorite activity was accomplished can be modified to allow engagement. For example, a gardener who undergoes bilateral lower extremity amputation because of diabetes can continue to garden from a wheelchair if the beds are raised (Harnish, 2001). Figures 13-4 and 13-5 show other examples of contextual adaptation to enable performance. See Chapters 30 to 34 for ways to compensate for particular disabilities to enable role performance.

The fourth reason for adapting activities, especially work activities that are engaged in for long periods of time, is to prevent cumulative trauma injury. Examples of such adaptation are changing the table height to reduce strain on the back or upper extremities or doing the work task while seated to reduce stress on the low back.

As with all therapeutic techniques, it is vital for the patient to understand the reason why an activity is adapted (Peloquin, 1988). Ways to modify activities are described here and summarized in Procedures for Practice 13-5.

Positioning the Task Relative to the Person

The position of the person relative to the work to be done dictates the movement demanded by the activity, and

DEFINITION 13-3

Characteristics of a Good Adaptation

- Accomplishes the specific goal
- Does not encourage or require odd movements or postures
- Is not dangerous to the patient
- Intrinsically demands a certain response that the patient does not have to concentrate on
- Does not demean the patient; some contrived adaptations seem ridiculous to the patient and thus are embarrassing

Figure 13-3 **A.** Standard-sized cribbage board demands fine coordination. **B.** Enlarged cribbage board and pegs allow a person with deficient fine coordination to play (occupation-as-end) or demand greater range of motion of reaching (occupation-as-means).

therefore, which muscle groups are likely to be used (McGrain & Hague, 1987). Poor positioning of work equipment relative to the size of the person may result in musculoskeletal discomfort or repeated stress injuries (Sung et al., 2003). Adaptation by positioning refers to changes in incline of work surface, height of work surface, location of work equipment, or placement of pieces to be added to the project.

Activities that are usually done on a flat surface, such as finger painting, board games, and sanding wood, can be made more or less resistive by changing the incline of the surface. For example, if the surface is inclined down and away from the patient, resistance is given to shoulder extension and elbow flexion. If the incline is up and toward the patient, resistance is given to shoulder flexion and elbow extension.

The standard horizontal work surface itself can be raised or lowered to make demands on certain muscle groups or to alter the effect of gravity. For example, a table raised to axilla height allows flexion and extension of the elbow on a gravity-eliminated plane and may enable a person with grade 3+ muscles to eat independently.

Placing items, such as nails, mosaic tiles, pieces of yarn, beads, darts, bean bags, and paint brushes, in various locations changes the motion required to reach them when performing the activity in an otherwise standard manner. Placement may be high enough to encourage shoulder flexion or abduction; lateral to encourage shoulder rotation, trunk rotation, or horizontal motion; or low to encourage trunk flexion or lateral trunk flexion. All of the placements would encourage improvement in dynamic balance (Fig. 13-6).

Arrangement of Objects Relative to Each Other

To grade an activity for increasing perceptual skills (e.g., figure-ground discrimination, unilateral neglect), the arrangement of objects to be used, the printing on a page, and so on can be graded from sparse to dense (i.e., fewer objects or words with space between versus many objects or words with no space between). Putting game pieces on the right side of the game board encourages use of the right hand, while placement on the left encourages use of the left hand. Placement of ingredients on a

Figure 13-4 A pull-out shelf with holes that accommodate bowls or pots enables a person confined to a wheelchair to cook efficiently.

kitchen counter across the room from the mixing bowl encourages walking in the kitchen that would not occur if all were together. On the other hand, placing all objects needed for a task together reduces the energy required to do the task.

Changing Length of the Lever Arm

The amount of work a muscle or muscle group is doing depends on the resistance. Resistance is determined by the pull of gravity on the limb and the implements the patient is using, which together act as the resistance lever arm. The effect of a given amount of resistance can be altered by lengthening or shortening the resistance arm. The longer the resistance arm, the greater the force required to counterbalance it. The resistance arm can be altered by shortening or lengthening the limb; for example, flexing the knee, which shortens the limb, offers less resistance to hip extension than if the knee were extended. Another example is carrying an object close to the body, which

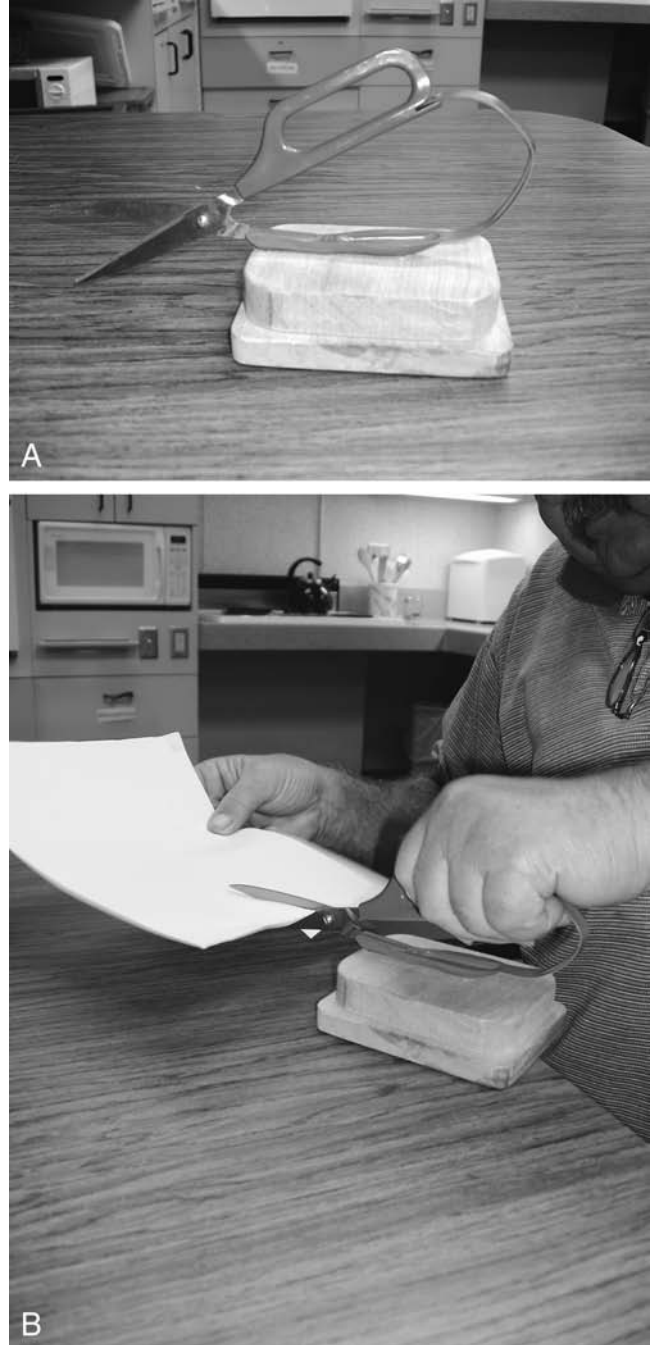

Figure 13-5 A, B. Scissors have been stabilized in a wooden block to enable cutting by a person who lacks finger dexterity.

requires less activity of back muscles than if the object is carried at arm's length.

On the other hand, increasing the length of the force lever arm decreases the muscle activity needed to accomplish a task. For example, in Figure 13-7, if the clothespin were adapted to have longer handles, less pinch force would be required to open it the same distance.

PROCEDURES FOR PRACTICE 13-5

Adaptations for Therapeutic Purpose

Adaptation	Therapeutic Purpose	Adaptation	Therapeutic Purpose
Position the task relative to the person	Increase ROM Specify muscles, motions Enable person to do the task	Change color contrast between objects	Improve figure–ground discrimination Enable performance by those with low vision
Arrange objects in relation to others	Improve perceptual responses Require specific movements Decrease energy expenditure	Change method of doing the activity	Enable person to do the task Increase strength Increase ROM Increase coordination, dexterity Increase cognitive-perceptual demands
Change lever arms	Increase strength Reduce strength needed Prevent injuries	Modify tool	Enable the person to do the task Prevent deformity Prevent cumulative trauma disorders
Change materials or texture of materials	Increase strength Increase coordination Challenge sensory system	Add weights	Increase strength Reduce incoordinated movements Provide PROM
Padding handles of tools	Reduce stress on painful joints Enable use of tools or utensils	Add springs or rubber bands	Increase strength Reduce incoordinated movements Provide PROM Assist weak muscles
Change level of difficulty	Increase cognition Increase perception Increase motor planning Enable person to do the task		
Change the size or shape of objects	Improve dexterity Enable activities, such as feeding, with enlarged handles on utensils Increase strength Increase ROM		

Attention to lengths of lever arms is important not only in adapting an activity to make it more therapeutic but also in adapting utensils and tools used in daily life tasks to enable weak persons to use them (Fig. 13-8). Furthermore, this idea guides workers in methods of lifting and handling on their jobs to avoid musculoskeletal injuries. See illustrations of lever arms in Chapter 21.

Change of Materials or Texture of Materials

Gradation along the strengthening continuum may be accomplished by selection of material by type and also by

variations of texture or density to change resistance. Resistance can be changed, for example, by starting a cutting project with tissue paper and then progressing to heavier materials. Metal tooling can be graded for resistance by choosing materials in grades from thin aluminum to thick copper. Sandpaper is graded from extra fine to coarse, and resistance increases as the grade coarsens. Mixing can be graded from making gelatin dessert to scrambled eggs to biscuit batter and so on. If materials are graded in the opposite direction, that is, from heavy to light, the activity demands increased coordination from the patient. Weaving may begin using rug roving and be graded toward fine linen threads as the patient progresses in coordination.

Figure 13-6 Christmas tree lights are placed to the left of a right-handed person to encourage reaching and development of dynamic standing balance.

Figure 13-8 A patient who has weak upper extremities is able to crush cans for recycling because the handle (force arm) of the crusher has been elongated.

Figure 13-7 Retrieving toast with a spring clothespin.

Cutaneous stimulation changes with the amount of texture of objects or surfaces. By making balls from yarn or terry toweling, carpeting the surfaces the person works on, padding handles with textured material, and so on, the therapist adapts the activity to increase sensory stimulation.

Pad Handles of Tools or Utensils

Padding the handles of utensils or tools with high-density foam or other firm but soft material (Fig. 13-9, A & B) reduces stress on painful finger joints and/or enables persons with poor grip to use the utensil or tool.

Change in Level of Difficulty

Patterns for craft activities, game rules, extent of task (e.g., prepare instant coffee versus espresso), and level of creativity can be downgraded to enable the patient to succeed or upgraded to demand per-

Figure 13-9 A. Writing using a built-up handle. B. Therapist adapting the pen.

formance at higher levels. Changing the difficulty entails changing the number of pieces or the ideas that must be manipulated, changing the problem-solving level from concrete reasoning to abstract reasoning, changing the directions from specific to general, and so on. For example, a patient with traumatic brain injury may be unable to pay the bills if the top of the desk is littered with bills and papers but may be able to manage if one bill is taken out at a time.

Change the Size or Shape of Objects

Playing pieces of board games can vary in size and shape and can therefore offer a therapeutic benefit that the standard objects would not. For example, checkers, which are usually flat pieces approximately 2.5 cm in diameter, can be cylinders, squares, cubes, or spheres; can range in size from tiny to as large as a person's grasp permits; or can have handles attached (Fig. 13-10, A & B).

Reducing the size or changing the shape of the pieces being worked on facilitates the goals of increased dexterity and fine coordination. Therapists creatively change sizes of craft materials (e.g., weaving thread, tiles, paint-by-number guidelines, and ceramic pieces) and recreational materials (e.g., puzzle pieces, chess pieces, and target games) to increase coordination. Tools and utensils can be adapted by changing the length, diameter, or shape of their handles or by adding handles to tools that do not normally have them.

The actual size of the tool can be chosen to offer more or less resistance. For example, saws range in size from small coping saws and hacksaws to large cross-cut and rip saws. Resistance of saws can also be graded by the number of teeth per inch on the blade; the fewer the teeth, the greater the resistance. Woodworking planes vary in size, and the amount of exposed blade can be adjusted to provide resistance. Size of scissors, screwdrivers, stirring spoons, and other tools and utensils can also be varied.

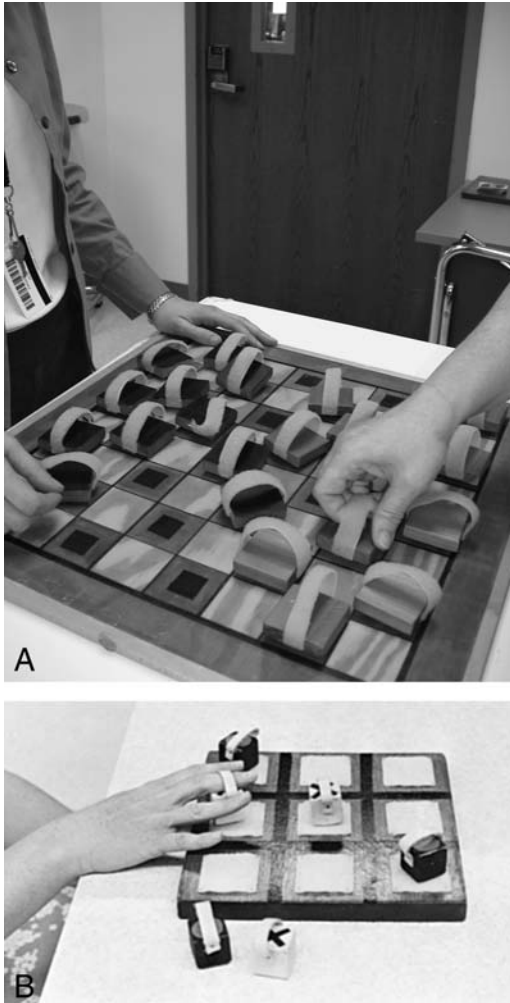

Figure 13-10 A, B. Checkers and tic-tac-toe pieces adapted with handles. This enables a person to play who otherwise could not (occupation-as-end) or challenges abilities not used when playing standard games (occupation-as-means).

Change of Color of Multiple Objects

Neistadt et al. (1993) suggested grading challenge to figure-ground discrimination ability by changing game objects from contrasting colors to increasingly similar colors.

Change of Method of Doing the Activity; Change Physical Context

Change of method is used both for occupation-as-means (Fig. 13-2) and for occupation-as-end (Figs. 13-3B, 13-4, 13-11, A & B, and 13-12). Such compensatory adaptation

allows performance of an activity that would otherwise be impossible because of the person's disability. Bowling, basketball, and many other sports can be done seated instead of standing. Change of rules adapts some sports, such as track and field events, to certain requirements of the physically impaired. Sewing and needlework, normally bilateral activities, can be made unilateral by adaptations that hold the material steady for the working hand (Fig. 13-13). Books, notebook computers, or other tools can be transported via a rolling backpack or rolling table instead of carrying them.

By altering the physical context, individuals are able to move at the edge of their competence (Nilsen, Kaminiski, & Gordon, 2003). For example, if a person cannot flex his shoulder against gravity, by placing him in a side-lying position, the effects of gravity are minimized, allowing the movement. Movement organization in a gravity-eliminated plane, however, differs from movement in an against-gravity context.

Movement organization is also different in simulated contexts using simulated objects compared with natural contexts with actual objects (Dunn, Brown, & McGuigan, 1994; Flinn, 1999; Ma, Trombly, & Robinson-Poldolski, 1999; Mathiowetz & Wade, 1995; Trombly & Wu, 1999; Wu et al., 1998, 2000). As movement organization is sensitive to contextual changes (Nilsen, Kaminiski, & Gordon, 2003), some rehabilitation centers now have manufactured "real" environments or have renovated their clinic spaces to allow patients to practice in realistic contexts to enable best performance and to facilitate carry over to actual contexts (Fig. 13-14).

Use of Modified or Supplemental Tools and Utensils

Using tools when normally none are used or modifying tools or utensils enables a person to accomplish activities and tasks that he or she would not be able to do otherwise. For example, toast can be retrieved from a toaster by use of a wooden spring clothespin when sensory precautions are in effect (Fig. 13-7). Angling the handles on carving knives allows a person with rheumatoid arthritis to cut meat or vegetables without putting deforming forces on the wrist and fingers. Changing keyboard or mouse designs can prevent carpal tunnel syndrome. Including the tool in a specially designed splint can reduce symptoms caused by prolonged holding (Bockman, 2004). Although manufacturers are offering tools and household utensils designed to enable persons with weak grasp or arthritic pain to use them comfortably, therapists must not assume that tools labeled "ergonomic" produce better positioning or less discomfort than nonadapted tools. Patients' perceptions of comfort and ease of use need to guide the selection (Tebben & Thomas, 2004).

Figure 13-11 A. Golf is made possible for a person with the use of only one side of the body by changing the method of swinging the club. B. Watching the ball land. (Photographs by Jim Hanson.)

Add Weights

The addition of weights adapts an activity to meet such goals as increase of strength, promotion of co-contraction, and increase of passive ROM by stretch. Some nonresistive activities can be made resistive by adding weights to the apparatus directly or by use of pulleys; others may be made resistive by adding weights to the person, as with weighted cuffs (Fig. 13-15). Tools also are weights, and they can be selected or adjusted to offer graded resistance; for instance, hammers range from lightweight tack hammers to heavy claw hammers.

Add Springs or Rubber Bands

Springs and rubber bands are means of adapting activity to increase strength through resistance, to assist a

weak muscle, or to stretch muscle and other soft tissue to increase passive ROM. When offering resistance, the spring or rubber band is positioned so that its pull is opposite to the pull of motion of the target muscle group, whereas if used for assistance, the spring or rubber band is set to pull in the same direction as the contracting muscle group. Springs and rubber bands applied for the purpose of stretching are placed so the pull is against the tissue to be stretched.

Springs of graduated tensions may be applied directly to larger pieces of equipment. Rubber bands can be added to smaller pieces of equipment and can be graded from thin with light tension to thick with heavy tension. For example, a rubber band can be wrapped around the pincer end of a spring-type clothespin to add resistance when it is used in games involving picking up small pieces.

Figure 13-12 A patient with spinal cord injury is learning to feed himself in a new way. He is using a mobile arm support, a fork held in a universal cuff, and a plate guard to prevent food from being pushed off the plate.

Figure 13-13 An adapted hoop that fastens to the table enables a person with the use of only one hand to embroider.

Evidence Table 13-1 Best Evidence for Occupational Therapy Practice Regarding Selection, Gradation, and Adaptation of Occupation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task constraints: #1—different sized handles; #2—different weight cups	#1: three ceramic cups 12 cm high, weighing 309.0 g, having handles of 2 cm, 4 cm, and 8 cm. #2: two cups, 12 cm high with 2-cm handles, weighing 309.0 g and 705.9 g when filled with water.	30 healthy women aged 20–45 years.	3 trials for each cup. Carried out in a laboratory.	One group, repeated-measures design, randomized to condition. IB1b	Mixed. #1: Yes. The size of the handle significantly affected the number of fingers being placed through the handle; the larger the handle, the more fingers. #2: No. Weight did not significantly affect the number of fingers used to support the cup.	#1: $\chi^2_{(2)} = 49.8$, $p < 0.001$; effect size could not be calculated. #2: not significant.	Fuller & Trombly, 1997
Exercise apparatus adapted into a game	Experimental: Exercise using a game apparatus that required supination to dump dice out to score. Control: Exercise using the same apparatus without the game.	30 patients with acute stroke, mean age = 68.4 years.	Two sets of 10 trials for each condition; different days.	Randomized controlled trial. IC2c	Yes. The game significantly increased the degrees of handle rotation (supination) achieved. Mean of 13.4° more in experimental group compared with control group.	$p = 0.016$, $r = 0.42$.	Nelson et al., 1996

<p>Functional activity (goal object present) vs. rote exercise (goal object absent)</p>	<p>Present: Reach to scoop coins off the table in the laboratory. Absent: Reach forward without functional goal in a laboratory.</p>	<p>14 patients with chronic stroke, mean age = 61.8 years. 24 healthy persons, mean age = 63.2 years.</p>	<p>10 trials within 1 day.</p>	<p>Randomized controlled trial. IC1c</p>	<p>Yes. Both groups demonstrated significantly better movement organization with goal object present. Results are reported for the stroke patients only: The force of movement did not differ significantly.</p>	<p>Overall effect size = 0.63. Speed, $p = 0.003$, $r = 0.70$; straightness of path, $p = 0.002$, $r = 0.72$; smoothness, $p = 0.005$, $r = 0.66$; automaticity of movement, $p = 0.001$, $r = 0.75$. Force of movement, $p = 0.28$, $r = 0.17$.</p>	<p>Wu et al., 2000</p>
<p>Grade speed of action; grade work surface</p>	<p>Condition: 1: rest 2: unilateral horizontal sanding at 15 cycles/min 3: same as 2 at 30 cycles/min 4: unilateral sanding with board inclined to 15° at 15 cycles/min 5: same as 4 at 30 cycles/min.</p>	<p>8 patients with stroke of unknown chronicity, mean age = 67.6 years.</p>	<p>3 minutes each of 5 conditions with rests between; all conditions within 1 day.</p>	<p>One group, repeated-measures design without randomization to condition. IIC2c</p>	<p>Mixed. When tested together, speed and angle significantly increased cardiopulmonary measures above resting. When separated, only different velocities affected the outcome.</p>	<p>$p < 0.01$; effect size could not be calculated. No statistical information available concerning the tests of angle and speed separately.</p>	<p>Muraki et al., 1990</p>
<p>Weighted cuff</p>	<p>Weighted cuff applied to forearm to decrease tremors and increase functional feeding in adults. Each person ate ½ the meal with the weighted cuff and ½ without the cuff. Weight determined individually by trial and error.</p>	<p>5 adults aged 30–81 years. All had tremor secondary to various diagnoses.</p>	<p>8 or 16 meals.</p>	<p>AB single-case design; conditions alternated randomly. IVC3b</p>	<p>Partial benefit for some participants. Time to acquire food on utensil decreased significantly for 4/5 participants. The number of spills decreased significantly for 2/5 participants. The amount of food consumed did not change significantly.</p>	<p>Time to acquire food on utensil: $p < 0.013$; effect size for 4, $r = 0.97$. Number of spills: $p < 0.012$; effect size for 2, $r = 0.96$.</p>	<p>McGruder et al., 2003</p>

SUMMARY REVIEW QUESTIONS

1. What are the general characteristics required of an activity to be used to treat motor impairments?
2. How does analysis relate to selection of an occupation or activity?
3. What would a therapist need to know to select occupation-as-end for a particular patient?
4. What goal(s) might be accomplished by engaging a patient in occupation-as-means that requires moving at different speeds?
5. What are two reasons for adapting an occupation used as means? Occupation-as-end?
6. What are the five characteristics of good adaptations?
7. What therapeutic goals can be accomplished by the following?
 - Changing the position of the task relative to the person
 - Adding weights to tools or game pieces
 - Adding springs or rubber bands to craft equipment or tools
 - Changing the length of lever arms of tools, equipment, or the limb itself
 - Changing the material to be used in a project
 - Changing the method of doing an activity

ACKNOWLEDGMENTS

I thank my former students Dr. Steven Cope, Dr. Susan Fasoli, Janice Ferguson, Yvonne Fuller, Dr. Hui-Ing Ma, Dr. Susan Murphy, Julie Pope, Natalia Ramsbey, Ellen Rosenberg, Dr. Pimjai Sudsawad, Dr. Pei-Luen Tsai, and Dr. Ching-Yi Wu for their research assistance and conversations about occupation. I am especially indebted to the occupational therapists and patients at Sister Kenny Institute, Minneapolis, MN, for their assistance with photography for this chapter. Specifically, I thank Jake Beckstrom, Cindy Bemis, Arlan Berg, Tricia Bonavoglia, OTR/L, Michelle Brown, M.Ed., OTR/L, Krista Elfink, M.S., OTR/L, Larry Larkin, Mary Vining Radomski, M.A., OTR/L, Jennifer Theis, M.S., OTR/L, and Valerie Wheeler.

CHAPTER 14

Learning

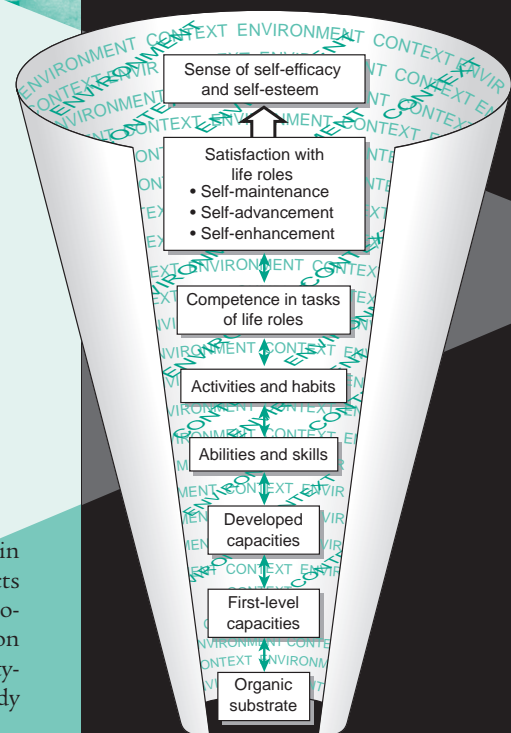

Nancy Ann Flinn and Mary Vining Radomski

¹ Readers will note that the terms “patient” and “client” are used at various points in this chapter. In acute medical and rehabilitation settings, the term “patient” reflects a more passive role of the person receiving care; it is also the term used by other professionals on the health care team. The term “client” is used in reference to a person living in the community who is receiving outpatient, home-based, or community-based services. It reflects the assumption that the person receiving services is ready to assume a more directive role in organizing his or her care.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Differentiate between patient¹ performance and patient learning.
2. Outline clinical considerations necessary for planning patient-specific teaching.
3. Explain the roles of context, feedback, and practice in the acquisition of both task-specific skills and general strategies.
4. List phases of teaching patients and describe the advantages and disadvantages of various teaching technologies.
5. Identify strategies for facilitating caregiver education and training.

Glossary

Glossary

Automaticity—The phase of learning resulting from numerous consistent repetitions in which a person accurately carries out a skill or task with little or no cognitive effort (Sternberg, 1986).

Contextual interference—Changes across trials in intrinsic and extrinsic factors that force learners to use multiple and variable processing strategies (Shea & Morgan, 1979).

Encoding—Processes in which stimulation of our senses is translated into codes and then stored in memory (Mann & Sabatino, 1985).

Encoding specificity—A phenomenon of information processing wherein we store a given memory along with information about the context in which the memory occurred and, as a result, elements of the context may trigger recall and recognition of that memory in the future.

Feedback—Intrinsic or extrinsic information that patients receive while learning to perform a new skill or strategy.

Generalization—The ability to apply a skill or strategy to an altogether new task in an environment that is different from the one in which the original training occurred.

Learning—The result of processes associated with practice or experience that leads to relatively permanent changes in a person’s knowledge, skills, and behavior (Schmidt, 1988).

Performance—Temporary changes in response during practice.

Practice—The repetition of a to-be-learned task, a key ingredient in the learning of skills and strategies.

Retrieval—The search for and location of information stored in long-term memory that occurs when people remember (recall or recognize) something that they have learned (Eysenck & Keane, 1990).

Transfer—The ability to perform a new skill in an environment that is different from the training environment.

Learning is a primary therapeutic mechanism underlying many, if not all, occupational therapy interventions. Occupational therapists teach patients to use adaptive equipment, new ways to move, and a variety of compensatory skills and strategies. As teachers, therapists must determine whether and when learning has taken place. For example, after a 30-minute dressing session, a patient who has had total knee replacement surgery is able to don his pants, socks, and shoes. From a traditional learning perspective, the patient’s performance at the end of the session reflects the extent to which he or she has learned the desired skill or strategy. However, what if a nurse later reports that the patient is unable to carry out the activities he demonstrated proficiency with the day before? One can easily deduce that while within-session performance was buoyed by cues and practice, true learning did not occur.

Schmidt’s (1988) contemporary definition of motor learning allows us to differentiate learning from within-session performance. According to Schmidt (1988), “motor learning is a set of processes associated with practice or experience leading to relatively permanent changes in the capability for responding” (p. 346). Based on this definition of learning, we would expect the knee replacement patient to demonstrate similar levels of proficiency after the occupational therapy session as during. The term *performance* is used to describe what is seen during training, that is, short-term capabilities resulting from instruction, cues, or assistance. For occupational therapy to help patients resume occupational roles, therapists must understand the process of transforming performance into learning and employ teaching methods that help the patient learn the skills.

This chapter discusses the role of information processing in learning and then summarizes the array of variables that affect the patient-specific teaching plan. We detail key influences on learning and conclude with specific applications to occupational therapy practice. Regarding issues of learning, there has been a traditional division in the research between motor tasks and cognitive tasks. In clinical practice, however, it is unusual to find motor tasks that do not have a cognitive component or cognitive tasks that do not have a motor component. As this distinction does not translate well into practice and because principles in the two areas are similar, they are reviewed together in this chapter.

HUMAN INFORMATION PROCESSING MODEL OF LEARNING

Learning is inextricably linked to memory, specifically the **encoding** and **retrieval** of information. As explained in Chapter 9, people hold environmental stimuli very briefly in a series of short-term sensory stores before transferring it to limited-capacity working memory (Atkinson & Shiffrin, 1971). In working memory, also called short-term memory, people may use control processes to encode information for storage in long-term memory (Schneider & Shiffrin, 1977). These control processes include but are not limited to rehearsal, coding, and imaging (Atkinson & Shiffrin, 1971). Rehearsal is rote repetition of information, whereas coding entails linking the new information to something already meaningful. Imaging transforms verbal information to

visual images that are stored in memory. Craik and Tulving (1975) found that the durability of the memory trace is a function of depth of processing. That is, deep processing, as in the time-consuming process of linking new information to personally relevant old knowledge, results in better retention than shallow processing, such as rote rehearsal. If the learner does not use some form of conscious control, the memory trace quickly fades from working memory and cannot be recovered or stored (Atkinson & Shiffrin, 1971). From the standpoint of human information processing, learning is the transfer of information from short-term or working memory to long-term memory (Shiffrin & Schneider, 1977).

Controlled Versus Automatic Information Processing

Consider the attentional resources required of you the first time you drove a car compared with the attention required for the same task now. After years of experience, the car seems to drive itself, freeing the driver to concentrate on plans for the day or talk to a passenger. This example typifies the difference between controlled and automatic processing.

Controlled Processing

A controlled process is technically a temporary activation of a series or sequence of elements in long-term memory under the control and attention of the thinker (Schneider & Shiffrin, 1977). For example, the new driver must actively recall specific rules and instructions and direct his or her attention to each motor sequence of the task. Controlled processing is limited by the capacity of working memory and, therefore, effortful but flexible in handling novel situations. When learning a new task or skill that requires effortful concentration, people employ controlled processing. Thus, patients learning new skills or behaviors can process only a limited number of inputs (instructions, cues, environmental distractions) at a time.

Automatic Processing

With enough controlled processing, a task requires less and less concentration to carry out (Shiffrin & Schneider, 1977). That is, the task becomes increasingly automatic, as in the example of the proficient driver. Automatic processing occurs when specific contextual stimuli internal or external to the person trigger the activation of a specific learned sequence in long-term memory (Schneider & Shiffrin, 1977). Given enough repetition, the individual performs the skill or task in a consistent manner with little or no attention. Sternberg (1986) suggested that development of a full level of automatization requires at least 200 trials of a task but that automatization begins in as few as 10 trials, so long as those trials involve consistency. With

DEFINITION 14-1

Errorless Learning

Errorless learning is a technique that involves encoding new information without error (Tailby & Haslam, 2003). Learners are helped to do it right each time the new skill is performed by introducing and then fading preemptive cues and/or assistance. Wilson and Evans (1996) propose errorless learning methods for persons with severe memory impairments. They suggest that these individuals have difficulty remembering what they learned if they made errors during the training process. Guessing and trial-and-error are avoided, and because training generally occurs in the context in which the new skills will be used, expectations of transfer are minimized.

fully automatic skills, people cannot stop themselves from performing the overlearned sequence unless control processes are employed to override it. Definition 14-1 discusses implications related to helping patients with memory impairment to reacquire skills.

According to Giles (2005), overlearning is practice of a skill or strategy well beyond demonstration of learning or proficiency; it increases the likelihood that the skill or strategy will become automatic. These automatic skills and strategies become the easiest behaviors to initiate from an array of possible behaviors (Giles, 2005), minimizing demands on attention and decision making. Habits and routines are examples of automatic motor sequences that, according to Kielhofner, Barris, and Watts (1982), organize a person's tasks, space, and time. Characteristic of automatic skills and strategies, habits and routines are responsive to the environmental conditions under which they are learned and develop with repetition (Kielhofner, Barris, & Watts, 1982; Wood, Quinn, & Kashy, 2002). Habit learning is a form of implicit learning, which is described in Definition 14-2. Occupational therapists often help patients resume or relearn self-maintenance tasks so that they are once again automatic. See Chapter 29 for a more thorough discussion of that process.

Implications of the Information Processing Memory Model

Attention and memory play important roles in many aspects of learning. Therefore, occupational therapists assess these domains before they try to teach patients skills or strategies. Sensitivity to distractions, such as pain, fatigue, and noise, allows therapists to optimize the likelihood that patients will use limited-capacity cognitive resources to hold and ultimately store stimuli related to the new skills or strategies. Therapists also facilitate memory storage and retrieval by helping patients use effective control processes,

DEFINITION 14-2

Implicit and Explicit Learning

People learn through two key processes that are supported by separate brain structures and have very different characteristics.

Explicit learning (sometimes called declarative learning) refers to the conscious encoding and recollection of specific events, task rules, and facts (Deckersbach et al., 2002; Eldridge, Masterman, & Knowlton, 2002). It relies on the integrity of the medial temporal lobe and diencephalic structures, particularly the hippocampus (Eldridge, Masterman, & Knowlton, 2002). It can be facilitated by a therapist through direct instruction about key environmental features, task-relevant feedback, and cues (Reber & Squire, 1994). Explicit learning is more flexible than implicit learning and has been shown to generalize more easily, probably because it is not as context dependent (Squire, 1994).

Implicit learning (also called procedural learning) refers to an unconscious change in behavior resulting from repetition within a stable context. There appear to be several forms of implicit learning including skill and habit learning, some forms of conditioning, and the phenomenon of priming (Squire, Knowlton, & Musen, 1993). Much of the learning of a motor task is thought to be implicit, including the dynamics of force production in the task, which is the interaction of active and passive components of the multiple joints involved in the task. The therapist facilitates implicit learning by structuring the environment to create consistent cues and frequent opportunities for appropriate task practice (Gentile, 1998). Implicit learning is more robust than explicit learning and retains its strength even when the explicit knowledge about a task has decayed (Lee & Vakoch, 1996). The basal ganglia support implicit learning rather than the medial temporal lobe (Packard & Knowlton, 2002). This suggests that even people with impaired explicit memory systems (e.g., Alzheimer's disease) are capable of implicit learning (Eldridge, Masterman, & Knowlton, 2002).

such as linking the new information to something they already know. Finally, therapists recognize that, for many skills, the learning end point is not proficiency but **automaticity**. Therapists ultimately enable their patients to carry out these tasks with accuracy and ease if they encourage consistency in performance (consistent environment, consistent sequence of steps).

CLINICAL CONSIDERATIONS IN TEACHING CLIENTS

In advance of every teaching intervention, occupational therapists make deliberate decisions regarding appropriate teaching methods. These decisions are based on

the characteristics of the learner, anticipated length of intervention, desired learning outcome (specific task vs. general strategy), and expectations for **transfer** and **generalization**.

Learner Characteristics

A client's learning potential is determined by many factors. Variables affecting cognitive status (reviewed in Chapter 9) are critical contributors to learning potential. They include neurobiological, affective, experiential, and sociocultural influences. In brief, the *neurobiological influences* on cognitive function are largely associated with the physiological and anatomical integrity of a person's brain. *Affective influences* may interfere with learning because depression and anxiety, for example, distract a person from attending to new information and storing that information in memory. Therapists consider other personal affective influences with similar effects on learning, such as motivation to improve function and pain and fatigue. (Chapter 10 discusses assessing these aspects of personal context.) Finally, each individual brings his or her *experiential sociocultural* background to the lesson. Remember, all of these considerations apply to family caregivers as well as patients (see Procedures for Practice 14-1). Literacy is one important dimension of the experiential sociocultural influence on learning, with many implications regarding teaching methods. (Again, see Chapter 10 regarding assessing literacy.) Neistadt (1995) suggested that occupational therapists attempt to answer four questions regarding patients' learning capacities during the course of their traditional evaluation. These questions include the following:

1. What modes of input (e.g., visual, auditory, tactile) can this patient process most easily?
2. What approaches to tasks (outputs or behaviors) are still available to this patient?
3. What tasks remain meaningful or are most likely to facilitate learning for this patient?
4. How well is this patient able to transfer learning, that is, apply specific skills to a variety of tasks under a variety of circumstances?

Anticipated Length of Treatment

Occupational therapists also consider how many teaching sessions are likely to be available. Typically this is dictated by expected length of stay at the hospital, rehabilitation center, or nursing facility; insurance coverage of rehabilitation services; acuteness of medical condition; and learning potential of the patient. Awareness of time constraints for teaching allows the clinician to anticipate what stage of learning the patient will attain by the completion of treatment. Discharge planning then incorporates recom-

PROCEDURES FOR PRACTICE 14-1

Caregiver Education and Training

Ever-decreasing hospital lengths of stay continue to increase the demands and responsibilities of family caregivers (Clark et al., 2004). Occupational therapists and other rehabilitation professionals can contribute to clients' quality of life by providing multidimensional education and training to their caregivers (Kalra et al., 2004; Pasacrete et al., 2000). Here are some important considerations and strategies:

- Acknowledge and validate the pivotal role that family caregivers play in the recovery and quality of life of your client. Make sure that your occupational therapy intervention plan incorporates specific goals, strategies, and timelines for caregiver training.
- Appreciate the complex demands placed on people when they assume caregiver roles. Remember that family caregivers typically have to juggle the needs of other family members and their own jobs and activities in addition to their caregiving responsibilities (Carter & Nutt, 1998; Pasacrete et al., 2000). Adjust your teaching methods in consideration of these demands and distractions on caregivers and expect that you will need to repeat information and instructions more than once.
- Try to empathize with the emotional burden often carried by family caregivers. Appreciate that they often carry an array of worries about their loved one's condition, the quality of care their loved one is receiving, and what the future holds in terms of their caregiving responsibilities (Hong, 2005). Make a point of structuring your education and training efforts to address these worries.
- Incorporate caregiver education and training into your intervention from day 1 by showing family members how to participate in providing care. Ask family members to attend therapy sessions and include them as active participants. Show them how they can extend the benefits of occupational therapy intervention by, for example, prompting and assisting with activities of daily living or reinforcing the use of adaptive equipment.
- Collaborate with other health care professionals to ensure that caregiver education and training is multifaceted and ongoing. Appreciate that current and premorbid family functioning is an important predictor of caregiver stress and adjustment (Clark et al., 2004). Refer caregivers and their family members to counselors, psychologists, and social workers when necessary.
- Take responsibility for helping family caregivers to transfer what they have learned in the hospital or clinic setting to their home and family contexts. Consider making a home visit before discontinuing your services to review information and techniques within the client's home environment.
- Set up a caregiver education plan that extends beyond the duration of occupational therapy intervention. Identify possible resources for continued caregiver education and support in the future.

recommendations for continuing and extending the learning that began in treatment.

Stages of Learning

In 1967, Fitts and Posner described three sequential stages of learning, or acquisition, of motor skills: cognitive, associative, and autonomous; each of the stages requires different kinds of attention resources (Eversheim & Bock, 2001). During the cognitive stage, the patient tries to understand the requirements of the task. The patient uses conscious control to acquire the new skill or strategy: thinking through or verbalizing the steps, attending to visual and verbal **feedback** from the therapist, and determining what cues to heed.

In the associative stage, the patient has determined the most effective way of doing the task and begins to make refinements in performance. The learner relies less on vision and verbal feedback and begins to use internal feedback

mechanisms. During this stage, practice takes on primary importance; this important dimension of learning is discussed in more detail later in this chapter.

During the autonomous stage, the new skill or strategy becomes increasingly automatic or habitual. The patient can accurately perform most of the skill or strategy without thinking about it and is less subject to interference from other activities or environmental distractions.

Desired Learning Outcomes: Task-Specific Skills Versus General Strategy Related to Expectations for Transfer and Generalization

Recipients of occupational therapy services have a variety of learning needs. Two categories of learning end points include acquisition of task-specific skills and acquisition of general strategies. Therapists deliberately determine the patient-specific learning end point because it dictates

teaching methods, length of treatment, and expectations for transfer and generalization.

Task-Specific Skills and Transfer of Training

After a stroke, many patients receive occupational therapy services to learn task-specific skills such as how to dress themselves using only one hand. Acquired skills are expected to enhance function solely within the training tasks. For example, a client who receives home-based treatment may learn techniques specific to donning her housecoat and slippers (her usual attire) at the side of her bed, which rests on shag carpeting. Teaching in this situation (within the environment and context that the skill will be used) is task specific. The learning process is embedded in the performance environment, with surroundings and objects becoming cues. The therapist does not expect the client to apply skills learned in this sequence to a whole host of new tasks, and therefore, training time is minimized. Typically the therapist hopes that, given enough consistent repetition, the routine will be carried out automatically.

However, occupational therapy intervention, such as activities of daily living (ADLs) training, typically begins while the patient is hospitalized. Patients often learn one-handed dressing techniques from hospital beds in rooms with very different characteristics from those of their homes. For the intervention to improve the patient's level of independence after discharge, the therapist must train to transfer. That is, therapists employ teaching techniques that optimize patients' chances of being able to apply the task-specific dressing skills learned at the hospital when they get home.

Transfer of learning refers to a person's ability to carry out the same task in a different environment. According to Togliola (1991), transfer is not an all-or-none phenomenon. She described four levels of transfer—near, intermediate, far, and very far—based on the number of differences in the surface characteristics between the learning and real-life environments. In general, near transfer requires the person to apply the same skill in very similar circumstances, whereas far transfer implies greater differences in application environment (Perkins, 1995). Transfer is associated with perceptual similarities of tasks, not similarities in underlying principles (Perkins, 1995). Therefore, transfer places minimal demands on metaprocessing abilities (see Chapter 9) and requires less training time than generalization of newly learned strategies (Saloman & Perkins, 1989).

Strategies and Generalization of Learning

Whereas acquisition of task-specific skills involves learning targeted behavioral sequences, the acquisition of strategies entails learning rules or principles that can be broadly applied. For example, many therapists expect persons with stroke to learn this general strategy: dress the weak side first, and undress the weak side last. This rule or principle enables patients to don and doff sweatshirts,

dress shirts, slacks, and outwear, but it presumes generalization of learning.

Generalization occurs when the person is able to apply the newly learned strategy to a new task in a new environment. For example, the patient who demonstrates the ability to get dressed one-handed in the hospital can use the same strategies to put on a raincoat at home. Generalization, as it is here defined, depends on the learner's mindful abstraction of a principle and is based on conceptual similarities between the learning task and environment and the real-world application (Perkins, 1995). Generalization of learning places greater demands on patients' metaprocessing abilities (Saloman & Perkins, 1989). In fact, the more abstract the strategy, the more difficult it is to learn (Kirby, 1984). (It is easier for a patient to learn to dress the weak extremity before the strong one than to learn to use a higher order problem-solving strategy.)

FUNDAMENTALS OF THE TEACHING-LEARNING PROCESS

Clearly, the value of occupational therapy intervention will largely be judged by the extent to which new skills and strategies are carried out in patients' real-life environments. Therapists interested in helping patients achieve transfer and generalization objectives incorporate research findings about critical constructs in teaching-learning theory. These constructs relate to the therapeutic use of context, feedback, and practice.

Therapeutic Use of Context

The term "context" broadly refers to the setting in which an event or activity occurs. Many conceptions of context as a facilitator or barrier to function can be found in the occupational therapy and rehabilitation literature (American Occupational Therapy Association [AOTA], 2002; Dunn, Brown, & McGuigan, 1994; Fisher, 1998; World Health Organization, 1997) (see Chapters 10 and 11). The Occupational Therapy Practice Framework (AOTA, 2002) suggests that context has many dimensions: cultural, physical, social, personal, spiritual, temporal, and virtual. It also defined activity demands in terms of objects and their properties, space demands, social demands, sequencing and timing, and required actions as influencing the performance of skills and patterns. We now briefly discuss the influence of environmental context and activity demands on learning.

Role of Context in Learning

Research indicates that objects used in activities, the characteristics of those objects, and the goals of the activities performed have a strong influence on motor performance

and must be carefully manipulated in treatment. Wu, Trombly, & Lin (1994) demonstrated that college students elicited smoother and faster arm movements when using real objects in movement tasks. Students were asked to perform three movements: picking up a pencil and preparing to write their name (materials-based task), pretend picking up a pencil and preparing to write their name (imagery-based task), and moving the arm forward to a target (exercise task). Students performed the three tasks differently, with the material-based task eliciting the smoothest and fastest movements. In addition, other groups of students were more successful in learning to eat with chopsticks if they used real food items during practice than if they had practiced manipulating non-food items (Ma, Trombly, & Robinson-Podolski, 1999)

The finding that the use of real objects elicits different movements and learning than imagery-based tasks or rote exercise has also been demonstrated by persons with disabilities such as cerebral palsy, stroke, and multiple sclerosis (Mathiowetz & Wade, 1995; Trombly & Wu, 1999; van der Weel, van der Meer, & Lee, 1991; Wu et al., 2000). Mathiowetz & Wade (1995) demonstrated that both subjects with multiple sclerosis and those without benefited from the information provided by real objects. Subjects were asked to eat applesauce, with a spoon, bowl, and applesauce available (materials-based task); pretend to eat applesauce, with a spoon and bowl available (partial-support task); and pretend to eat applesauce without a spoon or bowl (imagery-based task). Again, the movement patterns in the three conditions were significantly different. Trombly and Wu (1999) demonstrated that subjects who had strokes benefited from having objects to reach to rather than just reaching for a point in space. These findings support occupational therapy approaches that emphasize the significance of real-life tasks in optimizing function (Mathiowetz & Haugen, 1994). (See Chapters 6 and 22 for more about this approach.)

Environmental context is equally important to cognitive learning. In a classic study by Godden and Baddeley (1975), scuba divers who learned lists of words while underwater recalled them better underwater than on dry land, while divers who learned the lists on dry land recalled them better in that setting. These and previous findings are likely explained by two important principles: **encoding specificity** and **contextual interference**.

Encoding Specificity

The principle of encoding specificity suggests that events are stored in memory in such a way as to be inseparable from their contexts (Tulving & Thompson, 1973). That is, people encode features of the learning task and environment along with the newly acquired skill or strategy. Encoding specificity limits transfer and generalization because new tasks and environments do not have the same

cueing properties as those present during original learning, making retrieval from long-term memory more difficult. For example, imagine that a therapist works with a patient on the same grasp and release task every day; even the work space is consistent. Although the patient improves performance on the task, the information about control of grasp and release is stored along with the context of the practice task and environment, and he or she may not be able to elicit these skills during ADL.

Contextual Interference

One way to mitigate the influence of encoding specificity on learning is to employ high contextual interference training (Battig, 1978). Low contextual interference occurs when the context and training task are invariant, allowing the learner to perform the same task repetitively in a consistent environment, as in the previous example. On the other hand, high contextual interference occurs when the task and environment keep changing throughout the learning process. This principle asserts that task and environmental variation force people to use multiple and varied information processing strategies, which makes retrieval easier. Contextual interference forces elaborate processing strategies, and transfer is facilitated.

Put another way, high contextual interference is a barrier to rote responding because it introduces problem-solving demands with each change of the context (Lee, Swanson, & Hall, 1991). Had the therapist from the previous example provided a variety of grasp and release activities in a variety of settings, the patient would have used more complex processing strategies during the learning process. Information about many similar grasp and release movements would be stored in memory along with a variety of environments and objects. As a result, the patient would be more likely to use the newly learned skills to solve problems within the inevitable variety of the real world. Therefore, to facilitate transfer of task-specific skills and generalization of newly learned strategies, therapists deliberately vary the learning tasks and environments.

Therapeutic Use of Feedback

Feedback also can enhance or interfere with learning. Occupational therapists understand the functions of feedback and deliberately select the types and schedules of feedback in designing a patient's learning experience. Procedures for Practice 14-2 discusses videotaped feedback.

Functions of Feedback

Feedback regarding performance has several functions (Salmoni, Schmidt, & Walter, 1984). It has a temporary motivating or energizing effect and a guidance effect that

PROCEDURES FOR PRACTICE 14-2

Teaching Technologies: Videotape Feedback

Many researchers have investigated the use of videotape for feedback to improve learning (Brotherton et al., 1988; Morgan & Salzberg, 1992; Tham & Tegner, 1997). It has been applied to a broad variety of situations and a large number of patient populations. These studies have consistently demonstrated that videotape feedback can improve a patient's awareness of his or her performance. However, researchers have also found that simply showing a videotape of performance does not lead to improvements. Effective feedback must be structured by the clinician to focus the attention of the patient on pertinent actions and events. The advantage of videotape feedback is that the therapist can stop the tape at critical points, focus attention on specific features, and ask the subject to analyze and suggest appropriate changes. For example, in an investigation of the effectiveness of videotape feedback in the treatment of neglect syndrome, patients were videotaped performing a simulated cooking task that involved arranging pastries on a baking tray (Tham & Tegner, 1997). Therapists showed the subjects structured videotapes of their performance and provided feedback during the viewing. Subjects improved on follow-up on this test, but no generalization was noted.

Videotape has also been used to assist with social skills training of patients with brain injuries and severe mental retardation (Brotherton et al., 1988; Morgan & Salzberg, 1992). In both cases, the videotape feedback was used to help patients identify problematic behaviors, which was followed by rehearsal of appropriate behaviors. Again, in these cases, the therapist structured viewing of the videotape, with identification of the problems and the appropriate behaviors, as part of an ongoing dialogue. Rehearsal of appropriate responses was also part of the training program.

Finally, videotape may be especially helpful in teaching complex motor skills. Hodges, Chua, and Franks (2003) used video to facilitate learning and retention of a complex bimanual activity. Those participants who had access to the video during training performed significantly better on the post-test and were better able to identify errors in performance than those individuals who did not have access to video feedback during training. This was especially true for those individuals who performed worst at the pre-test. It is suggested that, by using video feedback, participants were able to formulate a model of the action they were to perform and were then able to come closer to that model during training and retention trials.

As these studies show, the use of videotaped feedback can assist in the teaching process, but it must be used in a structured and purposeful way. Showing patients specific sections of tape, pointing out relevant details, and asking patients to describe their behavior and solve problems are all effective ways to use videotape. Furthermore, if reasonable for the specific task, rehearsal of appropriate responses provides patients with a repertoire of appropriate behaviors.

informs the learner how to correct an error on the next trial. However, feedback can permanently impair motor learning if provided beyond the point that the person has a rough idea of the desired motion.

Types of Feedback

To help patients learn and sustain skills and strategies, therapists initially provide extrinsic feedback on performance but ultimately facilitate the development of intrinsic feedback.

Extrinsic Feedback: Knowledge of Results and Knowledge of Performance

Therapists typically provide feedback about performance in verbal form. Extrinsic information presented after task completion falls into two categories, knowledge of results and knowledge of performance. This feedback allows subjects to alter or adapt their responses or behaviors on subsequent trials. Knowledge of results provides information about outcome, such as “You’ve got your shirt on” or “You

took the cap off that jar.” A second type of feedback, knowledge of performance, is related to qualitative descriptions of a performance, such as “You shifted your weight too far to the left” or “You bent your elbow.” This information directs patients’ attention not to outcome but to components of movement that they need to change or attend to. This type of feedback duplicates information patients already have available through intrinsic feedback but on which they may not be focusing.

Other external information provided to patients during practice falls into the category of encouragement. It is important that patients and therapists do not confuse encouragement (“Keep going”) with feedback (“You’re doing great”), especially if the latter is not true, as incorrect feedback is highly detrimental to learning (Buekers, Magill, & Hall, 1992).

Intrinsic Feedback

Intrinsic feedback, or internal feedback, is information that patients receive through their own senses, such as seeing an egg break as it hits the floor after dropping it or

feeling the pain of hitting the ground after an unsuccessful transfer. Although this information is readily available to patients, they may need cueing to focus on the most important components of a skill or strategy, such as learning to use vision when moving an anesthetic limb. Intervention that incorporates self-monitoring and self-estimation (task difficulty, completion time, accuracy score, amount of cueing, or assistance needed) enables patients to create mechanisms for self-generated feedback (Cicerone & Giacino, 1992; Toglia, 1998), lessening dependence on therapists for successful performance.

Feedback Schedules

The frequency and content of feedback are critical to the learning process and must be considered when a teaching situation is planned.

Immediate and Summary Feedback

The frequency and time at which feedback is given can profoundly influence the acquisition and learning of task-specific skills and strategies. Studies in this area evaluate learning during a “retention trial,” which is done some time after teaching is completed. For example, Lavery (1962) wanted to know which schedule of feedback best facilitated learning: immediate feedback provided after each trial was completed, also referred to as constant feedback; summary feedback provided after a number of trials were completed; or both. Lavery found that subjects who received immediate or combined feedback improved their performance of the task more quickly during the acquisition phase than the group receiving only summary feedback. However, when tested for retention of the task 4, 37, and 93 days after training, the subjects who received only summary feedback did significantly better than those who received either immediate feedback or both types.

Lavery hypothesized that people who received immediate feedback came to rely on it when performing the task and those that received only summary feedback were forced to analyze their own movements. The subjects who received both immediate and summary feedback did just as poorly as those who received only immediate feedback, suggesting that the immediate feedback interfered with the processing of the summary feedback. Beyond its implications about the schedule of feedback, these findings support the idea that performance during the training phase does not reflect actual learning of the skill.

Faded Feedback

Therapists are often concerned that providing only summary feedback after a series of trials will not help their patients understand tasks that are complex or new. Weinstein and Schmidt (1990) evaluated the effectiveness of

feedback given on 50% and 100% of trials on the learning of a task by college students. The 50% feedback was faded, with the feedback given on every trial initially and then decreased to no feedback at the end of training, with feedback being given on an overall average of 50% of all the trials. They found a slight advantage for the 100% feedback group during acquisition of the skill, but there were significant differences during the retention phase, which is the true test of learning. The group that received faded feedback performed significantly better than the immediate feedback group on the retention trials; the trials were performed at 10 minutes and 2 days, with the effect at 2 days more noticeable. Remember that, from the standpoint of encoding specificity, subjects who were on the 50% schedule received no feedback at the end of the acquisition phase and were performing the task in exactly the same way as they did during the retention phase. Also, these findings point out an important irony: factors that degrade performance during acquisition may improve learning.

Bandwidth Feedback

With bandwidth feedback, an acceptable range of performance is defined, and the subject receives feedback only when performance is outside of that range. As the subject’s performance improves, feedback is provided less frequently. Research Note 14-1 further discusses this point (Goodwin & Meeuwssen, 1995).

Therapeutic Use of Practice

In addition to planning feedback, the design of a treatment session factors in the nature of instructions and a plan for practicing the material.

Internally or Externally Focused Instructions

Recent research supports instruction that is focused on the task rather than on the patient’s performance (Wulf et al., 2002). For example, Fasoli et al. (2002) found that persons who had had a stroke reached faster and more smoothly when cued to focus on an object and what they were going to do with it, rather than focusing on their arm as they did the task. This means that the instructions given to patients should focus their attention on the objects and the task, rather than on the movements that they will be using to achieve the goal.

Blocked Versus Random Practice

As discussed earlier, traditional models of learning did not distinguish between learning and performance. These models also promoted blocked forms of practice, such as drill, as the most efficient schedule for learning a task.

RESEARCH NOTE 14-1

Abstract: Goodwin, J. E., & Meeuwsen, H. J. (1995). Using bandwidth knowledge of results to alter relative frequencies during motor skills acquisition. *Research Quarterly for Exercise and Sport*, 66, 99–104.

Goodwin and Meeuwsen (1995) examined the effect of using bandwidth feedback on a golfing task. Subjects were assigned to four groups. The first group received feedback on every trial that did not hit the hole, whereas the second group received feedback on every trial in which the ball was more than 18 inches from the hole. The third group was given feedback on a shrinking bandwidth schedule, tolerating increasingly smaller errors (initially if the ball missed the hole by 27 inches, then 18 inches, 9 inches, and 0 inches). The fourth group received feedback on an expanding schedule, tolerating increasingly larger errors, starting with 0 inches and then increasing to 9 inches, 18 inches, 27 inches, and finally 36 inches. Interestingly, the groups that received the least feedback (i.e., the group that got feedback only when the ball was more than 18 inches from the hole and the expanding [fourth] group) performed the best during the retention phase. The third (shrinking) group performed similarly to the group that received feedback whenever the ball did not hit the hole. These findings led the authors to suggest that receiving high frequencies of feedback at the end of the acquisition phase increases the subject's dependence on that feedback and is as detrimental to learning as providing high frequencies of feedback throughout the acquisition phase.

Implications for Practice

- Frequent indiscriminate feedback seems detrimental to learning. Therefore, therapists must monitor the timing and frequency of comments to patients as they learn new skills and strategies.
- When it comes to feedback, it appears that less is more. Patients who receive less feedback may increasingly rely on intrinsic feedback and be more likely to retain the new skill or strategy than persons who get a lot of feedback when they make errors. Therapists should provide opportunities for patients to determine when and why they have made errors.

Using a blocked format, the same skill or strategy is practiced over a number of repetitions, after which the next skill or strategy is rehearsed. As such, blocked practice is a form of practice with low contextual interference.

Shea and Morgan (1979) studied whether increasing the contextual interference by random practice during

skill acquisition leads to improved retention and transfer of motor skills. Their experiments entailed knocking over wooden barriers with a tennis ball held in the hand. In brief, they found that blocked practice provided low contextual interference, whereas random practice provided high contextual interference, requiring subjects to formulate a new movement plan for each trial. Subjects who practiced with high contextual interference demonstrated better retention and transfer than those who used blocked practice. This study demonstrated two important findings: (1) performance during acquisition of a skill does not necessarily relate to later learning; and (2) conditions that may improve performance during acquisition do not necessarily create better learning. In fact, structuring training to improve performance during practice by using blocked practice schedules is actually detrimental to learning.

The advantage of random practice over blocked practice was also demonstrated for patients with hemiplegia (Hanlon, 1996). Patients practiced a multistep functional activity that consisted of reaching for a cupboard door, opening it, picking up a coffee cup by the handle, transferring it to a counter, and releasing the handle. The subjects practiced these steps in either a blocked or a random pattern. The random pattern group performed significantly better than either the blocked or control group on both the 2-day and 7-day retention trials.

Part-Whole Practice

Therapists also decide whether patients practice the whole task or components of a task (referred to as part-whole training). Ma and Trombly (2004) evaluated the characteristics of movement under part and whole task conditions. The task involved reaching for a pen, bringing the pen to paper, and signing the name. The three segments of movement were performed separately and then as a single task for each individual. The performance of the whole task elicited greater efficiency of movement, greater force during the task, and smoother movements. Mane, Adams, & Donchin (1989) manipulated two dimensions of practice while teaching a task: whole versus part task and speed of performance. Participants learned to play a goal-directed computer game. The part-whole study examined the extent to which practicing part of the task improved performance of the whole game. In this study, subjects who practiced a critical skill extracted from the game did improve performance on the overall game. However, changing the speed of practice was met with varying success. Practice at the slowest speed fundamentally changed the demands of the task, leading to poor transfer of skills to the task at original speeds. On the other hand, slight slowing of task speed during training enhanced learning.

Winstein et al. (1989) examined the effect of part-task practice with gait training. One group of patients with

hemiplegia received traditional physical therapy gait training. The second group received traditional physical therapy and specific training in standing balance symmetry (proposed as a reasonable critical component of symmetrical gait). After several weeks of training, the group that had practiced symmetry in standing showed improvement in that component of the activity, but there was no carryover to the whole task of gait. There was no significant difference in gait symmetry between the two groups.

These findings demonstrate that, although part-whole training may work in some situations, such as the computer game, it is not successful in all situations. Furthermore, therapists may not be able to identify the specific critical components that would improve overall learning. It will require much more research to identify the components that will transfer to the whole task before part-task training can be the preferred method. Winstein et al. (1989) suggested that tasks that are continuous and cannot be easily separated into component parts may not be appropriate for part training. Examples of this type of movement include walking or driving a car—tasks that require many adjustments with components that occur simultaneously and cannot be easily separated.

MAKING PERSONAL CHANGE

Employing a newly learned skill or strategy is fundamentally a personal change. Using a new skill or strategy in daily life depends not only on recall, transfer, or generalization but also on learners' beliefs about their competence and their stage in the change process.

Bandura (1977) posited that people's beliefs about their ability to handle a new situation largely determine whether they attempt the new task and their ultimate performance. Self-percepts of efficacy (self-perceptions of competence) predict success with a wide range of acquired health behaviors, including smoking cessation (Stewart, Borland, & McMurray, 1994), exercise maintenance (McAuley, 1993), medication compliance (DeGeest et al., 1994), and use of energy-conservation techniques to manage fatigue (Mathiowetz, Matuska, & Murphy, 2001). Bandura (1977) demonstrated that people make judgments about their competence (self-efficacy) by thinking about past accomplishments, vicarious experience (observing others who are similar), verbal persuasion, and emotional arousal, such as anxiety. Since self-percepts of competence seem to explain the discrepancy between what people can do and what they actually do (Bandura, 1982), occupational therapists actively create opportunities for patients to demonstrate to themselves that they are indeed competent with the new skill or strategy.

Many patients served by occupational therapists have had sudden onset of changes in physical functioning.

Persons who are insulated from ramifications of these changes (perhaps those who have been hospitalized continuously since onset) may not fully appreciate the need for the skills and strategies therapists are attempting to teach them. The Stages of Change Model (Prochaska & DiClemente, 1982) helps therapists target their teaching-learning interventions to address the learning predispositions of the client and family.

This model identifies four stages of change: contemplation, determination, action, and maintenance. During the first stage, clients become aware of the problem or concern; in the determination stage, they resolve to do something about it; during the action stage, clients work to address the problem or issue; and clients must still put forth some degree of effort to sustain the desired skill or behavior during the maintenance stage. The researchers suggested that verbal intervention strategies are most appropriate during the first two stages (pointing out the problem and discussing possible approaches), whereas action-oriented behavioral interventions are most helpful during the last two stages. For example, before a client routinely employs strategies for scanning the left visual field, he or she must believe that parts of the environment are missing or that personal safety is in jeopardy. Merely elucidating the problem is not enough. Once convinced and motivated, the client is taught specifically how to handle the problem.

OCCUPATIONAL THERAPIST AS TEACHER

The extent to which occupational therapy contributes to a client's resumption of roles depends to a large extent on the effectiveness of the therapist as a teacher. Principles of teaching parallel therapy: assessment, goal setting, intervention, and evaluation (Redman, 1997). Although this process rarely follows a predictable, orderly sequence, these steps serve as a checklist to ensure that therapists consider variables affecting the outcome of their teaching efforts (Redman, 1997).

Assess Learning Needs and Readiness

Before teaching begins, therapists complete a traditional occupational therapy assessment so as to understand the client's occupational needs, priorities, capacities, skills, and competencies. Therapists attempt to identify barriers to learning, such as low literacy; distracters, such as pain and fatigue; lack of human or financial support; awareness of problem areas; and incongruous values between patient and therapist (Vanetizian, 1997). Dynamic assessment provides information about the circumstances (task, environment, strategies, and cueing) in which the patient

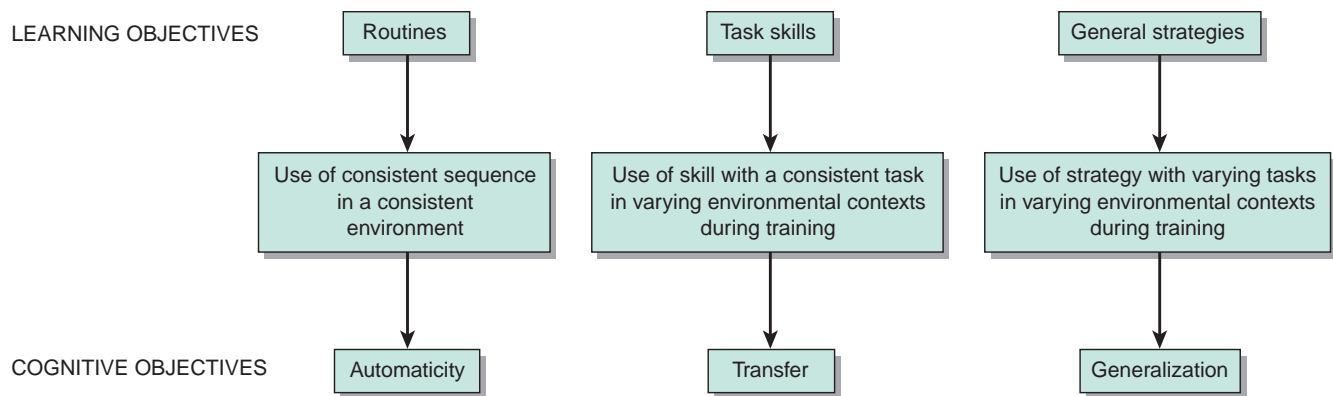

Figure 14-1 Teaching objectives in occupational therapy.

is best able to learn (Toglia, 1989) (see Chapter 9). Therefore, the therapist determines who will be the subject or subjects of the teaching—the patient, family member (if the patient seems unlikely to retain the information), or both.

Set Client-Specific Learning Goals

Therapists use the results of their assessments and estimates of the treatment time available to set learning and cognitive objectives for each patient (Fig. 14-1). Therapists plan treatment around transfer and generalization goals by identifying reinforcements in the natural environment and incorporating into the treatment stimuli common to both training and real-world environments (Sohlberg & Raskin, 1996). If the intervention ultimately is to change an existing routine, skill, or strategy, the therapist attempts to determine where in the process of change the learner is. For example, a patient with little or no aware-

ness of a memory problem is likely to have minimal interest in learning to use compensatory memory techniques. Therefore, the therapist sets goals that move the patient toward the contemplative stage of change by allowing him or her to take the consequences of forgetting. Finally, therapists merely recommend learning goals. Goals that direct teaching-learning efforts are set in collaboration with patients and their families.

Create Learning Opportunities Throughout Intervention

Therapists deliberately use context, feedback, and practice to help patients meet learning goals (Procedures for Practice 14-3). They try to enhance motivation and recall by linking new skills or strategies with patients' specific interests, knowledge, and abilities. Effective teachers also make an effort to overcome barriers to learning. They select the optimal time of day and environment for teaching

PROCEDURES FOR PRACTICE 14-3

Therapeutic Use of Context, Feedback, and Practice to Promote Transfer and Generalization

- Vary the training environmental context to achieve transfer; vary training tasks and environments to achieve generalization of new strategies.
- Provide extrinsic feedback just until the learner understands the desired movement, skill, or strategy. Use cueing and the patient's own performance prediction and analysis to help the learner increasingly rely on intrinsic feedback.
- Provide summary feedback when possible. Tolerate a slower or longer acquisition phase of learning, appreciating the later benefits in terms of retention, transfer, and generalization.
- Fade therapist feedback and cues so that these elements of training do not get encoded with the new skill or strategy.
- Attempt to teach movement, skills, and strategies within whole tasks. Address components or subskills only when they are critical to whole-task performance.

PROCEDURES FOR PRACTICE 14-4

Addressing Low Literacy in Patient Teaching

Problems with literacy pervade all socioeconomic and ethnic groups (Thomas, 1999). People with low literacy tend to be ashamed of their difficulties with reading and are reluctant to admit the problem, even to family members (Parikh et al., 1996). Thomas (1999) offered the following suggestions for addressing this issue in occupational therapy:

- Incorporate a brief evaluation of literacy into the occupational therapy assessment process (see Chapter 10 for a discussion of REALM).
- Limit the quantity of information to the most important messages. Collaborate with the patient, family, and other team members to establish priorities.
- Reduce the reading level of printed materials by using one- or two-syllable words, shortening sentences to 10 to 15 words, and targeting materials to the fifth- or sixth-grade reading level.
- Make sure text and graphics are well organized. Davis et al. (1998) found both preference for and improved comprehension with a question-and-answer list format over a paragraph format for text.
- Use materials that are racially and culturally sensitive. As recommended by Thomas (1999), “make sure that patients can ‘see themselves’ in materials provided.”

and change their schedules occasionally to adapt to family needs. Clinicians recognize that literacy affects comprehension and use of health-related written materials for many adults (Davis et al., 1998). Citing the results of the 2003 National Adult Literacy Survey, Schneider (2005) reported that 13% of all Americans had “Below Basic” English literacy for prose material. This means that 30 million Americans cannot do much more than sign a form or review a document to see what they are allowed to drink before a medical procedure (Schneider, 2005). Another 22% had only “Basic” literacy, meaning, at best, they can find information in a pamphlet about how jurors were selected for a jury pool (National Center for Education Statistics, 2005). Therefore, clinicians create and use written materials that are well organized and limit the demands on reading (Procedures for Practice 14-4). Finally, to achieve transfer and generalization goals, therapists use

the continuum of care to reinforce long-term learning. Often this means teaching family members how to extend the learning process and providing copies of the discharge instructions to other providers, such as the home health occupational therapist, vocational specialist, and nurse case manager.

Evaluate Achievement of Learning Goals

Effective teachers routinely assess clients’ progress toward learning goals, typically by changing the training task or environment and evaluating carryover. Family members perform return demonstrations of new techniques, such as transfers. Based on performance or other changes in learning status, therapists adjust learning goals throughout the intervention.

Evidence Table 14-1

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Videotape feedback	Experimental group received videotaped feedback after performance of a task; control group did not.	14 consecutive stroke survivors, all RCVA, 7 in experimental arm and 7 in control arm. Mean age = 67.9 years.	A single episode of video feedback, with follow-up testing 3 hours after feedback session.	Randomized controlled study. IC1b	Yes. The treatment group improved more than the control group but only on the trained task.	Baking Tray Task: $p = 0.02$, $r = 0.81$.	Tham & Tegner, 1997
Training in a task in a natural or simulated context	Participants practiced an eating task using chopsticks in a natural or simulated context.	40 right-handed college students without disabilities and without previous experience with using chopsticks. Mean age = 23.75 years.	60 training trials on 1 day, 24-hour retention measured on a transfer task.	Randomized controlled study. IB1c	Participants in natural context performed better than those in a simulated context on the transfer task.	Natural context: $p = 0.03$, $r = 0.30$ for success rate at retention trial in the transfer task.	Ma, Trombly, & Robinson-Podolski, 1999
Effect of goal-directed action	Experiment 1: Subjects reached in a goal-directed action or to a spatial location. Experiment 2: Subjects reached for phone, disconnected receiver, and a stick.	14 stroke survivors (9 LCVA, 4 RCVA, 1 bilateral CVA). Mean age = 65 years; average time since onset of stroke = 39 months.	Each participant tested under several conditions.	Randomized controlled repeated measures counterbalanced design. IC1b	Participants reaching for an object were faster, smoother, and took less time to reach peak speed than when they reached for a point in space.	Experiment 1: number of movement units, $p = 0.05$, $r = 0.55$; movement time $p = 0.02$, $r = 0.62$; percentage of reach to peak velocity, $p = 0.04$, $r = 0.57$; peak velocity, $p = 0.01$, $r = 0.66$. Experiment 2: no effect.	Trombly & Wu, 1999

Evidence Table 14-1 (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Presence or absence of objects used in movements	Participants evaluated for movements with object or without object.	14 stroke survivors (9 LCVA, 5 RCVA, and 1 bilateral CVA) and 25 neurologically intact adults.	Each participant was tested under 2 conditions: reaching to scoop up coins and reaching to where the coins would have been.	Randomized controlled repeated measures counterbalanced design. IC1b	Using real objects elicited better performance of reaching, as measured by decreased movement time, decreased displacement, higher velocity, and fewer movement units.	Stroke survivor data: movement time, $p = 0.0028$, $r = 0.70$; total displacement, $p = 0.0019$, $r = 0.72$; percentage of reach where peak velocity occurs, $p = 0.0011$, $r = 0.75$; movement units, $p = 0.0055$, $r = 0.66$.	Wu et al., 2000

RCVA, right cerebral vascular accident; LCVA, left cerebral vascular accident; CVA, cerebral vascular accident.

CASE

EXAMPLE

Learning as Part of Home-Based Intervention for a Client with Motor and Perceptual Deficits

Occupational Therapy Intervention Process

Client Information

Mr. O. is a 69-year-old married man seen by occupational therapy in home care 1 month post stroke. He had received therapy in both the acute hospital setting and in a rehabilitation unit. During his initial interview, Mr. O. indicated that he wanted to resume the following pre-morbid roles: working as the head of an advertising agency, golfing, driving, and being independent at home. He indicated that his goals for therapy included being safe during short periods of being left alone, being able to walk and drive independently, and being independent in self-care, light meal preparation, and going to the bathroom. He also wanted to use his involved left arm like he did before. He viewed these skills and tasks as pre-requisite to resumption of his identified roles.

Mr. O. was assessed at home with the following results:

- ADL: Mr. O. was able to dress with minimal assistance and cues but needed maximal assistance in toileting, bathing, and meal preparation.
- Upper extremity function: He did not use his left arm in any functional activities, although he did have active movement and strength of muscle grades 3 to 4 throughout. He had difficulty using the available motion in tasks requiring movement at more than one joint.
- Walking and mobility: He was able to stand with moderate assistance but was unable to propel his wheelchair in the house. He walked with moderate assistance and a wide-based quad cane.
- IADL: Driving was not evaluated. Due to his need for assistance in standing, golf was not evaluated initially.
- Patient's safety: Mr. O. fell several times in the hospital and had been labeled impulsive. However, conversation with the patient revealed that the problem was not so much impulsivity as awareness. As he put it, "I forget that my leg and arm don't work when I stand up but remember as I'm falling."
- Problems in performance were related to severe left neglect, which the patient strongly denied. He knew adapted dressing techniques but needed cues regarding neglect of his left arm. There were also environmental barriers to using the wheelchair, and adaptive equipment was needed for the bathroom.

Clinical Reasoning Process

Objectives

Appreciate the context

Develop intervention hypotheses

Select an intervention approach

Reflect on competence

Examples of Therapist's Internal Dialogue

"Mr. O. struck me as someone who is used to being in charge—doing what he wants, when he wants. I could tell that he was frustrated with his dependence on his wife and by the fact that he continued to need supervision. I was not interested in arguing with him about goals that I viewed as unrealistic at this time (especially the driving) but instead helped him focus on the first steps of managing himself independently at home."

"I was actually surprised by how much strength Mr. O. had in his left arm because I never observed him using it during functional activities. It was clear to me that Mr. O. could be much more self-reliant once we installed some adaptive equipment in the bathroom. It seems that Mr. O's left neglect is a real barrier to his safety, however. The neglect appears to be at the heart of his need for ongoing supervision and certainly interferes with his use of his left arm. He seems to get rather defensive at the suggestion that neglect is a problem. Again, I have no intention of arguing with Mr. O. about this but will try to teach him about the impact of his neglect if and when situations arise.

1. By providing adaptive equipment, I thought I could help Mr. O. to become more independent in a number of the ADLs that matter to him.
2. I figured that if I can help Mr. O. become more aware of his left neglect, he may learn to compensate for it and realize improved upper extremity function and safety.

The following are intervention approaches that I used:

1. Change the physical environment/context
2. Teach compensatory skills
3. Restore left upper extremity function

"I have never treated someone whose left neglect is so profound but have worked with clients with brain injury who have similar problems with awareness, so I feel competent to provide services to Mr. O."

Recommendations

Home-based occupational therapy was recommended for four times a week for 3 weeks, then two or three times a week for 3 weeks, followed by transition to outpatient occupational therapy. Short-term goals for home care (3 weeks) were identified as (1) minimal assistance in toileting and clothing adjustment, (2) standby assistance with showering, (3) safety and independence for short periods during the day (30–60 minutes), and (4) independence in light meal preparation.

Consider the client’s appraisal of performance

“Even though Mr. O. didn’t initially appreciate the significance of his left neglect, he seemed very committed to his therapy program and quite clear about his goals. He’d have me come every day, if my schedule permitted.”

Consider what will occur in therapy, how often, and for how long

“I recommended a fairly intense home-based therapy program to start with because we really had a lot to do. Both Mr. and Mrs. O. were frustrated with his level of assistance, especially in the bathroom, and I knew that it would take a few visits to get that in order. But since we were practicing in his own home, I felt that Mr. O. could make good progress quickly.”

Ascertain the client’s endorsement of plan

Summary of Short-Term Goals and Progress

The first week of therapy focused on environmental adaptations so that Mr. O. could move about the house in his wheelchair. Also, a raised tub seat, raised toilet seat, and grab bars were installed in the bathroom to increase safety and decrease his dependence on his wife. Attempts to increase his awareness of neglect were integrated into almost all contacts. He did make some improvements in compensation for the left neglect, specifically as it related to wheelchair propulsion and toileting.

During the second week of home care, the patient attempted to walk without assistance and fell. He received a large gash to his face and ear and spent the night in the emergency room. When the occupational therapist arrived the next day, he announced that this “left neglect thing” might be more of a problem than he had thought and that he was now willing to work on it. A number of functional tasks were practiced, including playing cards and doing crossword puzzles, activities he had previously enjoyed. Over the next 2 weeks, he became more aware of his left visual space, compensating spontaneously in most simple activities around the house and becoming much safer at home.

During this same 2-week period, he continued to make gains in gait and all ADL. Improvements in both strength and compensation for neglect allowed him to go to the bathroom and transfer into and out of the bathtub with minimal assistance. However, he continued to need constant cueing to incorporate his left arm into most activities. When cued to use his arm, he insisted that it had been involved with the activity or that he always did that task with only his right arm.

In summary, after 3 weeks of home-based therapy, Mr. O. met his goals related to toileting and clothing adjustment (requiring just minimal assistance) and remaining safe and independent for brief periods of time. He had made progress toward his other goals related to showering and meal preparation.

Assess the client’s comprehension

“Both Mr. and Mrs. O. were very pleased with the bathroom equipment. Mr. O.’s brother is a home-repair expert, and he came over to install the grab bars in the shower/tub area. I just don’t feel comfortable installing anything into ceramic tile myself. The equipment made an immediate difference in Mr. O.’s independence.”

Understand what he is doing

Compare actual to expected performance

Know the person

“I was relieved that Mr. O.’s fall didn’t result in a more severe injury; he was lucky, and he knew it. This incident ‘put the fear in him,’ and I tried to capitalize on that in therapy. He was willing to do the table top activities that I gave him as homework, which safely occupied him while Mrs. O. did the laundry in the basement.”

Appreciate the context

“Even though I’m seeing progress in terms of Mr. O.’s safety and independence in self-care activities, I’m really not seeing the gains I had hoped to in terms of his arm function. Again, the left neglect is the big barrier and Mr. O. seems to be tiring of my pointing out issues that he simply can’t see. He strikes me as someone who doesn’t like to be prompted or cajoled; for that matter, I suppose I wouldn’t like that either.”

Next Steps

1. Use visual feedback to improve awareness of left neglect

In an attempt to increase his awareness of the use of the left arm, video feedback was employed during a golfing task. The client tried putting several times, and these attempts were videotaped. The client consistently neglected his left hand but insisted that he was using it. Following the unsuccessful cues, four more putts were taped. Mr. O. was then shown the videotape as a form of summary feedback. He was surprised by his lack of use of his arm and hand and identified that as part of the cause of his poor performance. Following the viewing of the tape, he putted some more. The client consistently incorporated his left arm into the

Anticipate present and future client concerns

“I wanted to allow Mr. O. to see what I was seeing relative to his left arm use and function so that he might begin to prompt himself rather than simply endure what seemed like endless nagging from me. I specifically chose to videotape his performance during a golfing task because I knew that that activity really mattered to him. Mr. O. received important feedback in two key ways: seeing himself on tape and then observing his own improved task performance when he used both arms. He and I came up with a silly verbal prompt to

task, and his performance improved. Most surprisingly, this awareness transferred to other activities, increasing his safety and efficiency in a variety of tasks, including transfers, walking, meal preparation, and emptying the dishwasher.

2. Continue with revised goals

After the first 3 weeks of treatment, new goals for therapy were set. They included: (1) independence in light meal preparation, (2) independence in toileting, (3) standby assistance for transfers in and out of shower, and (4) safety and independence for short periods (1–2 hours).

Analyze client's comprehension

Decide if he or she should continue or discontinue therapy and/or return in the future

use whenever he seemed to be neglecting his arm. It is something like, 'sometimes the right hand doesn't know what the left hand is doing.' Mrs. O. uses it now too, and Mr. O. doesn't mind. Now that Mr. O. is more aware of his tendency to neglect the left side, I think he's ready to tackle more complex activities such as meal preparation and getting in and out of the shower."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Differentiating Between the Acquisition of Skills Versus Strategies

Mr. O.'s assessment suggested a number of learning needs related to his self-identified goals. List learning needs characterized as task-specific skills. List learning needs that are best characterized as general strategies. Compare Mr. O.'s learning processes for the task-specific skills and general strategies in terms of speed and ease of acquisition and teaching methods.

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Training for Transfer and Generalization

Mr. O.'s treatment took place in his home in the context of his everyday activities. Describe how encoding specificity contributed to the acquisition of skills and strategies in this setting. Imagine that Mr. O. works toward similar goals while a patient in a rehabilitation unit. In what ways should his treatment program change to optimize the likelihood of transfer and generalization of skills and strategies?

SUMMARY REVIEW QUESTIONS

1. List the types of practice patterns and discuss the advantages and disadvantages of each.
2. Design two ADL training sessions, one for learning a specific task and the second for learning a general strategy.
3. Discuss the different feedback schedules and compare their advantages and disadvantages.
4. Identify Fitts and Posner's three stages of learning. Describe the characteristics of performance that you might see as patients learn to use a piece of adaptive equipment.
5. List characteristics of practice mostly likely to facilitate transfer and generalization of practice.
6. Describe the influences on the learning readiness of a family caregiver. What will you do to optimize the learning process in response to these influences?

CHAPTER 15

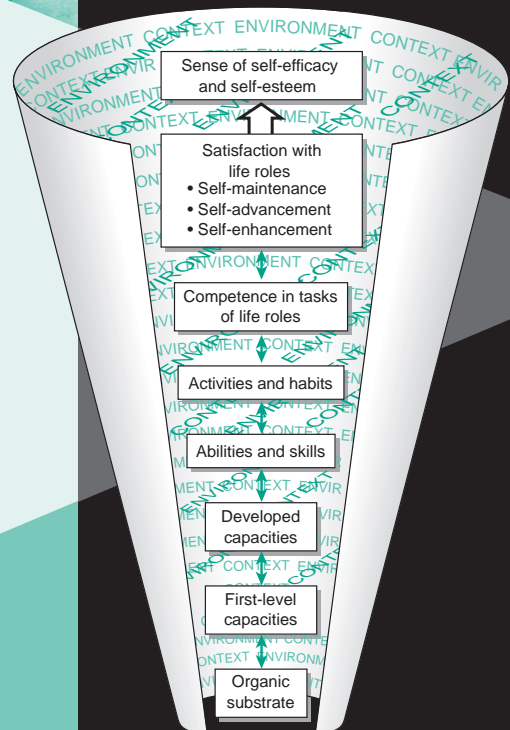

Therapeutic Rapport

Linda Tickle-Degnen

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Define high therapeutic rapport.
2. Describe how rapport influences intervention and the client's occupational functioning.
3. Describe how collaboration between therapist and client contributes to achieving high therapeutic rapport.
4. Select methods to enhance rapport with a client.
5. Identify therapists' and clients' attributes that can influence the development of rapport.
6. Apply knowledge of ethics of practice to the therapeutic relationship.

Glossary

Glossary

Mutuality—Interaction between the client and therapist in which they influence one another.

Nonverbal communication—The process of interpreting another's nonverbal behavior and expressing one's own thoughts and emotions through nonverbal behavior. Nonverbal behavior includes positions and movements of the face and body and qualities of the voice, such as vocal tone, intensity, and speed.

Therapeutic rapport—The qualities of experience and behavior between client and therapist that affect the client's performance and involvement in therapy.

Verbal communication—Interpreting another's words and expressing one's own thoughts and emotions through words.

Working alliance—Working together to achieve agreed upon goals.

The origins of the term *rapport* reflect an emphasis on communication and connection between individuals (*Oxford English Dictionary*, 2005). Individuals who are finely tuned to one another's actions and ideas, such that they respond to one another “immediately, spontaneously, and sympathetically” (Park & Burgess, 1924, p. 893), are said to be in rapport with one another.

Although rapport can occur in any social situation, the type of rapport developed in therapy has its own special characteristics. Rapport is one *mechanism*, or means, by which a client achieves positive therapeutic outcomes, or in the case of occupational therapy, confident and competent occupational functioning. It involves the interpersonal influences arising between client and therapist that can support the client's desire to try occupational therapy, to maintain continued involvement in therapy despite the need for considerable effort and courage, and to participate with the therapist in constructing a new vision of life possibilities that project into the client's occupational future (Mattingly & Fleming, 1994; Peloquin, 2002).

A client who shares a high rapport with the therapist at the point of assessment may want to try therapy simply because of an initial liking for the therapist and, once in the midst of therapy, carry through with the work because of having a competent and caring ally in the achievement of mutually derived occupational goals. In addition, many, if not most, daily life occupations are conducted in a social milieu. People do occupations together and in the presence of one another, and their occupations are supported naturally by their immediate, spontaneous, and sympathetic responses to one another. The therapist can provide this natural supportive function while expertly guiding occupation-as-means to achieving therapeutic goals.

This chapter defines the behaviors and feelings associated with therapeutic rapport, describes conditions affecting its development, and discusses the ethics of a therapeutic relationship. Although this chapter focuses on therapeutic rapport with a single client, its content can be applied to developing rapport with caregivers and family members as well (Clark, Corcoran, & Gitlin, 1995).

DEFINITION OF HIGH THERAPEUTIC RAPPORT

High **therapeutic rapport** (Definition 15-1) involves the mutual experience and behavior of the client and therapist as they interact with each other as well as the outcome of the interaction for the client:

1. It is an optimal interpersonal *experience* for both the client and the therapist that involves concentration, masterful communication, and enjoyment (Csikszentmihalyi, 1990; Tickle-Degnen, 2006).
2. It occurs with *behavior* that reflects high levels of mutual attentiveness, interpersonal coordination, and mutual positivity (Tickle-Degnen & Gavett, 2003; Tickle-Degnen & Rosenthal, 1992).
3. It has a *beneficial effect* on client performance and follow-through with intervention plans (Ambady et al., 2002; Di Blasi et al., 2001; Feinberg, 1992; Hall, Harrigan, & Rosenthal, 1995; Martin, Garske, & Davis, 2000; Porszt-Miron, Florian, & Burton, 1988).

MUTUALITY AND THERAPEUTIC RAPPORT

Mutuality in the relationship between client and therapist is relatively new in the espoused philosophy of occupational therapy. In the first half of this century, occupational therapists were expected to be friendly and cheerful but not intimate with clients (Aitken, 1948; American Occupational Therapy Association, 1948). Therapists and clients were not to affect each other through the force of their personal attributes. Starting at mid-century, the “therapeutic use of self” (Frank, 1958) became the prevailing philosophical position guiding the therapeutic relationship. Therapists recognized that not only modalities but also their own selves could be agents of therapeutic change in their clients. By being role mod-

DEFINITION 15-1

de·fin·i·tion

High Therapeutic Rapport

Qualities of Experience

Concentration	The client and therapist experience a deep and effortless concentration on the interaction. Distractions, worries, and self-concern disappear.
Masterful communication	They are challenged by the interaction yet feel skillful in meeting the challenge. The goals of the interaction are experienced as clear and shared by both. Each understands immediately how well these goals are being met.
Enjoyment	They experience the interaction with deep satisfaction.

Qualities of Verbal and Nonverbal Behavior

Attentiveness	The client and therapist demonstrate verbally and nonverbally that their attention is focused on the other.
Interpersonal coordination	They demonstrate a highly tuned responsiveness to each other such that behavior and emotional expression are highly coordinated between the two.
Positivity	They demonstrate verbally and nonverbally that their feelings are positive toward one another and the interaction.

Beneficial Effects for the Patient

Enhanced client performance	Qualities of the client–therapist interaction are beneficial if they improve client performance during evaluation and intervention.
Client follow-through with therapeutic activities	Qualities of the client–therapist interaction are beneficial if they support clients' continued involvement in activities that enable them to make progress toward their goals.

els to their clients and by behaving in certain ways, they could help clients change. Although therapists could influence clients, therapists were to remain somewhat professionally detached to ensure that they themselves were not unduly affected by clients.

Starting in the late 1960s, with the inception of the human rights, human potential, and consumer movements, and continuing into the early 2000s, occupational therapy's view of the therapeutic relationship has been undergoing a major transformation. The profound shift has been toward viewing the relationship as a mutual and collaborative exchange between equals, a perspective exemplified by Yerxa's (1973) work: "The therapist allows himself to feel real emotion as he enters into mutual relation with the client. . . . The authentic occupational therapist is involved in the process of caring and to care means to be affected just as surely as it means to affect" (p. 8).

The current philosophy of the therapeutic relationship has advanced the mutuality perspective to the image of covenanting partner or friend (Peloquin, 2002). This image is revolutionary in that it conveys that the client and therapist *together* engage in mutually satisfying occupation and interaction (e.g., Clark, 1993). Although the relationship between client and therapist can embody a mutual respect similar to that of good friends, it usually does not involve the same reciprocity of a typical social friendship;

rather, it is *client centered* (Egan et al., 1998). A client and an occupational therapist usually meet and grow to know one another because the therapist is expected to provide a service to the client. This service relationship may arise when it is difficult for the client, because of suffering or impairment, to experience or communicate feelings that contribute to the development of rapport (Rosa & Hasselkus, 2005). Finally, the therapist usually is paid for the services, and is accountable to institutional and professional systems that are charged with monitoring therapy and tracking clients' response to therapy.

Despite a therapeutic focus on the client, clients and therapists mutually influence one another. Evidence suggests that, if either the client or the therapist is not attentive, responsive, or positive, or perceived as such by the other, high therapeutic rapport is difficult to achieve (Tickle-DeGnen & Rosenthal, 1992).

EXPERIENTIAL AND BEHAVIORAL QUALITIES OF HIGH THERAPEUTIC RAPPORT

Health care research findings and client autobiographical accounts demonstrate that both the therapist and

client contribute to the development of a relationship. The following sections discuss therapist and client rapport qualities.

Therapist Concentration and Attentiveness

A person who is paying attention to another will tend to orient his or her body and eyes toward the other to pick up information coming from the other person. In therapy, this type of behavior enables the therapist to watch the client and to pick up emotion and thought cues from the client's face and body. Therapists also show that they are paying attention to clients by taking the time to sit down and talk with them (Figs. 15-1 and 15-2). Verbal and non-verbal attentiveness has been found to be positively associated with client disclosure about the subjective experience of illness (Duggan & Parrott, 2000), participation in occupational therapy (Feinberg, 1992), client satisfaction (Hall, Roter, & Katz, 1988), and occupational performance outcomes (Ambady et al., 2002).

Paying attention to a client goes beyond conducting a standardized evaluation, and it goes beyond physical attention. It requires listening carefully to what the client has to say about his or her life, the illness, and the experience of intervention (Crepeau, 1991; Kleinman, 1988; Padilla, 2003) and remaining open to changing one's own therapeutic ideas in response to what is heard (Rosa & Hasselkus, 2005). Without this kind of attentiveness, the therapist may apply a "cookbook" intervention that is not individualized to the needs of the client, as happened to McCrum (1998) during rehabilitation following a stroke. During therapy, McCrum felt like a 3-year-old child playing with letters of the alphabet:

Figure 15-1 Mutual attentiveness by therapist and client forms the basis for effective communication and the development of a successful working relationship.

Figure 15-2 The therapist who is distracted by time pressure or other concerns loses the interpersonal connection with the client.

"Sitting in my wheelchair with my Day-Glo letter-blocks I could not escape reflecting on the irony of the situation. If only Milan Kundera, Kazuo Ishiguro, or Mario Vargas Llosa, whose texts I had pored over with their authors, could have seen their editor at that moment!" (p. 139)

Simple tabletop activities in and of themselves are not at fault here. They can be exactly what a particular client needs although in this case, they apparently were not. Therapists usually are well intentioned, but unless their intentions are consistent with what the client perceives to be important, they may be less than beneficial. Reflecting upon her hospital experiences as a child with spina bifida, Saxton (1987) considered the saddest aspect of her experiences to be that so many practitioners were trying to help her, yet:

"They never asked me what I wanted for myself. They never asked me if I wanted their help. . . . I just wish all disabled children would say to their helpers: 'Before you do anything else, just listen to me.'" (p. 55)

Craig (1991) described how her husband's nurse, during each home visit, listened and heard:

"[S]he began by listening. And anything Ed wanted to tell her was relevant. She let him tell her, in his own way and in his own time, about everything that was happening to his body. And in that way, she came to know his soul." (p. 241)

Client Concentration and Attentiveness

Therapists need attention from their clients as well. A client who does not attend to the therapist cannot give or get important information from him or her. Many pathological

conditions (e.g., traumatic brain damage) affect the ability to concentrate and pay attention to others, including the therapist. In addition, clients who feel anxious and thus avoid eye contact (Baker & Edelmann, 2002; Bernieri et al., 1996) may not be able to engage attentively with a therapist.

Clients may be more involved and attentive when they value their therapy than when they do not value it. McCrum (1998), quoted earlier, did not find value in the form of his therapy, particularly in juxtaposition to his occupation as an editor for brilliant writers. Unfortunately, it appears that the therapist did not engage the client collaboratively in the determination of intervention activities. Despite strong collaborative values and ethics in occupational therapy, research finds that therapists often fall short of fully and collaboratively involving clients and their families in decision making (Brown & Bowen, 1998; Hasselkus, 1991; Northern et al., 1995; Rosa & Hasselkus, 2005).

Therapist Communication and Interpersonal Coordination

It is impossible for even the most attentive therapist to apprehend and feel exactly what the client feels about his or her own illness and life. Likewise, the client cannot fully comprehend the personal experience and role obligations of the therapist. Each is a unique individual with a unique life history and perspective. Despite these differences, the therapist and client can teach each other their personal perspectives through **verbal** and **nonverbal communication** (Crepeau, 1991; Padilla, 2003).

The fundamental condition for the therapist to communicate effectively with the client is for the therapist to direct her attention toward the client. The next step is for the therapist to *interpret* accurately the client's verbal and nonverbal behavior (Tickle-Degnen & Rosenthal, 1992; Tickle-Degnen & Lyons, 2004). This interpretation process involves first the observation of how another person has behaved, and then the translation of this observation into an inference about the other's thoughts and emotions (Fig. 15-3). Svidén and Säljö (1993) found that, over 18 months, the impressions of occupational therapy students about clients became increasingly complex. For example, at a student's first viewing of a client's videotaped behavior, her impression consisted of the following seven words: "It was rather difficult for her psychologically" (p. 495). That same student's impression 18 months after beginning her training consisted of at least 71 words. It included a description of the client's gaze and vocal behavior and conjectures about the feelings the client may have had, such as hopelessness, confusion, lack of happiness, and embarrassment. By this second viewing, the student had a better articulated and more complex impression of the client and, as a result, would have been able to engage in a more effective dialogue with the client to confirm or refute elements of the impression.

Figure 15-3 The client's backward lean may indicate that she is withdrawing from the therapist or from the information the therapist is giving her. The therapist must determine whether or not the client's behavior is a sign of withdrawal and then whether to adjust her own behavior to maintain rapport. This therapist may decide to become less confrontational, relaxing her posture and making less intense eye contact.

Therapists rapidly form impressions of a client's emotional and social attributes, and these impressions can be accurate or inaccurate (Lyons et al., 2004; Tickle-Degnen & Lyons, 2004). Accuracy can be enhanced if the client gives feedback to the therapist about the accuracy of the therapist's impressions (Marangoni et al., 1995). If the client cannot give verbal feedback to the therapist about the accuracy of the therapist's interpretations, the therapist may be able to learn what the client is feeling simply by reflecting on what the therapist's own emotions are. More than likely, what the therapist feels is very similar to what the client feels because the therapist and client unconsciously and subtly coordinate their bodily and facial movements to one another (Bernieri & Rosenthal, 1991; Dijksterhuis & Bargh, 2001) and literally feel their way into one another's emotions (Hatfield, Cacioppo, & Rapson, 1994). For example, while working with a client, a therapist may develop a stooped posture through a subtle mimicry of the client's behavior. The therapist may begin to have a feeling of dejection in response to the client's own bodily pattern of dejection. Typically, individuals are unaware of the degree to which another person's emotions influence their own and, consequently, do not reflect on their own emotions to discover what another person's are. Yet if therapists are aware of the possibility of this form of emotional influence, they may more accurately detect the unspoken emotions of clients.

After accurate interpretation of a client's message, the next step in effective communication is for the therapist to *express* her own emotions and thoughts in a manner that is clear to and beneficial for the client (Tickle-Degnen & Rosenthal, 1992; Tickle-Degnen & Gavett, 2003). When a therapist feels positive, hopeful, and engaged in treatment

Figure 15-4 The therapist and client show mutual positivity through their facial expressions and physical contact. Social physical contact, like holding a client's hand, is appropriate if it is an expression of professional warmth and the client gains comfort from it. Not all clients like being touched in this manner.

and is expressive of these feelings in an unambiguous manner, clients tend to have similar reactions and respond favorably (Fig. 15-4) (Ambady et al., 2002; Di Blasi et al., 2001; Hall, Harrigan, & Rosenthal, 1995). Nonverbal messages are typically conveyed more rapidly than verbal ones (Ambady, Bernieri, & Richeson, 2000), and they are usually conveyed unconsciously (Lakin & Chartrand, 2003). Watt (1996), a man in severe pain, described his favorite nurse:

"I believed she would make things better. It was never anything she said. It was something in her face." (p. 13)

The combination of verbal and nonverbal behavior that the therapist uses to express his or her feelings and attitudes toward the client can be profoundly moving for the client. Brack (Brack & Collins, 1981), a woman with multiple sclerosis, described how her physical therapist conveyed a sense of compassion and hope after a long period of hard work but little progress in therapy. As Brack was waiting for therapy in a line of wheelchairs, she could not suppress her tears of despair and shame at not being able to regain her ability to walk. Her therapist quickly pulled her chair out of the line and wheeled it down to the therapy office, where together they wept:

"Our eyes met. 'Do you want to quit?' [the therapist] said. 'I know it's tough and you know you may never get any better. But shall we try a little longer?' Right away I knew I had to. I smiled damply and dried my eyes. What a friend!" (pp. 71-72)

The therapist in this example does not simply say, "Keep trying, I know you can do it." Because she had

worked with this client for a long time, she could express her understanding of the client's feelings in a heartfelt and intimate manner, by weeping with the client. Brack continued her description by explaining how she and her therapist kept working at the parallel bars, never giving up. Eventually she was able to walk again. This example demonstrates that effective communication occurs not only through verbal and nonverbal behavior but also through the activities in which the therapist and client engage. The act of engaging in therapy, even when it seems that hope is lost, is a message to the client that hope is *not* lost.

Likewise, messages are conveyed through the tools that occupational therapists offer their clients. When an occupational therapist gives a buttonhook to a client, several messages are offered; among these messages is that the client is capable of using a buttonhook and that dressing independently is a valued goal of the client. In high-rapport and effective interactions, the client is aware of the goals of the interaction, feels control during the interaction, and feels that the therapist has an empathic understanding of the client's thoughts and feelings (Greenberg et al., 2001; Martin, Garske, & Davis, 2000; Tickle-Degnen & Gavett, 2003). Thus, the performance of activities that are clearly consistent with the client's goals communicates that the therapist understands the client's perspective, and the client may respond with renewed energy and engagement in therapy. Hanlan (1979), a man with amyotrophic lateral sclerosis, wanted to maintain his daily functioning:

"Of increasing importance to me is the help of occupational therapists. . . . My first OT, a man with a direct and kind manner, provided me with a buttonhook, so I could button and unbutton my clothing. I had an almost child-like, happy response to discovering this little tool." (p. 40)

Client Communication and Interpersonal Coordination

Some clients cannot accurately interpret a therapist's social behavior. Individuals with brain damage, particularly in the right hemisphere, have difficulty perceiving and interpreting social nonverbal cues (Brozgold et al., 1998). Among individuals with left hemispheric damage, those with a receptive form of aphasia may be unable to understand the therapist's speech. It is difficult for clients with these types of problems to make sense of the therapist's social overtures and respond appropriately to them. For clients who have interpretation difficulties, the therapist must make frequent and multimedia attempts to communicate (Tham & Kielhofner, 2003). For example, the therapist can express information verbally, nonverbally, in writing, and in picture form.

Likewise, problems of expression could interfere with the development of rapport. Right brain damage and Parkinson's disease have been found to interfere with an individual's ability to nonverbally express interpretable emotions to others (Brozgold et al., 1998; Tickle-Degnen & Lyons, 2004). DeGroat, Lyons, and Tickle-Degnen (2006) found that people with Parkinson's disease appear to be able to express verbally their emotions and preferences quite well during an interview about meaningful activities (Research Note 15-1). Clients with an expressive aphasia, however, may have difficulty communicating verbally their thoughts and needs and may need to rely on nonverbal gestures. For clients in general, it is wise for the therapist to seek information from multiple communication channels, such as through the verbal, facial, and bodily behavior of the client.

Therapist Enjoyment and Positivity

Individuals who are genuine and openly expressive inspire cooperative effort and trust, whereas those who hold back and are indifferent inspire disengagement and distrust (Boone & Buck, 2003). In the therapeutic encounter, the expression of positive feelings and warmth is particularly important. A study of occupational therapy students found that those who tended to express negative feelings, as opposed to those who tended to express positive or neutral feelings, had less rapport with their colleagues and were rated as being less clinically skilled by fieldwork supervisors (Tickle-Degnen & Puccinelli, 1999).

Practitioners may express their warmth and liking through a variety of nonverbal behaviors, such as leaning forward and smiling (Fig. 15-4). Clients interpret these and other types of friendly verbal and nonverbal behavior as positive (Ambady et al., 2002) and respond with increased follow-through with intervention regimens (Feinberg, 1992) and with more successful occupational performance (Ambady et al., 2002) and health outcomes (Di Blasi et al., 2001).

Peloquin (1993a) has eloquently described how health professionals can act in a manner that distances rather than connects them to their clients and saps their clients' courage. Beisser (1989), a man with polio, found that his dependency on hospital attendants for physical survival had a profound effect on his day-to-day view of himself and the world:

“Everything that affected them affected me. If I was cared for willingly and without reluctance, I felt good and the world was sunny. If my care was given grudgingly or irritably, in a callous way, powerful feelings of degradation swept over me.” (p. 34)

In Beisser's experience (1989), the helpers who enjoyed their work and were nurtured by their relationships with clients were most effective. With them, Beisser felt human

RESEARCH NOTE 15-1

Abstract: DeGroat, E., Lyons, K. D., & Tickle-Degnen, L. (2006). Verbal content during favorite activity interview as a window into the identity of people with Parkinson's disease. *Occupational Therapy Journal of Research: Occupation, Participation, and Health* 26, 56–68.

Abstract

The purpose of this study was to document the degree to which a brief segment of an occupational therapy interview about favorite activities served as a window into personal identity and experience in clients with Parkinson's disease. Two-minute segments of videotaped interviews of 12 participants with Parkinson's disease were transcribed and analyzed. The results indicated that the favorite activity interview served as a window primarily into the socio-emotional identity of the client. Client extraversion was positively correlated with the mention of social activities and activities occurring in the public domain; positive affect was positively correlated with the positive tone of the verbal content, as well as the number of positive words spoken during the interview, and negative affect was positively related to the negative tone of words.

Implications for Practice

- Client's preferences, feelings, and personality are quickly expressed during an interview about favorite activities.
- For example, a person who is extraverted and sociable, but who may not seem sociable in his or her nonverbal behavior, may talk about a favorite activity that is done with other people, while a person who is more introverted may talk about a solitary activity.
- It is important not to infer that clients are sociable or solitary, or have positive or negative feelings, based upon their interpersonal styles if they have nonverbal expressive disorders.
- When clients have nonverbal expressive disorders such as Parkinson's disease, therapists may be able to get to know the client by listening to the content of the client's words rather than focusing on the client's nonverbal behavior, such as facial expressions and bodily posturing.

again, able to reciprocate their warmth and concern. The body of evidence on therapeutic rapport suggests that connecting to clients in a respectful and positive manner, per the seminal work of Carl Rogers (1957), contributes to therapeutic effectiveness. The reverse is true as well: being effective contributes to a feeling of connectedness with clients (Rosa & Hasselkus, 1996, 2005).

What may be most important in therapists' expression of positivity toward clients is the genuine feeling and

communication of concern and caring (Peloquin, 2002). For example, Ambady et al. (2002) found that therapist nonverbal behavior that was more expressive and concerned, including both more smiling and frowning, predicted better outcomes for geriatric clients. Genuine feelings are not necessarily uniformly cheery and positive. Tickle-Degen and Gavett (2003) found that moderate levels of positivity were more characteristic of speech therapy dyads with secure therapeutic alliances, whereas very high or very low levels of positivity were more characteristic of dyads with insecure alliances.

It is not easy to achieve a high level of concern and caring in today's health care system, which emphasizes cost containment and adherence to protocol and provides little recognition for caring involvement (Peloquin, 1993b; Sachs & Labovitz, 1994). A supportive system composed not only of the therapist's personal commitment to caring but also of a societal and institutional commitment to caring are needed to sustain a therapeutic level of caring.

Client Enjoyment and Positivity

Clients who are very anxious or depressed demonstrate relatively little warmth nonverbally. For example, they smile infrequently and make little eye contact. Practitioners, especially those who are inexperienced and unlikely to interpret this behavior as a normal response to illness or a sign of disease, may take personally this lack of warmth by some clients (Rosa & Hasselkus, 2005).

Misery from illness may encompass the client's life, reducing the ability to respond warmly to others. As Brack, who was suffering from multiple sclerosis, noted:

“Thanks’ is a near-forgotten word among us clients as we wallow in our private miseries.”
(Brack & Collins, 1981, p. 47)

From an ethical and professional standpoint, practitioners are expected to rise above petty responses to unpleasant behavior in clients, but unfortunately, they may begin to resent those that they are supposed to help (Rosa & Hasselkus, 2005).

For example, Beisser (1989) found that his helpers on the polio ward had a powerful form of retribution for clients who were thought to be difficult:

“You cannot get mad in hospitals. If you do, you may be in trouble. . . . Angry clients come last. So I quickly learned to smile patiently. . . . I had to be careful, for they were more in control of my body than I was.” (p. 19)

Even practitioners who do not engage in this form of retribution may find it hard to work with a client who lacks warmth and happiness. Schindler, Hohenberger-Sieber, and Hahlweg (1989), for example, found that during a first

therapeutic encounter, the more frequently clients gave reports of success and the less frequently they merely described their problems, the more positive the therapists felt. Rosa and Hasselkus (2005) similarly found that both novice and expert occupational therapists preferred clients who were enthusiastic and ready participants in therapy. These therapist responses may have unfortunate effects on a client who is feeling poorly. Research suggests that creating a climate in which a person must suppress negative emotions, as what Beisser (1989) experienced in the hospital, actually impairs rapport and increases the blood pressure of both interaction partners (Butler et al., 2003).

In occupational therapy, clients may have strong negative reactions to the frustrations of trying to perform what they perceive to be simple tasks (Darragh, Sample, & Krieger, 2001). Puller (1991), a Vietnam veteran with bilateral upper extremity amputations, reports:

“There were times in OT when I felt like screaming as I tried to learn how to button clothes or to thread a needle.” (p. 181)

Such frustration is bound to impinge on the client's view of therapy and the therapist, and it should not be ignored. The therapist may have to reevaluate the balance of the emotional costs and physical benefits of particular forms of activity and to confirm that these activities support the client's own goals.

Evidence suggests that practitioners must be careful not to view all expressions of frustration, sadness, or anger as confirmation of pathology (Langer & Abelson, 1974). For example, Widome (1989) described how a nurse responded to an emotional outburst that apparently was Widome's expression of anger at being in the horrible predicament of having cancer. As Widome was walking down a hospital corridor, the nurse asked him how he was feeling:

“I let loose with a tirade of words. . . . Wouldn't she prefer no life to a thread of existence? . . . The nurse made a notation on my chart that I had made a decision to end my life, that I was considering self-destruction. I was now a marked man—suicidal.” (pp. 99-100)

Expressions of frustration and anger may be indeed be signs of a pathological process that requires diagnosis, or they may be normal responses to the experience of illness and intervention.

BENEFICIAL EFFECT AND HIGH THERAPEUTIC RAPPORT

Listed next are three of the possible reasons attentive, coordinated, and positive client-therapist interactions may

have a beneficial effect on the client's performance and follow-through with intervention:

1. The interaction provides the external scaffolding necessary for skill development by directing attention to important aspects of a task problem, by communicating the information necessary to solve the problem, and by giving motivational support for pursuing problem solution (Tham & Kielhofner, 2003; Tickle-Degnen, 2006; Tickle-Degnen & Coster, 1995).
2. The interaction improves physiological and emotional health, thus enabling individuals to focus energy and effort on occupation. Evidence is accruing that an individual's health is a mind-body-social dynamic (e.g., Di Blasi et al., 2001). Rapport involves bringing the therapist and client together in a close and meaningful relationship. The health effects of positive therapeutic relationships, including direct effects on immune and physiological functioning and indirect effects on adherence to health interventions, appear to be very similar to health effects of social support provided by positive familial relationships (DiMatteo, 2004).
3. The interaction creates a self-fulfilling prophecy of improved performance (Ambady et al., 2002; Harris & Rosenthal, 1985). Through verbal and nonverbal communication, a therapist conveys his or her expectations for the progress of a client, with the effect that the client's actual performance conforms to those expectations. Informative, warm, and respectful behavior may affirm to the client that he or she is a capable and valued human being, which mobilizes the client's psychological and physical resources toward fulfillment of those qualities.

DEVELOPMENT OF A HIGH THERAPEUTIC RAPPORT RELATIONSHIP

All relationships take time to develop. Yet evidence suggests that the critical development of rapport and a working alliance, that is, the experience of working collaboratively toward mutually agreed upon goals, is achieved within the first three to five sessions of therapy (Horvath & Luborsky, 1993; Tickle-Degnen & Gavett, 2003). First meetings tend to be somewhat superficial and rigidly constrained by role expectations. The therapist most likely performs an evaluation, and the client most likely tries to answer the questions or perform the activities of the evaluation. Through close adherence to cultural scripts of friendly, polite behaviors, they offer their identities to one another as valuable and likable (Clark, Pataki, & Carver, 1996).

In the first meeting, the client may convey private information to the therapist, but the depth of intimacy and mutuality continues to grow over subsequent interactions, although not in a linear fashion (Altman, 1993). A dialectical tension between the desires for intimacy and autonomy appears to manifest itself in a cyclical pattern of intimate and more distant behavior. After the first few therapeutic encounters, there appears to be a period of much fluctuation in the nature of the interpersonal interaction (Tickle-Degnen & Gavett, 2003), as if client and therapist are trying out different patterns of relating to one another. It also may be that these fluctuations are a result of shifts between therapeutic work and socializing. There is evidence that the grueling, attentive, task-focused work of therapy requires off-task periods of rest and recovery with opportunities for chit-chat. This chit-chat may serve to affirm the social connection between therapist and client (Hall, Roter, & Milburn, 1999).

Relationships that endure, whether they are personal or therapeutic, seem to have one primary attribute in common: the ability to control and manage the development of emotions, especially negative ones (Gottman, 1994). Although individuals in both successful and failing relationships have negative emotions and behavior, in successful relationships, people have interpersonal strategies for rapidly repairing the hurt or negative consequences of these emotions and preventing an escalation of negativity. In failing ones, the individuals are unable to curtail this escalation.

Therapists' and clients' characteristics and conditions in the therapy setting can facilitate or inhibit the development of high rapport. One study (Tickle-Degnen, 1998) found that occupational therapy students who were quiet and empathically concerned attained the highest supervisory ratings in physical rehabilitation settings. Different attributes appeared to be needed in other types of settings. These results suggest that therapists must adapt their interpersonal styles to different therapeutic contexts. Through self-reflection; feedback from supervisors, colleagues, and clients; and reflective clinical experience, the therapist should be able to learn how to make these adaptations.

Based on the evidence presented here, Procedures for Practice 15-1 gives guidelines for enhancing the development of rapport. It is not the client's responsibility to change to enhance the rapport; it is the therapist's. Therefore, the guidelines are directed at actions the therapist can take.

Typically, therapeutic relationships work toward a planned end to the relationship as goals are achieved or services are no longer needed. As discharge approaches, the therapist should work actively with the client to transform their relationship appropriately, so that the client does not feel abandoned (e.g., Clark, 1993; Klein,

PROCEDURES FOR PRACTICE 15-1

Therapist Guidelines for Facilitating the Development of High Therapeutic Rapport Create Conditions that Maximize Therapist's and Client's Concentration and Attention

1. Set aside time to listen to client.
2. Reduce distractions in therapy setting.
3. Reduce potential for client's embarrassment or anxiety.
4. Position own body to see and hear client clearly.
5. Position client so that client can see and hear therapist clearly.
6. Listen for issues that are most important to client.

Create Conditions that Maximize Therapist and Client Masterful Communication and Interpersonal Coordination

1. Remain open and sensitive to verbal and nonverbal messages from the client.
2. Provide assistance as needed for the client to express emotions and thoughts.
3. Check with the client to see whether therapist's interpretation of client's messages is accurate.
4. Clearly express emotions and thoughts that are consistent with the needs and goals of the client.
5. Check with the client to see whether the client is interpreting the therapist's messages accurately.
6. Create a challenging and interesting interaction, but one in which the client can interact skillfully.
7. Involve the client collaboratively in the development of goals and the planning of intervention.

Create Conditions that Maximize Therapist and Client Enjoyment and Positivity

1. Find a satisfying, fulfilling aspect to every interaction with a client.
2. Express genuine concern and caring for the client through verbal and nonverbal behavior.
3. Resolve personal problems and fulfill personal social needs outside of the client–therapist interaction.
4. Determine whether client's sadness or anger is normal or pathological, and respond appropriately to alleviate suffering.
5. Engage client in activities and interactions that are inherently enjoyable for the client.
6. During required activities that are not enjoyable, provide periodic opportunities for rest and off-task recovery.
7. Manage negativity so that it can be expressed as needed in a constructive manner and does not escalate.

1995). The form this transformation takes depends on the setting. For example, the therapist may help the client to develop other fulfilling relationships in the community or may keep in contact with the client through the phone or occasional clinic visits.

ETHICS AND THE THERAPEUTIC RELATIONSHIP

The Occupational Therapy Code of Ethics (American Occupational Therapy Association, 2005) outlines the key ethical elements of the therapeutic relationship. The ethical principles covered here are the ones most relevant to the therapeutic relationship.

Principle 1

Occupational Therapy Personnel Shall Demonstrate a Concern for the Safety and Well-Being of the Recipients of Their Services

A key element of this principle is that therapists must provide services in an equitable manner to all individuals. A therapist may have fears or negative attitudes about a particular client population, for example, such as individuals with AIDS (Hansen, 1990). Despite these feelings, it is the ethical imperative of therapists to provide services.

Although there is no ethical imperative to feel rapport with clients, the imperative to demonstrate a concern for the well-being of the recipient of services suggests that the therapist should make every effort to create a climate of therapeutic rapport. As a therapist works to create rapport, it is important that the therapist realize that his or her own beliefs about what is important for well-being and occupation are not necessarily equivalent to the beliefs held by the client, especially clients from different cultures (Iwama, 2003).

Principle 2

Occupational Therapy Personnel Shall Take Measures to Ensure a Recipient's Safety and Avoid Imposing or Inflicting Harm

The therapist should consider changing jobs or clinical specialization if he or she is unable to overcome negative feelings with clients typically seen in a particular setting or specialization area. Negative feelings may result in negative outcomes for the client. If the therapist has made an honest but unsuccessful attempt to support high therapeutic rapport, he or she may consider refer-

ring the client to a different therapist, perhaps one that is a specialist in such cases (Rosa & Hasselkus, 2005).

Another element of this principle is that therapists must maintain relationships that do not exploit the client sexually, physically, emotionally, financially, socially, or in any other manner. Mutuality of feeling, behavior, and goals is critical to the development of a relationship of high therapeutic rapport; interdependency or the expectation of reciprocal benefits, however, is not. The therapist who becomes dependent on a client for meeting a personal need is exploitive because of his or her higher power relative to the client's position of vulnerability. Furthermore, although the therapist is ethically responsible for helping the client, the client is not expected to help the therapist in any manner.

Principle 3

Occupational Therapy Personnel Shall Respect Recipients to Assure Their Rights

One element of the third ethical principle is autonomy. Respect for the client's autonomy requires therapeutic relationships in which clients collaborate to the best of their ability in the determination of goals and priorities during intervention. For clients to be able to collaborate, they must be informed about the nature, risks, and potential outcomes of the intervention and have the opportunity to suggest, reject, or refuse services or elements of services. This standard is both ethical and consistent with the nature of therapeutic rapport and the effective working alliance. Collaborative decisions are carried out not because of external pressures but because of an active feeling of personal control and responsibility (Fig. 15-5).

Other elements of this principle are privacy and confidentiality. During a relationship of high therapeutic rapport, the client may tell the therapist about matters that are private and confidential. The therapist must protect the confidentiality of information by not discussing it in an inappropriate context (for example, in a public elevator conversation) or manner (for example, laughing at the client's capabilities) with a colleague or any other person.

Principle 4

Occupational Therapy Personnel Shall Achieve and Continually Maintain High Standards of Competence

A relationship of high therapeutic rapport is a trusting one. The client trusts that the therapist is doing the best that

Figure 15-5 In a collaborative relationship, the therapist and client discuss the benefits and risks of participating in various occupational therapy interventions so that the client can make informed decisions about participating in these interventions.

can be done for him or her. It is the ethical responsibility of the therapist to uphold this trust by performing services competently. Part of this competence involves being able to critically examine current emerging knowledge relevant to practice and then being able to use this knowledge to engage the client in a collaboration based upon accurate information (Tickle-Degnen, 2000).

SUMMARY

High therapeutic rapport develops as the therapist and client are mutually attentive, coordinated to one another, and mutually positive. It is one mechanism by which the client achieves confident and competent occupational functioning. It supports the client's desire to try occupational therapy, to maintain continued involvement in therapy, and to participate with the therapist in constructing a new vision of life possibilities. Although rapport is based upon a perspective of mutuality and collaboration between client and therapist, it is the therapist's responsibility to manage oneself, guide the client, and modify the environment to support attentiveness, coordination, and positivity. Through self-reflection, feedback from others, reflection about clinical practice, and careful adherence to ethical standards, the therapist can learn to facilitate therapeutic rapport with a variety of clients in a variety of practice settings.

CASE

EXAMPLE

Establishing Rapport with a Reluctant Client

Occupational Therapy Intervention Process

Client Information

Mrs. K., a 75-year-old woman (widowed) with Parkinson's disease, was referred to the adult day program by her physician and her children who were concerned about her social isolation and reluctance to do basic grooming and self-care despite the physical and cognitive capacity to do so. The diagnosis of depression was ruled out. Mrs. K. moved slowly with a rigid, shuffling gait, had the facial mask of Parkinson's disease, and had bilateral tremor in her hands. Mrs. K. stated to the occupational therapist that she did not want to attend the program but was trying it out only because of her children's desires. Her favorite activity was to visit with her grandchildren and her best friend, Jane, yet she rarely visited them. On a health-related quality of life measure designed for people with Parkinson's disease, Mrs. K. identified that she felt stigmatized by her movement disorder and would prefer to stay home rather than let others see her, even friends and family. The assessment process identified that she had not learned compensatory strategies for handling the community and social aspects of the symptoms of Parkinson's disease.

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Appreciate the context

"Since Mrs. K. did not have cognitive or emotional impairment, I expected that she would be able to reflect upon and discuss her occupational functioning. To understand her limited functioning, it was important to hear and understand her perspective. The quality of life assessment procedure was appropriate for eliciting her reflection and generating a client-centered discussion."

Develop intervention hypotheses

"Mrs. K's social isolation and self-care issues may be related specifically to the stigmatizing aspects of the movement disorder of Parkinson's disease. I can't tell from her affect what interests her, and probably other people in her life can't either. Her eyes rarely move, there is little expression around the mouth, and her responses are slow to come, making it difficult to carry on an easy conversation with her. It seems that she doesn't like me, but that might be due to the effect of the disease on her ability to smile and be physically expressive. She appears to be engaged with me when talking about stigma and how to reduce it. Her verbal behavior tells me that she has the capacity to express interest and engagement."

Select an intervention approach

"I find that I can engage Mrs. K's interest through my eye contact and body positioning. I'll try to keep an unconditional positive and concerned feeling toward her and be my usual expressive self. It is necessary to establish a strong therapeutic alliance as a basis for gaining her commitment to examining and working on her occupational functioning. To establish this alliance, I must collaborate with Mrs. K., establish an affective bond, and work with her toward developing mutually acceptable intervention goals and tasks."

Reflect on competence

“I have not worked with many clients with Parkinson’s disease. I see that there may be many stigmatizing aspects to this disease. Mrs. K. is teaching me new things about what it is like to live with the disease.”

Recommendations

Because of a high risk of Mrs. K. refusing intervention, the occupational therapist suggested to Mrs. K. that they meet once per week for 3 weeks to get to know one another better before starting the day program. The immediate goal was to establish rapport and a strong working alliance, after which the therapist and Mrs. K. could address directly her occupational functioning needs.

Consider the patient’s appraisal of performance

“Mrs. K. is willing to meet with me for no more than three weekly 1-hour sessions before deciding about whether or not to participate in the day program. I plan to meet with her in an area where she can see what other participants in the program are doing. I believe that if she became familiar with the day program in a non-pressured manner, she might start to see how it might be helpful for her.”

Consider what will occur in therapy, how often, and for how long

Ascertain the patient’s endorsement of plan

Summary of Short-Term Goals and Progress

1. *Mrs. K. and the therapist will complete a task that is mutually interesting to one another.*

The therapist and Mrs. K. each completed an interest checklist and then discussed their responses with one another. They noted five mutual interests, one being an interest in poetry. They each brought a favorite poem to the following session to read to the other. At the end of the task, both agreed that they found the task interesting and then selected another task to do with one another in the following week.

Assess the patient’s comprehension

“Mrs. K. has come to every scheduled session. It has gotten easier to work with her as I have learned what cues indicate that she is happy, sad, angry, or frightened. Her positive attributes are easiest to see whenever we discuss or do things related to her favorite activities and interests. Mrs. K. appears to understand my role and the tasks involved in intervention. She responds positively to clear explanations and my undivided attention.”

Understand what she is doing
Compare actual to expected performance

2. *Mrs. K. and the therapist will have decided mutually upon one goal of intervention by the end of the third session.*

The therapist and Mrs. K. ended each session with discussing and writing down two possible goals of intervention. Tentatively they selected one potential goal by the end of the third session: the reduction of stigma associated with eating a meal in a restaurant. Mrs. K. did not see this goal as the one that she wanted to make a commitment to achieving as of yet.

Know the person

“I think her reluctance to attend the program is partly because she has not recently practiced socially interacting with her peers and, as a result, has not had the experience of seeing that others accept her despite the symptoms of Parkinson’s disease.”

Appreciate the context

3. *Mrs. K. and the therapist will have at least one positive experience during each session.*

The therapist and Mrs. K. agreed to try to do something that made them feel good or happy at least once during each session. They would assess their achievement of this goal during each session. At each session, they identified several times during which they experienced positive feelings. Therapeutic rapport was developing in a satisfactory manner by the third session. Mrs. K. continued to be reluctant to make a commitment to attend the day program but agreed to try it out for an additional 4-week period at two half-day sessions per week.

Next Steps

Revised short-term goals:

1. *Mrs. K. will express interest in participating in a group activity on identifying goals for daily living.*
2. *Mrs. K. will communicate about her ideas with the group members.*
3. *Mrs. K. will have a pleasant social interaction with at least one of the other group members.*

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if he or she should continue or discontinue therapy and/or return in the future

“I feel that Mrs. K. and I have developed a good rapport with one another and that now she understands she may be able to participate in friendly interactions with other people. She is ready to try a group activity in the day program. I must prepare for the possibility that Mrs. K. will decide not to continue the program after 1 month. I will discuss her concerns about the day program with her family and physician to determine how best to support her involvement in goal setting and to determine what alternatives are available for helping Mrs. K. to participate fully in her life activities.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****When to Refer to Another Therapist**

The therapist suspects that one reason that Mrs. K. does not want to be involved in the day program is because the therapist is of a different ethnicity than that of Mrs. K., who seems to have a negative attitude toward the therapist's ethnic group. How should the therapist attempt to deal with this possibility? What can be done to promote rapport? At what point and under what conditions should the therapist attempt to refer the client to another therapist or program?

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****An Ethical Dilemma**

Mrs. K. refuses involvement in the day program despite the therapist's, the family members', and the physician's encouragement for her to participate. What should the therapist do? What is the therapist's ethical responsibility? How will the therapist's decision affect the therapeutic relationship with Mrs. K.?

Evidence Table 15-1 Best Evidence for Occupational Therapy Practice Regarding Therapeutic Rapport

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Therapeutic alliance	A therapeutic relationship characterized by: (1) client-therapist collaboration; (2) affective bond; and (3) shared understanding of therapy goals and tasks to achieve the goals. Construct of therapeutic alliance grew out of client-centered approach in psychotherapy and is consistent with current client-centered occupational therapy approach.	4771 clients (66% females) primarily from psychiatric populations. One study involved a head trauma population (Prigatano et al., 1994).	Average of 22.18 sessions (SD = 18.76).	Meta-analysis of 79 studies.	Yes. Clients who have stronger alliances with their therapists have better therapy outcomes than clients who have weaker alliances.	Mean weighted effect size was $r = 0.22$, equivalent to a 22% success rate over control treatment.	Martin, Garske, & Davis, 2000

<p>Therapeutic non-verbal behavior</p>	<p>Physical therapist (PT) distancing behavior (not smiling, looking away, and remaining seated) during a single therapy session with each client, an indicator of consistent therapist behavior toward each client.</p>	<p>28 female and 20 male inpatients who were 75 years of age and older with mobility disorders, and 8 female and 3 male PTs.</p>	<p>Average of 9.3 days of inpatient therapy.</p>	<p>Correlational design (IIB3a) in which amount of PT distancing behavior was used to predict change in patient physical and cognitive functioning from admission to discharge and from admission to 3 months post intervention. Also was used to predict psychological functioning at discharge only (no change measured). Other behaviors besides distancing were measured. Distancing had some of the most consistent findings.</p>	<p>Yes. The less distancing the PT behavior, the greater the positive change in activities of daily living (ADL), the greater the reduction of confusion, and the less depression at discharge. There was little association with mobility. Similar findings were seen for the admission to 3 months post intervention period. Confounding is an alternative explanation: e.g., perhaps patients with less potential for change create a difficult communication context for PT.</p>	<p>Admission to discharge: ADL (Physical Self-Maintenance Scale), $p < 0.001$, $r = -0.34$; confusion (blinded interviewer judgment), $p < 0.05$, $r = 0.29$; mobility (Mobility Assessment Scale), $p > 0.05$, $r = 0.02$; correlation with discharge: depression (Geriatric Depression Scale), $p < 0.05$, $r = -0.27$.</p>	<p>Ambady et al., 2002</p>

SUMMARY REVIEW QUESTIONS

1. What are the elements of high therapeutic rapport?
2. How has the view of the client-therapist relationship changed over time?
3. How are the therapist's experience and behavior related to rapport?
4. How are the client's experience and behavior related to rapport?
5. What are three reasons high rapport may be beneficial for clients?
6. How can the therapist facilitate the development of high therapeutic rapport?
7. What are two ethical responsibilities that a therapist holds in a relationship with a client?

ACKNOWLEDGMENTS

The ideas in this chapter evolved during a Mary Switzer Research Fellowship supported by the National Institutes for Disability and Rehabilitation Research. A special thanks to Irene Zombek and Melissa Muns, who searched clients' autobiographies for excerpts. The photographer for this chapter was Robert Littlefield.

SECTION IV: Therapeutic Technologies

CHAPTER 16

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Define and discuss key concepts and terms related to orthoses.
2. Identify major purposes for using orthoses.
3. Explain general precautions relative to the use of orthoses.
4. Identify key factors to consider when selecting the most appropriate orthosis.
5. Given a photograph or illustration, identify the orthosis and a clinical problem for which it may be used.
6. Select an appropriate orthosis for a given diagnosis based on a specific clinical need.

Upper Extremity Orthoses

Lisa D. Deshaies

Glossary

Glossary

Arm sling—An orthosis that supports the proximal upper extremity to restrict motion, reduce pain, or prevent or reduce shoulder subluxation.

Arm trough—An upper extremity positioning device attached to a wheelchair armrest.

Dynamic splint—Orthosis that has moving parts; primarily used to regain joint mobility or facilitate function.

Lapboard—A portable tabletop that is applied to a wheelchair to provide a working surface or support an upper extremity; also known as a lap tray.

Mobile arm support—A mechanical device that uses ball-bearing joints, gravity, and possibly rubber bands to support the arm and assist in movement when proximal muscles are weak; may be mounted onto a wheelchair or table; also known as a balanced forearm orthosis, ball-bearing arm support, or ball-bearing feeder.

Orthosis—Any medical device added to a person's body to support, align, position, immobilize, prevent or correct deformities, assist weak muscles, or improve function; also known as a splint, brace, or support.

Serial casting—Applying casts at routine intervals as range of motion improves, with the goal of restoring joint mobility.

Serial static splinting—Remolding or fabricating new static splints as range of motion improves, with the goal of restoring joint mobility.

Static splint—Orthosis that has no moving parts; primarily used to support, stabilize, protect, or immobilize.

Static progressive splint—Orthosis that uses non-dynamic forces; primarily used to regain joint motion.

Wrist-driven wrist-hand orthosis—Flexor hinge orthosis that uses tenodesis to accomplish palmar pinch.

Orthoses are often an integral component of occupational therapy for patients with physical dysfunction. Orthotics entails prescription, selection, design, fabrication, testing, and training in the use of these special devices.

Successful use of orthoses is made possible only through an integrated team approach including the patient, his or her significant others, and health care providers. Several rehabilitation professionals may bring their expertise to different aspects of the orthotic process. The physician typically prescribes the device. The certified orthotist is an expert in the design and fabrication of permanent orthoses, especially complicated spinal, lower extremity, and upper extremity orthoses used to restore function. The rehabilitation engineer is an expert in technical problem solving involving mechanical and/or electrical solutions to unique needs of patients.

The occupational therapist, as an expert in the adaptive use of the upper extremities in occupational performance tasks, has the major responsibility for the recommendation of appropriate orthoses, the testing and training in the use of orthoses for the upper extremities, and the selection, design, and fabrication of thermoplastic splints. Occupational therapists often collaborate with orthotists and rehabilitation engineers to solve problems encountered by patients in performing their occupations and activities of daily life. The therapist presents the parameters of the problem to these professionals in terms of the patient's abilities and limitations and the functional and psychological goals that the prescribed device should meet or allow. The orthotist or engineer then proposes technical solutions, and together they apply them to the patient and evaluate the outcome.

Finally, and possibly most importantly, the patient and caregivers bring key physical, psychological, social, and functional characteristics to the orthotic process and should be considered the primary members of the team. For the orthosis to be successful, all team members must work in close collaboration.

KINDS OF ORTHOSES

The numerous kinds of upper extremity orthoses vary according to the body parts they include, their mechanical properties, and whether they are custom made or prefabricated.

Classification Systems

An **orthosis** is any medical device applied to or around a body segment to address physical impairment or disability (Lunsford & Wallace, 1997). Orthoses may also be called splints; the American Society of Hand Therapists (ASHT) (1992) validated that the two terms may be used interchangeably. *Brace* and *support* are other commonly used terms for orthoses. One challenge when discussing orthoses is the lack of uniform terminology in the medical literature, which makes it difficult to compare and contrast features and outcomes when a single orthosis may be known by many names.

Before the 1970s, there was no standard system for classifying orthoses, and orthoses were identified by proper names or eponyms based on the place of origin or the devel-

oper. A classification system was later developed to describe orthoses using acronyms based on the major joints or body parts they include. For example, a thumb carpometacarpal (CMC) support is a hand orthosis (HO); a wrist cock-up splint is a wrist–hand orthosis (WHO); an elbow brace is an elbow orthosis (EO); and a complete support for an arm is a shoulder–elbow–wrist–hand orthosis (SEWHO) (Long & Schutt, 1986; Lunsford & Wallace, 1997). Each classification may contain several types of splints. A wrist cock-up splint and a flexor hinge hand splint are both WHOs, although they serve different purposes.

To simplify, organize, and describe a standardized professional nomenclature, the ASHT developed the ASHT Splint Classification System in 1992. It classifies splints in terms of their function and the number of joints they secondarily affect. According to this system, a wrist cock-up splint is a wrist extension immobilization, type 0, because no other joints are affected. As this system becomes more widely accepted and used, it will likely serve as a universal language for referral, reimbursement, communication, and research.

This chapter uses the traditional or most commonly used names for the splints it describes.

Basic Types of Orthoses

Mechanical splint properties fall into three categories: static, static progressive, and dynamic (Colditz, 2002a; Wilton, 1997). The **static splint**, which has no moving parts, is used primarily to provide support, stabilization, protection, or immobilization. **Serial static splinting** can be used to lengthen tissues and regain range of motion by placing tissues in an elongated position for prolonged periods (Bell-Krotoski, 2002; Colditz, 2002a). With this process, splints are remolded as range of motion increases. Because immobilization causes such unwanted effects as atrophy and stiffness, a static splint should never be used longer than physiologically required and should never unnecessarily include joints other than those being treated.

Static progressive splints use nondynamic components, such as Velcro, hinges, screws, or turnbuckles, to create a mobilizing force to regain motion. This type of splinting, termed inelastic traction mobilization, offers benefits not available with serial static or dynamic splinting because the same splint can be used without remolding, and adjustments can be made more easily as motion improves (Fess et al., 2005).

Dynamic splints use moving parts to permit, control, or restore movement. They are primarily used to apply an intermittent, gentle force with the goal of lengthening tissues to restore motion. Forces may be generated by springs, spring wires, rubber bands, or elastic cords. This type of splinting is termed elastic mobilization (Colditz, 2002a; Fess et al., 2005).

With dynamic splinting to increase range of motion, two concepts are critical. The first is that the force must be gentle and applied over a long time (Brand, 2002; Fess, 1995). Safe force for the hand has been determined to be 100–300 g (Brand, 2002; Fess & McCollum, 1998); parameters for proximal joints are not yet clinically defined. Excessive force results in tissue trauma, inflammation, and necrosis.

The second concept is that, to be effective and prevent skin problems, the line of pull must be at a 90° angle to the segment being mobilized (Brand, 2002). To ensure this, forces are directed by an outrigger, a structure extending outward from the splint.

Outriggers may be high profile or low profile (Fig. 16-1). Each design has distinct advantages and disadvantages. Selection of outrigger design must be based on the specific patient's needs and abilities. High-profile outriggers are inherently more stable and mechanically efficient, require fewer adjustments to maintain a 90° angle of pull, and require less effort for the patient to move against the dynamic force. Low-profile outriggers are less bulky but require more frequent adjustments and greater strength to move against the dynamic force (Fess, 1995; Fess et al., 2005).

By allowing motion in the opposite direction, dynamic splints reduce the risk of joint stiffness from immobility,

Figure 16-1 Outriggers directing proper 90° line of pull. **A.** High profile. **B.** Low profile. (Adapted with permission from Hunter, J. M., Mackin, E. J., & Callahan, A. D. [Eds.]. [1995]. *Rehabilitation of the hand: Surgery and therapy* [4th ed.]. St. Louis: Mosby.)

as seen with static splinting. If successful, an increase in passive joint mobility can be expected within 2 weeks (Fess & McCollum, 1998).

In addition to gaining motion, dynamic splints can be used to assist weak or paralyzed muscles. These dynamic splints may be intrinsically powered by another body part or by electrical stimulation of the patient's muscles. Extrinsic power sources, including gas-operated devices and battery-powered motors, have also been used (Long & Schutt, 1986). In practice, these externally powered devices proved to be too complex and difficult to maintain, causing their use to decline (Clark, Waters, & Baumgarten, 1997).

ORTHOTIC SELECTION

Splinting is one of the most useful modalities available to therapists when used correctly and appropriately (Fess, 1995). Remember, the end result of splinting should always relate to the patient's function (Figs. 16-2 through 16-5). McKee and Rivard (2004) caution that: "Orthotic intervention may have become an end unto itself in the minds of therapists and clients rather than the means to enable occupational performance." The outcome of successful splinting is that the splint serves its purpose and that the patient accepts and wears it. To meet these ends, the therapist must think critically and often creatively.

The therapist's multifaceted role is to evaluate the need for a splint clinically and functionally; to select the most appropriate splint; to provide or fabricate the splint; to assess the fit of the splint; to teach the patient and caregivers the purpose, care, and use of the splint; and to provide related training as needed. The therapist must take a leadership role to ensure that the treatment team, including the patient and caregivers, work collaboratively in every phase of the orthotic process. A client-centered, occupation-based

Figure 16-2 Wrist splints enabling gardening.

Figure 16-3 Hand splint enabling keyboarding.

approach empowers the patient and caregivers to participate actively. This also positions them as the experts in the patient's occupations, lifestyle, values, image, and activity contexts, which complements the expertise that the health care professionals bring. The therapist should clearly explain rationales, make clinically sound recommendations, and offer choices to the patient whenever possible. This helps establish each team member's accountability and increases the likelihood that the patient will actually use the splint.

A problem-solving approach to splinting directs the therapist to answer several key questions before splinting proceeds:

- What is the primary clinical or functional problem?
- What are the indications for and goals of splint use?
- How will the orthosis affect the problem and the patient's overall function?
- What benefits will the splint provide?
- What limitations will the splint impose?
- What evidence is available related to the splint?

Figure 16-4 Thumb splints enabling driving.

Figure 16-5 Wrist–hand splint enabling function in the kitchen.

Based on these considerations, the therapist must select or design the most appropriate orthosis. In some cases, the best choice is no orthosis at all.

The growing array of commercial products has led to a greater number of choices. The first is whether the orthosis should be custom fabricated or prefabricated. Materials must also be considered. The therapist must be familiar with properties, benefits, and drawbacks of each. Options abound, with rigid, semirigid, and soft materials available (Breger-Lee, 1995; Canelon, 1995).

When making a splint selection, several key factors must be carefully weighed:

- Among the splint-related factors are type, design, purpose, fit, comfort, cosmetic appearance, cost to purchase or fabricate, weight, ease of care, durability, ease of donning and doffing, effect on unsplinted joints, and effect on function.
- Patient-related factors include clinical and functional status, attitude, lifestyle, preference, occupational roles, living and working environments, social support, issues related to safety and precautions, ability to understand and follow through, and financial or insurance status.

Several studies have been done on patients' preferences and factors that contribute to splint wear. They show that the following factors may encourage splint wear: flexibility

SAFETY NOTE 16-1

Orthotic Precautions

The therapist must consider, carefully monitor, and teach the patient and caregiver to report any of these problems related to orthotic use:

- Impaired skin integrity (pressure areas, blisters, maceration, dermatological reactions)
- Pain
- Swelling
- Stiffness
- Sensory disturbances
- Increased stress on unsplinted joints
- Functional limitations

of the splinting regimen and vigorous teaching to enable patients to understand the purpose and wearing schedule (Pagnotta, Baron, & Korner-Bitensky, 1998); individualized prescriptions focusing on the patient's comfort and preference (Callinan & Mathiowetz, 1996; Stern et al., 1996); strong family support (Oakes et al., 1970); positive attitudes and behaviors exhibited by health care providers (Feinberg, 1992); and benefits that are immediately obvious to the patient (Groth & Wulf, 1995). Rapport, trust, sensitivity to individual patient's learning styles, trial evaluations, and giving patients the opportunity to voice their concerns and frustrations can also greatly enhance the collaborative process and outcome (Collins, 1999). With the relatively small base of literature on orthotics, therapists must continue to put their clinical judgments and experience to the test and strive for evidence-based practice related to outcomes and factors that influence successful orthotic intervention.

Should problems with splint wear arise (Safety Note 16-1), the therapist should examine both the splint and the wearing schedule. The splint itself may not fit properly or comfortably. The patient's functional demands may outweigh the benefits of splint wearing, or the wearing schedule may be too complex. Actively engaging the patient in the problem-solving process is likely to improve the outcome. Although it is important to strive for the ideal, therapists must remain realistic in the scope of the patient's daily life.

PURPOSES OF ORTHOSES

In this chapter, orthoses are categorized according to several purposes (Definition 16-1). Although a specific orthosis is discussed under the category for which it is most commonly used, that purpose may not be its only one. Also, a single orthosis may fulfill several functions simultaneously. The orthoses presented here are by no means an exhaustive list but

DEFINITION 16-1

Purposes of Orthoses

- Support a painful joint
- Immobilize for healing
- Protect tissues
- Provide stability
- Restrict unwanted motion
- Restore mobility
- Substitute for weak or absent muscles
- Prevent contractures
- Modify tone

a representative sampling of commonly used or historically significant orthoses. Inclusion of specific orthoses should not be interpreted as an endorsement of one type over another. Whenever possible, published evidence-based data have been included. As the intent of this chapter is to provide an overview of orthotics, the reader is encouraged to explore the references and resources for more detailed information.

Support a Painful Joint

Pain in a joint or soft tissues can result from a wide variety of causes, including acute trauma (such as sprains and strains), nerve irritation (such as carpal tunnel syndrome and ulnar nerve neuritis at the elbow), inflammatory conditions (such as tendonitis and rheumatoid arthritis), and joint instability (such as degenerative arthritis, ligamentous laxity, and shoulder subluxation). When resting a joint is indicated to relieve pain, protect joint integrity, and/or decrease inflammation, supportive orthoses can be used. These orthoses are often worn all day, all night, or both to provide the maximum benefit; or they may be worn only during selected activities. Unless contraindicated, the orthosis should be removed at least once a day for skin hygiene and gentle range-of-motion exercises to prevent loss of joint mobility. The following are common examples of orthoses used for pain relief.

Support a Painful Shoulder or Elbow

Arm slings have been developed to prevent or correct shoulder subluxation or reduce pain in patients who have subluxation caused by brachial plexus injuries, hemiplegia, and central cord syndrome injuries. Sling designs are numerous, with some commercially available and others fabricated by the therapist.

Certain slings support and immobilize the whole arm. These slings, such as the standard pouch and the double arm cuff sling (Fig. 16-6) restrict motion by keeping the humerus in adduction and internal rotation and the elbow in flexion. Although these slings may take some of

the weight off the affected shoulder, downsides are that they place the extremity in a nonfunctional position, reinforce synergy patterns, and fail to provide the patient with the opportunity for motor and sensory feedback (Bobath, 1990; Moodie, Brisbin, & Margan, 1986). Other sling designs support the shoulder but leave the rest of the arm free for function, such as a humeral cuff sling (Fig. 16-7).

Figure 16-6 Rolyan® Figure-of-8 Sling.

Arm troughs, lapboards, and half-lapboards are also used to support the painful shoulder when the patient is seated in a wheelchair. These may be more acceptable to patients than slings, and they allow the arm to be ideally positioned with the scapula pulled forward and the hand supported (Bobath, 1990). It is important to remember that these supports lack the constant relationship between the patient and the support as exists with slings. Any change in postural alignment will alter forces and the support effectiveness (Spaulding, 1999). Lapboards (Fig. 16-8) are generally indicated for patients with poor trunk control or visual field deficits and for those who require greater variability of upper extremity positioning or a

Figure 16-7 Hemi shoulder sling.

Figure 16-8 Rolyan® Slide-On Adjustable Lap Tray.

work surface. Arm troughs (Fig. 16-9) are used for patients who need a device that does not interfere with wheelchair propulsion or transfer activities (Lange, 1999). The half-lapboard (Fig. 16-10) combines the positive features of both the arm trough and the full lapboard (Walsh, 1987). Full and half-lapboards can be purchased commercially or custom fabricated from acrylic or wood. Some designs allow the half-lapboard to be rotated up and out of the way instead of having to be removed from the wheelchair when the patient needs to transfer. Arm troughs are also commercially available or can be custom made.

The use of supports in reducing shoulder subluxation remains controversial. In addition, whether subluxation has a causal relationship to shoulder pain is in question (Zorowitz et al., 1996). There is no consensus as to which type of support is the best in the treatment of shoulder subluxation or whether a support should be used at all. The effects of various sling and support designs have proved variable in multiple studies over the years as summarized by Zorowitz et al. (1995).

Ultimately, it is agreed upon that, if a support is to be used, several types should be evaluated on the patient to optimize the reduction of shoulder pain, the function of the affected extremity, and the ease of donning and doffing (Zorowitz et al., 1995). Therapists need to consider the different mechanical forces each support produces on

Figure 16-9 Otto Bock™ Arm Trough.

Figure 16-10 Clear Flipaway Armrest in upright position.

the shoulder complex (Spaulding, 1999). Smith and Okamoto (1981) reviewed more than 22 distinctive hemiplegic sling designs and developed a checklist of 19 desirable and 4 undesirable characteristics to guide the therapist in examining and comparing slings for individual patients. The patient's acceptance of the sling also must be considered. Relative ease of donning and doffing the sling is imperative so the limb is not damaged further from improper wearing. More definitive research on the effectiveness of slings and orthoses in the management of the flaccid or subluxed shoulder is needed, and therapists should carefully consider all options before prescribing slings.

A gunslinger orthosis is another means of supporting a painful shoulder, such as from a brachial plexus injury. This type of orthosis is commercially available or can be custom fabricated for the patient. A commercial gunslinger (Fig. 16-11) can be easily adjusted to position the shoulder and elbow for maximal pain relief. A custom-fabricated gunslinger (Fig. 16-12) has the benefit of a much more streamlined design, allowing the patient to wear it under clothing as desired with minor garment adaptations (Lunsford, 1997). Also, this orthosis is much easier to don and doff. It is often the best solution for patients who require long-term or permanent use of a shoulder orthosis.

Commercial neoprene sleeves that provide neutral warmth, gentle compression, and soft dynamic support to the shoulder or elbow (Fig. 16-13) are often used to relieve pain from arthritis, tendinitis, sprains, and strains. *As occupational therapists are expanding their use of supports fabricated from neoprene, it is important to be aware of the potential for dermatological reactions to the material and to*

Figure 16-11 Commercial gunslinger orthosis.

teach patients to discontinue use of the support should symptoms develop (Stern et al., 1998).

The treatment of lateral and medial epicondylitis often entails the use of orthoses to relieve pain and prevent further stress to affected tissues. In both conditions, pain reduces grip strength and function. Counterforce braces (Fig. 16-14), of which there are several commercial models, are wide, nonelastic bands designed to reduce stresses on the common forearm extensor or flexor musculature origins (Wilton, 1997). These braces can also be custom fabricated from thermoplastic or strapping materials (Jacobs & Austin, 2003). The literature reports wide variation in the success of braces (Borkholder, Hill, & Fess, 2004; Wuori et al., 1998). *Complications can result from the brace*

Figure 16-12 Custom-fabricated gunslinger orthosis.

Figure 16-13 Commercial soft elbow support.

being applied too tightly, including nerve compression syndromes. The patient must be carefully taught accordingly.

A wrist splint placing the wrist in 45° of extension and worn in conjunction with a counterforce brace is often prescribed to rest the forearm musculature (Aiello, 1998).

Figure 16-14 VariPad Tennis Elbow Support.

The prescription of orthoses must be based on the patient's symptoms. It is vital that the cause of the problem and the biomechanics of loading forearm musculature are also addressed in relation to vocational or recreational demands (Wilton, 1997).

Support a Painful Wrist or Hand

Resting hand splints are used to support the wrist, fingers, and thumb. The normal resting position of the hand is determined anatomically by the bony architecture, capsular length, and resting tone of the wrist and hand muscles. This is typically 10–20° of wrist extension, 20–30° of metacarpophalangeal joint (MCP) flexion, 0–20° of proximal interphalangeal joint (PIP) flexion, the distal interphalangeal joints (DIPs) in slight flexion, the thumb CMC in slight extension and abduction, and the thumb MP and IP in slight flexion (Wilton, 1997).

A resting hand splint is commonly prescribed for patients with rheumatoid arthritis. Resting splints can reduce stress on joint capsules, synovial lining, and periarticular structures, thereby decreasing pain (Melvin, 1989) (see Chapter 44). With this population, splinting should be in a position of comfort regardless of whether this is the ideal anatomical position (Fess et al., 2005). During an acute exacerbation of the disease, splints are generally worn at night and during most of the day and removed at least once for hygiene and gentle range-of-motion exercises. It is recommended that splint use continue for at least several weeks after the pain and swelling have subsided (Fess et al., 2005; Melvin, 1989).

Resting hand splints can be volar or dorsal, depending on needs and preferences. Commercial splints, such as those fabricated from wire-foam (Fig. 16-15) or a malleable metal frame covered by dense foam padding (Fig. 16-16), may be used if the limited adjustments they allow for can provide the patient with a proper fit. This becomes more difficult if the patient has established joint deformities. Custom-fabricated splints (Fig. 16-17) allow for a precise, individualized fit.

If the thumb or IP joints of the fingers are not painful, a modified resting hand splint (Fig. 16-18) may keep these joints free. This often results in less stiffness related to

Figure 16-15 LMB Economical Resting Splint.

Figure 16-16 Progress™ Functional Resting Splint.

splint wear, some degree of hand function while the splint is worn, and improved splint wear and comfort.

Although health care professionals generally agree on the benefits of using splints to rest inflamed and painful joints, studies have shown that compliance with wearing resting hand splints as prescribed is less than optimal at approximately 47% (Feinberg, 1992). In a study by Callinan and Mathiowetz (1996), which compared soft versus hard resting hand splints on pain and hand function, results showed that pain was significantly decreased with splint wear and that 57% of patients preferred the soft splint, 33% preferred the hard splint, and 10% preferred no splint. The rate of compliance was greater for the soft splint (82%) than for the hard splint (67%). The authors advocate that therapists provide patients with options relative to comfort and preference to ensure patient satisfaction and improved outcome.

Wrist extension, or cock-up, splints are probably the most commonly prescribed type of orthosis for the upper extremity. Indications for use include sprains, strains, tendonitis, arthritis, carpal tunnel syndrome, wrist fractures following cast removal, and other conditions that cause pain. A wrist splint typically positions the wrist in 10–30° of extension, which is thought to be the best position for hand function (Fess et al., 2005). A well-fitting splint is one that clears the distal palmar and thenar creases to allow for unrestricted mobility of the fingers

Figure 16-17 Custom thermoplastic resting hand splint.

and thumb and that conforms to the palm to support the arches of the hand. Wrist splints may be volar (Fig. 16-19), dorsal (Fig. 16-20), or circumferential (Figs. 16-2 and 16-21) and can be custom fabricated or prefabricated. Since these splints are intended to provide wrist support while allowing functional use of the hand, fit and comfort are crucial.

A growing variety of commercial splints are available, with designs and materials offering a range of soft to rigid support. Elasticized wrist orthoses with an adjustable metal stay that slides into a volar pocket (Fig. 16-22) are commonly used because they are cost-effective and readily available. The drawbacks of these splints are they do not fully support the palmar arches, they do not completely clear the palmar and thenar creases, and the metal stay is often prepositioned at a 35–45° angle of extension. Therefore, it is critical to fit and adjust the stay to the desired angle before issuing the splint. Other commercial products are made of wire-foam, neoprene, leather, canvas, and other fabric blends, all of which offer features having distinct advantages and disadvantages.

Several studies have been conducted on the effects on hand function of different styles of wrist extension splints. Carlson and Trombly (1983) reported a decrease in hand function when normal subjects were tested without and then with a static wrist orthosis. Stern (1991) studied hand function speed in normal subjects who wore three styles of custom-fabricated wrist splints and a commercial elastic wrist splint. She found that, although all of the

Figure 16-18 Rolyan® D-Ring™ Wrist Brace with MCP Support.

Figure 16-19 Custom thermoplastic volar wrist extension splint.

Figure 16-20 Carpal Lock® Splint.

Figure 16-21 Comfort Cool™ D-Ring Wrist Splint.

Figure 16-22 Norco™ Wrist Brace.

splints significantly slowed hand speed, the elastic splint allowed for faster speeds and dexterity than the others. A later study on grip strength and dexterity across five styles of commercial wrist splints concluded that each style impeded power grip and dexterity but to different extents (Stern, 1996).

Splints vary in the amount of motion they allow or restrict. Collier and Thomas (2002) compared range of motion at the wrist with three commercial supports and a custom-made volar thermoplastic splint. The commercial splints allowed the same amount of motion (wrist flexion to about neutral and wrist extension to about 26–31°). In contrast, the thermoplastic splint allowed less wrist flexion (not past 14° of wrist extension) and more wrist extension (about 40°). This suggests a custom thermoplastic splint may be more appropriate for conditions where limited wrist flexion is desired.

Elastic wrist orthoses have been widely used in the treatment of arthritis to stabilize wrists, decrease pain, and improve function. Again, studies have shown conflicting results across different styles of orthoses in grip strength, dexterity, hand function, pain reduction, comfort, security during task performance, and adverse effects of stiffness or muscle atrophy due to orthotic wear (Pagnotta, Baron, & Korner-Bitensky, 1998; Stern et al., 1996). In a related study, most of 42 subjects knew their preferred orthosis within a few minutes of wear when given three styles to try (Stern et al., 1997). These studies reinforce the importance of task analysis, having a wide variety of splints to try with each patient, and a careful weighing of the benefits and limitations of splinting.

Another common indication for wrist splinting is carpal tunnel syndrome, a condition caused by median nerve compression, which results in symptoms including pain, sensory disturbances, muscle weakness, swelling, stiffness, and frequent dropping of items. Symptoms often are worse at night or with repetitive activity involving wrist flexion (see Chapter 42). For pain and related symptoms caused by carpal tunnel syndrome, conservative or postoperative treatment often uses wrist splints to prevent the elevation of carpal tunnel pressure by restricting wrist motion (Gelberman et al., 1988).

Figure 16-23 Custom thermoplastic long thumb spica splint.

The ideal position of the wrist to minimize pressure in the carpal tunnel varies according to sources from 10–15° of extension (Melvin, 1989) to neutral (Weiss et al., 1995) to slight flexion (Gelberman et al., 1988). There is a consensus that commercial wrist splints, which often place the wrist in excessive extension, may not be of any benefit unless they are modified to a less extended position. Dorsal wrist splints (Fig. 16-20) are often recommended because they do not create external pressure over the volar wrist. A systematic review of splinting for carpal tunnel syndrome showed benefits from splinting across splint types and wrist angles, with evidence suggesting custom splints and full-time splint wear promote better results (Muller et al., 2004).

A long opponens splint (Fig. 16-23), also known as a long thumb spica, can relieve pain from wrist and thumb arthritis or from DeQuervain's tendonitis of the abductor pollicis longus and extensor pollicis brevis. This splint is typically based on the radial aspect of the forearm and extends distally to immobilize the thumb CMC and MP joints. The wrist is generally splinted in slight extension, with the thumb in slight flexion and palmar abduction to enable opposition to the index and middle fingers (Wilton, 1997). If the thumb IP joint or the extensor pollicis longus tendon is involved, the IP joint can be included in the splint as well (Fig. 16-24). Prefabricated splints often provide a softer support, whereas custom-made thermoplastic splints give more rigid immobilization.

A thumb CMC stabilization splint, or a short thumb spica, is a static splint that encompasses the first metacarpal to provide stability, reduce pain, and increase hand function. It restricts motion of the CMC and MP joints but leaves the wrist relatively mobile and the thumb IP free. A static thumb

Figure 16-24 Liberty™ Wrist and Thumb Splint.

Figure 16-25 Custom thermoplastic short thumb splint.

MP splint allows for CMC and IP motion and can be used when the disorder is localized to the MP joint alone.

Indications for short thumb splints include rheumatoid arthritis or osteoarthritis of the thumb CMC or MP joints or trauma to soft tissues, such as the ulnar collateral ligament of the MP. The thumb is generally positioned to enable opposition to the fingers for function while in the splint, and the splint is most often worn during functional activities that cause or aggravate pain (Melvin, 1995). Commercially prefabricated rigid CMC and MP stabilization splints are often ineffectual because they fit poorly (Melvin, 1995). For a precise fit and rigid support, splints can be custom fabricated from thermoplastic materials (Fig. 16-25). Newer commercial products made of soft, breathable elastic material have moldable thermoplastic stays to enable a custom fit, combining comfort and ease of fabrication with the required individualized rigid support (Fig. 16-26). Rigid support may not always be needed. In comparing a custom-made thermoplastic splint and a soft neoprene support for osteoarthritis of the thumb CMC joint, Weiss et al. (2004) found that the prefabricated neoprene splint (Fig. 16-27) provided greater pain relief and function and was preferred over the thermoplastic splint by 72% of the subjects.

If the thumb or finger IP joints are painful from trauma or arthritis, lateral, dorsal, or volar gutter splints (Fig. 16-28) may be used for pain relief. Silicone-lined sleeves or pads (Fig. 16-29) can protect painful joint nodules from external trauma.

Figure 16-26 Custom-molded thumb splint.

Figure 16-27 Commercial soft thumb splint.

Figure 16-28 Custom thermoplastic volar gutter splint.

Figure 16-29 Silicone-lined digital sleeve and pad.

Pain, volar subluxation, and ulnar deviation of the MCPs are common sequelae of rheumatoid arthritis. MCP ulnar deviation supports may be used to provide stability, realign joints, reduce joint stress, and relieve pain. They may delay the progression of deformity but do not correct or prevent it (Melvin, 1995; Philips, 1989). These supports may be worn alone or incorporated into a resting hand splint.

Prefabricated and custom-designed orthoses with dividers or straps to align the digits include dynamic and static and soft and rigid. Rigid static splints (Fig. 16-30) used to achieve passive correction of deformity can create focal pressure points on the digits. It is therefore important not to try to achieve ideal alignment at the risk of creating pressure problems (Melvin, 1989).

Despite the variety of splint materials and designs, MCP ulnar deviation supports are reported to be not frequently prescribed or used by patients for a variety of reasons (Rennie, 1996). For some patients, immobilization of the MCPs impairs functional use of the hand and may increase stress and pain on the adjacent PIP joints (Melvin, 1995; Philips, 1989). Additionally, bulky or volar-based splints interfere with palmar sensation and impede the ability to grasp objects. Some patients, however, benefit from the improved digital alignment and pain reduction that supports offer. High patient satisfaction rates have been reported for a custom dorsal-based design (Rennie, 1996). Soft ulnar deviation splints are commercially available (Fig. 16-31) or can be custom fabricated (Gilbert-Lenef, 1994). The prime indicator for use and selection of an MCP ulnar deviation support should be the patient's preference (Melvin, 1995).

Immobilize for Healing or to Protect Tissues

Many of the orthoses previously discussed for pain relief can also be used to immobilize for healing or protection

Figure 16-30 LMB Soft-Core™ Wire-Foam™ Ulnar Deviation Splint.

Figure 16-31 Norco™ Soft MP Ulnar Deviation Support.

following injury or surgery. For example, a gunslinger orthosis used to relieve traction pain associated with a brachial plexus injury can also protect the nerve structures from overstretching during the healing phase. A thumb MP splint that relieves pain from arthritis may also be used while an acutely injured collateral ligament heals. These orthoses are not discussed in detail again; different ones are reviewed.

Immobilize or Protect the Shoulder, Upper Arm, or Elbow

The sling is the simplest and most commonly used device for the upper extremity when there is a need to limit motion of the shoulder yet allow for some motion of the arm on the thorax. The basic arm sling consists of a forearm pouch or cuffs, a strap, and a mechanism for adjusting and securing the strap. Guidelines for sling adjustment are in Procedures for Practice 16-1.

PROCEDURES FOR PRACTICE 16-1

How to Adjust a Sling

- Place the patient upright.
- Ensure that the elbow is flexed to 90° and is seated properly in the sling, with the hand and wrist also supported as the design allows.
- Adjust the strap or straps so that the arm is comfortably supported.
- Check for comfort.
- Teach patient and caregiver about proper donning and doffing of sling.
- Monitor the axilla and areas where sling straps cross the body for signs of skin breakdown.
- Monitor for signs of edema and joint stiffness.

Figure 16-32 Rolyan® Universal Shoulder Immobilizer.

To further limit mobility, shoulder immobilizers (Fig. 16-32) can be used. These devices, which relatively immobilize the shoulder and elbow, are typically used following shoulder surgical reconstructions, arthroplasty, and rotator cuff repair. Immobilizers are more complex than slings, involving strapping that wraps the body to stabilize the arm against the trunk. Several commercial designs are available.

Foam abduction pillows or wedges may be used to maintain the arm at a certain elevation from the body. Abduction braces, sometimes called airplane splints, are commercially available or custom fabricated from thermoplastics. These devices are based on the trunk and can position the shoulder in varying degrees of abduction or rotation and the elbow in varying degrees of flexion or extension. Commercial braces offer ease of adjustability with the use of wrenches but may need extra padding to prevent skin breakdown. Indications for use include postoperative shoulder repairs, burns, and skin grafts to the axillary region (Long & Shutt, 1986; McFarland et al., 1997).

The treatment of humeral shaft fractures often involves functional fracture bracing (see Chapter 41). A humeral fracture brace (Fig. 16-33) provides external stabilization and alignment of the fracture by compressing surrounding soft tissues while allowing for early mobilization of the shoulder and elbow. These braces may be prefabricated or custom fabricated by the therapist from low-temperature thermoplastics. They are circumferential in design, with D-ring straps to allow for a secure closure and size adjustments as edema subsides. They should be lightweight and made of a perforated material for ventilation.

Whether the brace is prefabricated or custom, the therapist should ensure that its distal end does not block elbow flexion motion and that its proximal end does not unnecessarily limit shoulder motion. Excellent results with the use of functional fracture bracing of the humerus have been reported (Wallny et al., 1997).

Figure 16-33 Commercial humeral fracture brace.

Casts, splints, and hinged braces can be used to immobilize and protect the elbow following fractures, burns, ligamentous injuries, or surgical procedures. Casts offer rigid immobilization and may be made according to a circumferential, posterior, or anteroposterior bivalve design that allows the cast to be removed for wound care or range of motion. Hinged braces are frequently used to protect healing ligaments while allowing motion of the elbow. Thermoplastic splints may be anterior or posterior and may be secured by Velcro straps or an elastic wrap. Anterior elbow extension splints (Fig. 16-34) are most commonly used to immobilize and position the elbow following skin grafting.

Figure 16-34 Custom thermoplastic anterior elbow extension splint.

Immobilize or Protect the Wrist or Hand

The maintenance of normal hand function requires strong tissue repair with free gliding between neighboring structures. Proper positioning of the wrist and hand is critical to prevent complications caused by injury, edema, and tissue healing. Splinting in the early stages of healing can counteract the typical joint contractures of the injured hand that produce the deformities of wrist flexion, MCP extension, IP flexion, and thumb adduction. It is essential to position joints correctly and keep uninvolved joints moving so that they will not stiffen (Stewart Pettengill, 2002). *Incorrect application of a splint or improper positioning while in a splint may lead to both joint limitations and tissue damage (Fess, 1995).*

Unless specifically contraindicated, the antideformity, or safe, position of immobilization is with the wrist in 10–30° of extension, the MCPs in 70–90° of flexion, the IPs in 0–15° of flexion, and the thumb in palmar abduction (Fess et al., 2005; Stewart Pettengill, 2002). This is most often accomplished through a volar custom-fabricated low-temperature thermoplastic splint (Fig. 16-35). If edema is present, the splint should be secured by an elastic wrap or gauze wrap to avoid a tourniquet effect from straps. *It is crucial never to force joints into the ideal position but to position joints as closely as possible to the ideal and serially revise the splint until the optimal position is realized.*

Antideformity splints are integral to the treatment of acute dorsal hand burns (see Chapter 45). An investigation of the literature found an overall lack of consensus on the design of these splints (Richard et al., 1994). The most commonly recommended position for joints is with the wrist in 15–30° of extension, the MCPs in 50–70° of flexion, the IPs in full extension, and the thumb in palmar abduction with the IP in slight flexion (Richard & Staley, 1994). Pre-formed splints are commercially available and may be used if adequate fit can be obtained given the size of the hand and any edema. Custom-fabricated splints, preferably of a perforated material, ensure the best fit. Splints may have to be adjusted daily for optimal fit and maintenance of proper joint positioning. For the grafting

Figure 16-35 Custom thermoplastic “safe position” wrist–hand splint.

and rehabilitation phases of burn treatment, splint design varies with the positions necessary to counteract the contractile forces of the scars.

Wrist splints, as discussed in the previous section, may be used for protection or immobilization of wrists following cast removal or to treat soft tissue injuries. Athletic injuries to the wrist and hand, such as contusions, sprains, strains, fractures, and joint dislocations, often require the use of protective splints to enable the patient to continue participation in sports. As with other splints, selection of material and design should be carefully tailored to the patient's needs. Materials may be thermoplastic, silicone rubber, plaster, fiberglass, cloth tape, or neoprene. Selection should be based on the degree of immobilization required, material durability and breathability, the player's sport position, governing rules of the sport, and the safety of other players (Canelon, 1995).

Treatment of tendon injuries and repairs may involve static positioning to immobilize the tendon for healing or dynamic splinting to protect the tendon while allowing controlled motion to increase tendon repair strength and gliding. Flexor tendon repair protocols vary, but a protective dorsal blocking splint (Fig. 16-36) positioning the wrist and MCPs in flexion and blocking the IP joints in 0° of extension is typically used. Rubber band traction may be added to hold the digits in a flexed position or to enable resistive extension and passive flexion exercises. The splint is usually custom fabricated from low-temperature thermoplastic and is often worn for as long as 6 weeks (Stewart Pettengill & vanStrien, 2002).

Extensor tendon injuries involve treatment and splinting based on the level of injury. For injuries at the DIP level that may result in a mallet finger deformity, the DIP is immobilized for 6–8 weeks in a slightly hyperextended position. The PIP joint is left free. The splints most commonly used are volar based and may be prefabricated or custom fabricated from padded aluminum strips or thermoplastics. Excellent results for the treatment of mallet finger have also been reported with custom-made dorsal splints (Evans, 2002; Foucher et al., 1996). For injuries at the PIP level, treatment includes digital cast (Fig. 16-37) or splint immobilization with the PIP in absolute 0° of extension for 6–8 weeks to prevent boutonniere deformity. For more

Figure 16-37 Plaster digit cast.

proximal tendon injuries, splinting may involve static positioning, dynamic assists, or both (Evans, 2002).

Splinting is an integral part of postoperative MCP arthroplasty treatment. Early positioning and motion following arthroplasty often uses a dynamic MCP extension assist (Fig. 16-38) to support the wrist, control MCP motion, correct the deformity, and assist with extensor power. This controlled stress allows for joint capsule remodeling over time (Kirkpatrick, Kozin, & Uhl, 1996; Melvin, 1989). Dynamic MCP extension assists may use high-profile or low-profile outrigger designs. They have slings to support the MCPs in neutral extension and deviation and to provide rotatory alignment. Outrigger kits are commercially available, or the outrigger may be hand fabricated. The dynamic extension splint may be supplemented by a static positioning splint at night (Fess et al., 2005).

To protect digits but allow for stabilization or controlled motion of the MCP, PIP, or DIP joints following injury or surgery, buddy straps (Fig. 16-39) (Jensen & Rayan, 1996), buddy sleeves (Bassini & Patel, 1994), or buddy splints (Lamay, 1994), which connect an injured finger to an adjacent finger, can be used. Common indications for these include stable fractures, PIP joint dislocations, collateral ligament injuries, and staged flexor tendon reconstructions.

Provide Stability or Restrict Unwanted Motion

Orthoses can be helpful in stabilizing joints when their integrity has been compromised by an acute injury or a chronic disease such as arthritis. Stabilization or restriction of motion can often greatly facilitate functional use of a limb.

Stabilize or Restrict Motion of the Shoulder or Elbow

In addition to the purposes previously described, slings, gunslingers, and hinged elbow orthoses can also be used to provide proximal stability that may enable improved distal function.

Stabilize or Restrict Motion of the Wrist or Hand

It is essential to determine the position in which a joint is to be supported relative to hand dominance and task

Figure 16-36 Custom thermoplastic dorsal blocking splint.

Figure 16-38 Custom thermoplastic low-profile dynamic MCP extension splint using Rolyan® Adjustable Outrigger Kit.

requirements because specific functional demands vary greatly among individual patients. The wrist is considered by many to be the key to ultimate hand function, and wrist splints are commonly prescribed to provide stability. Dorsal wrist splints allow for the greatest palmar sensation but are least supportive; volar wrist splints are most commonly prescribed and provide a moderate amount of stability; and circumferential wrist splints provide the greatest amount of stability (Wilton, 1997).

For optimum mechanical advantage to support the weight of the hand, the forearm portion of the splint should be two thirds the length of the forearm (Fess et al., 2005; Wilton, 1997). Although greater length is believed to

add to stability, studies have shown that a longer splint can decrease grip strength, slow finger dexterity, and decrease hand function speeds compared with a shorter wrist splint (Stern, 1996). For smaller or lighter hands and for patients who do not use their hands for high-demand activities, a shorter wrist support (Fig. 16-40) can increase comfort while being less obtrusive than a long splint (Melvin, 1995).

A lumbrical bar is a hand-based orthosis that extends over the dorsal aspect of the proximal phalanges to re-

Figure 16-39 Rolyan® Buddy Straps.

Figure 16-40 Liberty™ Short and Long Elastic Wrist Braces.

Figure 16-41 LMB MP Flexion Spring.

strict unwanted hyperextension of the MCPs, which can result from an ulnar nerve or combined median and ulnar nerve injury. By blocking this motion, IP flexion contractures can be prevented and functional hand opening improved as the power of the long finger extensors is transferred to the IPs for extension. Lumbrical bar orthoses using spring wire are commercially available (Fig. 16-41), but these tend to be bulky and limit the ability to grasp objects. Custom-fabricated thermoplastic splints (Figs. 16-3 and 16-42) provide for a more intimate and streamlined fit (Colditz, 2002b; Wilton, 1997).

This same principle of restricting undesired motion is used in a PIP hyperextension block, also known as a swan-neck splint. Swan-neck deformities are common sequelae of rheumatoid arthritis and a possible complication following an extensor tendon injury or repair. These deformities often cause difficulty with hand closure, as PIP tendons and ligaments can catch during motion, and the finger flexors have less of a mechanical advantage to initi-

Figure 16-42 Custom thermoplastic lumbrical bar splint.

Figure 16-43 Custom thermoplastic PIP hyperextension block.

ate flexion when the PIP is hyperextended. By blocking the PIP in a slightly flexed position, the patient can flex the PIP more quickly and easily.

For short-term use or for trial purposes, custom-fabricated thermoplastic swan-neck splints (Fig. 16-43) may suffice (McKee & Morgan, 1998). For long-term use or for use on adjacent digits, commercial swan-neck splints are often recommended because they are more durable, less bulky, more easily cleaned, and more cosmetically appealing. Custom-ordered ring splints made of silver or gold (Fig. 16-44) are attractive, durable, streamlined, and adjustable for variations in joint swelling, but they are more costly. Prefabricated splints made of polypropylene (Fig. 16-45), also available commercially, offer some of the benefits of silver splints with less cost. Heavy-duty metal splints, such as Murphy ring splints, may benefit patients who use their hands in highly demanding tasks. Swan-neck splints can also be used to provide lateral stability to unstable IP joints of the fingers or thumb.

Flexible boutonniere deformities may benefit from boutonniere splinting to block the PIP in a more extended position to allow for greater functional hand opening. These may also be custom made by the therapist or custom ordered from the companies that fabricate swan-neck splints (Fig. 16-46). Since there is direct pressure over the PIP, the dorsal skin must be carefully monitored for signs of breakdown.

Thumb stability is a requirement of almost all prehensile activities, so splinting of unstable thumb joints may have a particular value for function (Fess et al., 2005). Instability of the CMC often requires a long thumb splint that crosses the wrist because shorter splints may not adequately support the CMC. Short thumb spica splints (Fig. 16-25), also known as thumb posts or opponens splints, can provide MP stability and a stable post for pinching. Although a circumferential design is commonly used, problems with marked MP deformity can make donning and doffing of the splint difficult, and direct pressure over the MP may lead to breakdown of fragile skin.

Restore Mobility

Orthoses play an integral role in the restoration of mobility by correcting soft tissue or joint contractures that can

Figure 16-44 Siris™ Silver Swan Neck Splint.

Figure 16-45 Oval-8™ commercial ring splints.

occur as a result of poor positioning, trauma, scarring, or increased muscle tone. Devices providing low-load, prolonged stretch have proven to be effective in the contracture management of patients having a neurological or orthopedic disorder (Hill, 1994; Nuismer, Ekes, & Holm, 1997). As described earlier in this chapter, different types of splinting may be used: serial static plaster or thermoplastic, dynamic, and static progressive.

A therapist implementing a splinting program to regain motion must understand how splints work to effect positive change. Range of motion is gained not by tissue stretching but by actual tissue elongation from new cell growth (Bell-Krotoski & Figarola, 1995; Fess et al., 2005). *The forces used must be gentle and carefully applied, and the tissue must be closely monitored for signs of excessive stress, such as redness and inflammation, which are indicators to mediate or stop treatment.* Inelastic mobilization applies constant forces needed to remodel tissues and is the most effective means for gaining motion in chronically stiff joints. Elastic mobilization is most indicated for acute joint stiffness or more supple joints because forces can be more easily controlled and fine adjustments made (Fess et al., 2005).

Fixed contractures and chronically stiff joints often respond best to inelastic mobilization from **serial casting**. Plaster is an ideal material because it conforms intimately and is more rigid than thermoplastics. Casts are changed as motion gains are achieved.

Dynamic splinting is more effective when used for early contractures (Bell-Krotoski & Figarola, 1995). It allows for motion in the opposite direction, which helps prevent unwanted stiffness. Splints can also be removed for hygiene and function. Often dynamic splints are worn at night so

Figure 16-46 Siris™ Silver Boutonniere Splint.

as not to interfere with use of the limb. This decrease in wearing time, however, means that tissues are not kept under constant tension, and less rapid gains may result. The amount and direction of force must be carefully monitored and adjusted as joint angles change.

Static progressive splinting is often indicated for fixed contractures. It has the advantage of being worn for shorter periods throughout the day, allowing for motion and functional use of the limb.

Restore Mobility of the Shoulder, Elbow, or Forearm

A serial static abduction splint can be used to apply pressure to and elongate burn scars in the axilla. The benefits of wearing this type of splint must be carefully weighed against the complete lack of function that it imposes. For flexion contractures of the elbow, thermoplastic anterior elbow extension splints (Fig. 16-34), serial casts or dropout casts, and dynamic elbow extension or static progressive elbow extension splints can be used.

Serial casting, which typically entails changing the cast weekly, is thought to be most effective with contractures that have been present for less than 6 months (Keenan, 1997). When the contracture is a result of increased tone, such as in the patient with a brain injury, casting is often used in conjunction with nerve blocks or surgical procedures. *Great care must be taken with casting in the presence of severe tone, as pressure areas may develop.*

Dropout casts (Fig. 16-47) use the force of gravity to assist in reducing an elbow flexion contracture. The posterior portion of the cast above the elbow is removed, allowing the forearm to drop into extension. This type of

casting is effective only if the patient is upright most of the day.

A bivalved cast, also known as an anteroposterior splint (Fig. 16-48), is often used to maintain range of motion once it is achieved through casting or other means. This splint is well padded, with several straps holding the two halves together. The caregiver must be thoroughly trained so that it is applied properly and in the correct

Figure 16-47 Plaster elbow dropout cast.

Figure 16-48 Fiberglass anteroposterior elbow splint with wrist and digits included.

alignment to prevent pressure problems and skin breakdown.

Dynamic or static progressive splints (Fig. 16-49) have been reported to be successful in the treatment of elbow burn flexion contractures when static splinting was not effective. An average of 5–10° can be gained per day (Richard, Shanesy, & Miller, 1995). They have also proved to be effective in the treatment of neurological and orthopedic flexion contractures (Nuismer, Ekes, & Holm, 1997).

Elbow extension contractures, which are less commonly seen, can be treated with serial casting into flexion, dynamic flexion splinting, or static progressive splinting.

Loss of forearm rotation, often seen following spinal cord injury, peripheral nerve injury, or fracture, can be treated with dynamic forearm rotation splinting. Splints can be custom fabricated (Collelo-Abraham, 1990) or obtained commercially as a pre-formed product or kit (Fig. 16-50). Altering the direction of force when using these

Figure 16-50 Rolyan® Preformed Dynamic Pronation/Supination Splint.

Figure 16-49 JAS Static Progressive Elbow™ Orthosis.

splints can produce supination or pronation. A static progressive supination splint has also been described by Murphy (1990) as achieving favorable results.

Restore Mobility of the Wrist or Hand

Serial short arm casts, with or without the fingers or thumb, can be used in the treatment of flexion or extension contractures related to increased muscle tone. Serial plaster slab splinting (Tribuzi, 2002) can be especially effective in the presence of muscle-tendon unit shortening that can result in the inability to compositely flex or extend the wrist and fingers. Long flexor tightness can develop as a result of the wrist being in a prolonged position of flexion, such as with wrist drop from radial nerve palsy, wrist fracture immobilization, and protective positioning following flexor tendon repair. A plaster slab splint or a volar thermoplastic splint that positions the wrist and fingers in maximum composite extension can help to correct tightness of the long finger flexors.

Serial static thermoplastic wrist splints, dynamic wrist splints (Fig. 16-51), and static progressive wrist splints can be used for limitations in wrist flexion or extension. These may be custom fabricated or pre-formed. Dynamic or static progressive component kits can also be purchased commercially. This allows the therapist to custom mold the splint bases while more easily assembling force units.

Lack of MCP flexion can devastate hand function. Many dynamic splint designs to regain MCP motion are available. Custom-fabricated thermoplastic splints use individual finger loops over the proximal phalanx (Fig. 16-52). Attached to these loops are rubber bands or springs that provide the needed force for sustained tension. An outrigger is used to direct the line of pull at 90°. It is important to clear the distal palmar crease so as not to block full flexion range of motion. These splints may be forearm based or hand based, depending on the mechanical ad-

Figure 16-52 Custom thermoplastic dynamic MCP flexion splint.

vantage needed, any adhesions, and the patient's wrist strength and stability (Fess et al., 2005).

Commercial hand-based dynamic splints use springs, coiled spring wire (Fig. 16-41), or rubber bands to provide flexion force to the MCPs as a unit. These splints are effective only if all MCPs are uniformly stiff. Some force adjustments can be made, but individual finger force amount or angle adjustments are not possible, as they are with custom-made thermoplastic splints having separate finger loops. Finger flexion gloves (Fig. 16-53), which incorporate rubber band traction, can be used to gain composite flexion of all joints, but they have the most effect on the MCPs.

Limited PIP flexion makes grasp difficult, and limited PIP extension interferes with the ability to open the hand in preparation for grasp or to release objects. PIP flexion contractures are a frequent complication of trauma or poor positioning, and extension contractures can be seen following dorsal hand burns or prolonged immobilization for fracture management.

To address these contractures, forearm- or hand-based dynamic thermoplastic splints similar to those designed

Figure 16-51 Custom thermoplastic dynamic wrist extension splint using Phoenix Wrist Hinge.

Figure 16-53 Finger flexion glove.

for MCP flexion and extension can be used by extending the distal part of the splint across the MCP to just proximal to the PIP joint. Immobilizing the MCP applies force to the PIP.

Prefabricated spring wire and spring coil splints are also available to gain flexion or extension range of motion. In a study of prefabricated spring wire (Fig. 16-54) and spring coil (Fig. 16-55) extension splints by Fess (1988), exerted forces were found to vary in the same splint design and to vary also according to the degree of joint contracture. Some forces were alarmingly high, well above recommended limits. Callahan and McEntee (1986) found similar results and expressed concern about whether these splints fit accurately and about forces being distributed over small surface areas as compared with custom-fabricated splints. Designs have since been improved so that tension can be somewhat modified. If used, these splints must be carefully monitored to avoid further joint or tissue damage.

Spring coil extension splints, sometimes called Capener splints, may be custom fabricated and are described in the literature (Callahan & McEntee, 1986;

Figure 16-54 LMB Spring Finger Extension Assist.

Figure 16-55 Rolyan® Sof-Stretch Coil Extension Splint.

Colditz, 1995). A study of dynamic splinting in the management of PIP flexion contractures using Capener and low-profile hand-based outrigger splints found the two to be equally effective, suggesting that the patient may prefer the less bulky Capener splint if offered a choice (Prosser, 1996). Additional findings concluded that the longer the flexion contracture was present, the less it resolved and that splint wearing time was a significant factor affecting outcome.

A commercial neoprene dynamic finger extension tube (Fig. 16-56) provides circumferential pressure and a dynamic force into extension via an angled seam on its volar surface. It may also offer other therapeutic values, such as heat, mild joint distraction, and longer tolerable wearing times (Clark, 1997). PIP extension can also be gained through serial plaster casting or splinting.

Thermoplastic gutter (Fig. 16-28) or circumferential splinting and dynamic traction splinting are useful in the treatment of mild contractures, whereas serial plaster dig-

Figure 16-56 Rolyan® Dynamic Digit Extensor Tube™ Splint.

Figure 16-57 Custom thermoplastic thumb abduction splint.

ital casting (Fig. 16-37) has been advocated for moderate to severe contractures (Bell-Krotoski, 2002). Plaster casting offers the advantages of intimate conformity, rigidity, breathability, and uniform distribution of pressure. Casting does require the patient's cooperation in keeping the cast dry, and casts have the disadvantage of not being removable for function or motion. For most effective results, casts should be changed every 2–7 days (Bell-Krotoski & Figarola, 1995) or sooner if they become loose or wet. The DIP joint may be left free if its motion is not limited. It is at times beneficial to involve the DIP in the cast if increased mechanical advantage is desired for PIP extension. Variations of many of these splints can be used for the treatment of DIP contractures or contractures of the thumb MP or IP.

Adduction contractures of the thumb, which are commonly seen in burns and nerve injuries, are most often treated with serial static thumb abduction splints, which

conform to the first web space (Fig. 16-57). It is important to ensure that abduction forces are directed to the CMC joint by involving as much of the distal aspect of the first metacarpal as possible (Fess et al., 2005). Strapping must be designed to apply pressure in the proper direction and to prevent distal migration of the splint. This often requires a strap that crosses the wrist.

Substitute for Weak or Absent Muscles

Orthoses are commonly used to assist patients in maximizing the functional use of an affected upper extremity. Orthoses may be used temporarily, as in the case of recovering nerve injuries or neurological diseases such as Guillain-Barré, or they may be prescribed for long-term use, such as in complete spinal cord injury or progressive neuromuscular conditions like postpolio syndrome. They are generally worn only during the day or for specific functional tasks. An orthosis successful in improving the ability to function is often much more accepted and appreciated by the patient than orthoses prescribed for other purposes.

Substitute for Weak or Absent Shoulder or Elbow Muscles

Proximal arm devices can support the shoulder and forearm to encourage motion of weak proximal musculature, allow for distal function, and enable occupational performance as well as prevent loss of motion and provide pain relief.

Suspension arm devices (Fig. 16-58) suspend from above the head, generally on an overhead rod that is

Figure 16-58 Suspension arm devices. **A.** Suspension sling with horizontal bar. **B.** Suspension sling without horizontal bar. **C.** Suspension arm support. (Adapted with permission from Redford, J. B. [Ed.]. [1986]. *Orthotics etcetera* [3rd ed.]. Baltimore: Williams & Wilkins.)

mounted to a wheelchair. The arm swings as in a pendulum from straps attached to the overhead rod. The ease of management and low cost have contributed to the long-standing popularity of these devices (Long & Shutt, 1986). The following variations are commercially available and in current use.

The suspension sling has a single strap suspended from the overhead rod. A horizontal balance bar with multiple holes for adjustment of the fulcrum supports separate wrist and elbow cuffs. The suspension sling without horizontal bar has two straps that originate directly from the overhead rod with cuffs to support the elbow and wrist. The suspension arm support has a forearm trough suspended from a single point on the overhead rod. It can also be easily attached to an overhead frame on the patient's bed. Springs of various tensions may be added to the straps that support the limb, allowing a patient with only slight active motion to produce accelerated shoulder movement by bouncing the arm up and down. Suspension devices can be adjusted to allow for certain motions (Procedures for Practice 16-2) but lack the fine adjustment that extremely weak patients may need.

Figure 16-59 Mobile arm support.

PROCEDURES FOR PRACTICE 16-2

How to Adjust Suspension Arm Devices

Suspension Arm Sling

- For horizontal abduction, rotate the overhead rod laterally.
- For horizontal adduction, rotate the overhead rod medially.
- For external rotation, move the arm cuffs back on the balance bar to shift weight toward the elbow.
- For internal rotation, move the arm cuffs forward on the balance bar to shift weight toward the hand.
- For elbow flexion, move the point of suspension backward on the overhead rod to put the hand toward the patient's face.
- For elbow extension, move the point of suspension forward on the overhead rod to put the hand away from the patient's face.
- For height adjustments, vary the length of the strap or straps that connect to the overhead rod; or raise or lower the bracket on the wheelchair upright.

Suspension Arm Support

- For horizontal motion and height adjustments, see list under Suspension Arm Sling.
- For elbow flexion, move the rocker arm farther from the trough elbow dial.
- For elbow extension, move the rocker arm closer to the trough elbow dial.

A **mobile arm support** (MAS) (Fig. 16-59) is a mechanical device that supports the weight of the arm and provides assistance to shoulder and elbow motions through a linkage of ball-bearing joints (Long & Shutt, 1986; Lunsford, 1997; Yasuda, Bowman, & Hsu, 1986). The MAS is typically mounted to a patient's wheelchair, but it can also be attached to a tabletop. Their mechanical principles are threefold: (1) use of gravity to assist weak muscles, (2) support of the arm to reduce the load on weak muscles, and (3) reduction of friction by using ball-bearing joints. Criteria for use include:

- A defined functional need.
- An adequate source of power from neck, trunk, shoulder girdle, or elbow muscles.
- Adequate motor control such that the patient can contract and relax functioning muscles.
- Sufficient passive joint range of motion, with 0–90° of shoulder flexion and abduction, 0–30° of external rotation, full internal rotation and elbow flexion, and 0–80° of pronation preferred.
- Stable trunk positioning.
- A motivated patient.
- A supportive environment that provides the patient with the opportunity and assistance to use the device.

Patients who may benefit include those with cervical spinal cord injury, muscular dystrophy, Guillain-Barré

Figure 16-60 Standard components of a MAS.

syndrome, amyotrophic lateral sclerosis, poliomyelitis, and polymyositis.

Selection of MAS components, assembly of parts, and balance and adjustment of the MAS generally requires postgraduate hands-on training. Balance and adjustment principles are presented in Procedures for Practice 16-3 to give the reader a basic overview and appreciation for what is possible. This does not negate the need for additional training or consultation with experienced therapists to ensure that the best possible adjustments are made to give the patient maximal mechanical advantage.

The standard MAS assembly described in this chapter consists of an adjustable arm positioner bracket (also known as a semireclining bracket), standard proximal and

distal arms, a standard rocker arm assembly, and a basic forearm trough (Fig. 16-60). The many commonly used special MAS component parts include the outside rocker arm assembly and the elevating proximal arm (Fig. 16-61). The outside rocker arm (or offset swivel) has a ball-bearing joint that allows for greater freedom in vertical motion, thus facilitating hand-to-mouth or hand-to-table movements. The elevating proximal arm is useful for a patient with poor to fair deltoid strength. As the patient initiates the elevating motion, the rubber band assists, allowing the patient to flex and abduct the humerus to a higher level. A less complicated and more user friendly MAS system is also available (Fig. 16-62). It is easier to set up and allows adjustments to be made without any tools.

Figure 16-61 Special MAS components: **A.** Outside rocker arm. **B.** Elevating proximal arm.

PROCEDURES FOR PRACTICE 16-3

MAS Assembly and Training Principles

How to Assemble and Balance the Standard MAS Assembly

- Assemble tools (Phillips and flathead screwdrivers, Allen wrenches) and MAS parts (bracket, proximal arm, distal arm, rocker arm, trough).
- Inspect ball-bearing components for smooth operation.
- Ensure that the patient is seated properly in the wheelchair, with pelvis well back in chair and trunk in good vertical alignment.
- Fit the trough to the patient's arm by bending the elbow dial toward the radial side of the trough.
- Attach the rocker arm to the trough by placing the screws in the third and fifth holes from the dial.
- Attach the bracket to the wheelchair at approximately the midhumerus level so that it is neutrally rolled¹ and pitched².
- Attach the proximal arm to the bracket.
- Attach the distal arm to the proximal arm.
- Attach the trough to the distal arm.
- Balance the arm support to neutral by adjusting the pitch of the bracket and the distal end of the proximal arm so that the bearing tubes are perpendicular to the floor.
- Place the patient's arm in the trough.
- Observe for abnormal shoulder elevation and adjust the height of the bracket as needed to correct it.

MAS Hand-to-Mouth Movement Pattern

Instructions to Patient

- Push down on the trough dial while adducting your humerus.
- Externally rotate your shoulder.
- Shift your body weight toward the MAS.
- Straighten up or lean back in your chair.
- Rotate your trunk toward the MAS.
- Turn your head toward the MAS.

Equipment Adjustments to Aid this Motion

- Move the rocker arm farther from the trough elbow dial.
- Pitch the MAS at the bracket assembly toward the wheelchair back.
- Raise the bracket assembly on the wheelchair upright.

¹Roll is the rotation of the bracket assembly on the wheelchair upright governing the side-to-side (horizontal) slope. The name comes from the side-to-side swaying of a ship.

²Pitch is the tilt of the ball-bearing tube on the bracket assembly governing the upward-downward (vertical) slope. The name comes from the backward-forward pitch of a ship as it goes over waves.

MAS Hand-to-Table Movement Pattern

Instructions to Patient

- Lift and internally rotate your shoulder to lower your hand.
- Shift your body weight away from the MAS.
- Roll your shoulder forward.
- Rotate your trunk away from the MAS.
- Tilt or turn your head away from the MAS.

Equipment Adjustments to Aid this Motion

- Move the rocker arm closer to the trough elbow dial.
- Pitch the MAS at the bracket assembly toward the patient's feet.
- Lower the bracket assembly on the wheelchair upright.

MAS Horizontal Abduction and Adduction Movement Patterns

Instructions to Patient

- Shift your body weight in the direction you want to move.
- Rotate your trunk toward the direction you want to move.
- Turn your head briskly in the direction you want to move.

Equipment Adjustments to Aid this Motion

- Roll the bracket assembly on the wheelchair upright toward the patient for adduction.
- Roll the bracket assembly on the wheelchair upright away from the patient for abduction.

MAS Controls Training and Use Training

Controls Training

- Teach the patient the effects of head, trunk, and proximal movements on the movement of the MAS.
- If bilateral MASs are used, begin with one side first.
- Begin with horizontal motions by having the patient practice moving the MAS as far as possible from side to side and front to back.
- Proceed with vertical motions by having the patient practice moving the hand to the table and up to the mouth at various points within the horizontal range.

Use Training

- Teach the patient to use the MAS for specific desired functional activities, such as eating, grooming, writing, keyboarding, page turning, and power wheelchair driving.
- Encourage practice and independent problem-solving skills.

Figure 16-62 JAECO/Rancho MultiLink MAS.

An alternative MAS design, the linear MAS (Fig. 16-63), uses linear bearings and straight rods without joints. This streamlines the overall width of the support and lets wheelchairs more easily fit through doorways (Clark, Waters, & Baumgarten, 1997).

For a patient who can walk, a gunslinger orthosis can provide both proximal stability and mobility. This type of shoulder–elbow orthosis consists of a metal forearm trough that is mechanically coupled to a plastic hemigirdle anchored on the patient’s pelvis. This device is most useful for patients having good distal function but proximal weakness from brachial plexus injuries, spinal cord injuries, or postpolio syndrome. Prefabricated gunslingers (Fig. 16-11) are commercially available, but for long-term use, a custom-designed orthosis (Fig. 16-12) is indicated (Lunsford, 1997).

Depending on the patient’s proximal muscle status and specific functional needs, the coupling between the trough and hemigirdle base can be customized to permit a variety of motions, such as glenohumeral internal–external rotation and flexion–extension. It can also be made to hold a very weak shoulder in a static position for function, which may be with the hand in midline. If the wrist also has weakness, the trough can be extended to support the hand. Usefulness must be determined for each individual case, con-

Figure 16-63 Linear MAS.

Figure 16-64 Custom dynamic elbow orthosis with flexion assist. (Adapted with permission from Goldberg, B., & Hsu, J. S. [Eds.]. [1997]. *Atlas of orthoses and assistive devices* [3rd ed.]. St. Louis: Mosby.)

sidering factors such as acceptance by the patient, ease of donning, cost, and especially functional benefit.

For patients having selective loss of elbow flexion strength, a dynamic elbow orthosis with an elbow flexion assist (Fig. 16-64) may be used. This functional orthosis typically has a spring-loaded elbow mechanism with a ratchet lock. When the patient initiates flexion using residual muscles or compensatory motions, the spring device assists with elbow flexion. A release button allows the elbow to be repositioned into greater flexion or to drop down into extension (Lunsford, 1997).

Substitute for Weak or Absent Wrist or Hand Muscles

The combination of sensory loss and motor imbalance caused by a peripheral nerve injury greatly impairs normal hand function. As Colditz (2002b) points out, it is impossible to build an external device that can substitute for the intricately balanced muscles that a splint attempts to replace. In splinting nerve palsies, the key concept is to understand the patient’s condition and neuromuscular status so as to prescribe or design an appropriate splint to increase function. Splints should keep areas of intact sensibility free if possible, should be as simple as possible, and should not immobilize joints unnecessarily. The splinting program must be closely monitored and altered in response to nerve recovery as the patient’s muscle status changes (see Case Example). In a study to assess factors that influenced splint wear in peripheral nerve lesions, the only significant variable was a positive effect as perceived by the patient. Fifty-two percent of patients reported terminating wear because splints hindered their daily life, and 23% reported terminating wear because splints had not been of any use. Interestingly, the highest effectiveness score was for day splints for the dominant hand aimed at replacing function (Paternostro-Sluga et al., 2003).

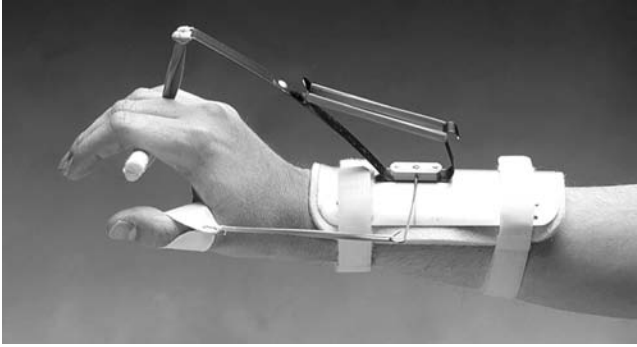

Figure 16-65 Bunnell™ Thomas Suspension Splint.

Radial nerve palsy, commonly associated with humeral fractures, can result in the complete loss or partial weakness of wrist, finger, and thumb extensors and weakness of forearm supination and thumb abduction. The loss of wrist extensor strength devastates hand grasp. Not only is the patient unable to position the hand properly, but the inability to stabilize the wrist in extension impairs normal function of the long finger flexors. Loss of extrinsic finger extension is much less of a functional problem, as the unaffected intrinsic muscles can actively extend the IPs. Supporting the wrist in extension is the primary goal of radial nerve splinting, and the use of a simple static wrist splint may suffice in improving hand function (Fess et al., 2005).

Prefabricated radial nerve splints, such as a Thomas suspension splint (Fig. 16-65) or a wire-foam splint, are designed to dynamically extend the wrist, MCPs, and thumb. It is usually preferable not to include the thumb because of the limitation in intrinsic motion it imposes and the danger of stressing the MP collateral ligament through poorly directed forces. Adding individual finger

loops to the palmar bar, thus removing bulk in the palm and allowing individual finger motion, can enhance the Thomas suspension splint. The palmar bulk of the wire-foam splint often impedes the ability to grasp large objects. *Caution should be used when prescribing a dynamic orthosis because strong unopposed flexors may easily overcome the dynamic forces trying to hold the wrist and hand in extension, negating functional benefits.*

A custom-fabricated radial nerve splint, also known as a Colditz splint, has been designed to allow for partial wrist and full finger motion and a facsimile of a normal tenodesis effect (Fig. 16-66). This splint consists of a low-profile outrigger attached to a dorsal forearm base (Figs. 16-5 and 16-67). Nonelastic cords connect the splint base to finger loops. The cord length is adjusted so that, when the MCPs actively flex, the wrist is brought into extension. Conversely, when the wrist flexes, the cord tension causes the MCPs to extend. Little training is required for the patient to be able to use the splint functionally, and grasp and release of objects is greatly enhanced. Further advantages of this splint are the maintenance of normal hand arches, the absence of splinting material covering the palm, the low-profile design, and the facilitation of wrist extensor strength as return of nerve function occurs (Colditz, 2002b). Pre-formed splints and outrigger kits are commercially available.

Splinting in median nerve palsy is geared toward substituting for weak or absent thenar muscles that render the thumb unable to pull away from the palm and oppose to the fingers. This is most often accomplished through a custom-fabricated thermoplastic opponens splint, which stabilizes the thumb in a position of abduction and opposition to enable pulp-to-pulp pinch (Fig. 16-25). Although such a splint often greatly improves fine motor prehension, this must be individually assessed because substitu-

Figure 16-66 Normal tenodesis effect. **A.** When the wrist is extended, the fingers flex. **B.** When the wrist is flexed, the fingers extend.

Figure 16-67 Custom thermoplastic radial nerve splint using low-profile Phoenix Extended Outrigger.

tion patterns from unaffected thumb muscles may provide sufficient thumb function (Colditz, 2002b; Fess et al., 2005). Patients may choose to wear an opposition splint for selected activities only.

In the presence of ulnar nerve palsy, the hand assumes a claw position, or intrinsic-minus position, with ring and small finger hyperextension of the MCPs and flexion of the IPs. This is a result of weakness or loss of lumbrical and interossei muscles, which are responsible for MCP flexion and IP extension. The prime splinting objective is to assist in grasp and release of objects by preventing the claw position. This is accomplished by a lumbrical bar splint, which blocks the MCPs in slight flexion, allowing the force of the unaffected long finger extensors to extend the IPs.

Dynamic splints, such as prefabricated spring wire splints (Fig. 16-41), do not work well because the spring tension is usually not sufficient to hold the MCPs in flexion when the patient actively opens the hand. Thus, the MCPs hyperextend against the force, which actually strengthens the long extensors and encourages deformity (Colditz, 2002b).

A static custom-molded thermoplastic splint is advocated as the best solution. It should be non-bulky, carefully molded to distribute pressure evenly over the dorsum of the proximal phalanges, and designed so as not to obstruct full flexion of all joints (Colditz, 2002b; Fess et al., 2005). The splint may include just the affected ring and small fingers (Figs. 16-3 and 16-68) or may include all fingers to distribute pressure more effectively and comfortably (Fig. 16-42). The latter splint is used in the treatment of combined median and ulnar nerve injuries, which result in the clawing of all four fingers.

For a patient who has only radial nerve function, a custom-fabricated RIC (Rehabilitation Institute of Chicago)

Figure 16-68 Custom thermoplastic lumbrical bar splint for ring and small fingers.

Figure 16-69 Custom thermoplastic RIC tenodesis splint.

Figure 16-70 Economy Wrist Support with Universal Cuff.

tenodesis splint (Fig. 16-69) may be used. This splint can provide minimal hand grasp by harnessing the power of the wrist extensors to bring the thumb, index finger, and long finger into a functional pinch. It has three molded thermoplastic pieces: one to position the thumb, one to position the index and long fingers, and a wrist cuff to serve as the base for connecting a static line from the wrist to the fingers (Colditz, 2002b).

Static orthoses, which allow passive holding of functional implements such as utensils or pens, may also be used in the presence of wrist or hand weakness. Examples include a hand-based universal cuff, an economy wrist support with universal cuff (Fig. 16-70), and a short or long design Wanchik writing splint (Fig. 16-71).

For patients with long-term or permanent loss of muscle function, as is the case in complete spinal cord injury or progressive neuromuscular disease, permanent functional orthoses may be used. These orthoses are fabricated by experienced orthotists from metal and are recommended by occupational therapists for individual patients based on neuromuscular status and specific functional needs.

Figure 16-72 Custom metal ratchet wrist-hand orthosis.

Often these distal orthoses are used in conjunction with proximal ones (such as a MAS) if proximal weakness is also present.

A ratchet wrist-hand orthosis (Fig. 16-72) may be used for patients with weak (below grade 3) wrist extension and finger strength, such as that seen with C5 tetraplegia (see Chapter 43). A thumb post positions the thumb in abduction and in alignment with the index and long fingers, and a finger piece assembly maintains the index and long fingers in a position for pinch. A ratchet system is used to close the hand in discrete increments. Closing is accomplished by manually pushing the finger piece to flex the fingers against the thumb using the contralateral hand, the chin, or the side of a table or chair. Release is accomplished by a spring that is activated by the press of a release button (Clark, Waters, & Baumgarten, 1997; Lunsford, 1997).

For patients with the potential for neurological return at the C6 level, a wrist-action wrist-hand orthosis (Fig. 16-73) can be used as a transition system (Clark, Waters, & Baumgarten, 1997). This orthosis allows for free wrist motion, with stops that can be adjusted to limit motion to a prescribed range. When no wrist extensors are present, the wrist is locked into a set position. As recovery occurs and

Figure 16-71 Wanchik writing splints. **A.** Short design. **B.** Long design.

Figure 16-73 Custom metal wrist-action wrist-hand orthosis with rubber band assist.

strength increases, progressive range of motion is allowed. Rubber bands are often attached to provide an extensor assist to weak muscles.

A **wrist-driven wrist-hand orthosis** (WDWHO) (Fig. 16-74) may be indicated for patients having 3+ or greater wrist extensor strength, such as a patient with C6 tetraplegia. Using the principle of tenodesis (Fig. 16-66), this type of flexor hinge orthosis transfers wrist extensor power to the fingers for grasping. Active wrist extension operates a mechanical linkage transferring power to flex the index and long fingers against the thumb. A properly adjusted orthosis allows for 1 pound of pinch for every 2 pounds of wrist extensor force. Gravity-assisted wrist flexion opens the hand for release. An activating lever at the wrist controls the size of the opening and the resultant position of prehension to allow for grasp of various size objects and different pinch forces.

Fitting the patient with bilateral WDWHOs may be tempting, but patients do not typically achieve a higher level of function with two orthoses than with one (Clark, Waters, & Baumgarten, 1997). Bilateral orthoses are difficult to use, requiring a great deal of balance, coordination, and practice to become successful. If the patient has inadequate proximal strength, it may be difficult to bring the arms into midline. If sensation has been lost, the patient must rely on visual compensation, which also makes bilateral orthotic use difficult. A patient generally uses one WDWHO, with the contralateral hand serving as a gross assist. Training principles are listed in Procedures for Practice 16-4.

Figure 16-74 Custom metal wrist-driven wrist-hand orthosis.

PROCEDURES FOR PRACTICE 16-4

WDWHO Controls Training and Use Training

Controls Training

- The patient needs to become proficient in basic orthotic skills, such as picking up, placing, and releasing objects of various sizes, textures, densities, and weights.
- Soft medium-sized objects or 1-inch firm, semirough objects are often best to start with; progress to more difficult objects as skill level increases.
- Encourage skills practice from a variety of heights because the patient may have to learn to abduct and internally rotate the shoulder to approach and handle objects appropriately.

Use Training

- Teach the patient to use the WDWHO to perform specific functional tasks, such as writing, eating, and oral hygiene.
- Have the patient practice activities under various conditions to encourage independent problem solving and spontaneous use of the orthosis.

Given the cost and complexity of fabrication and training, follow-up studies have been done to assess whether patients use WDWHOs over the long term after discharge from therapy. Knox, Engel, and Seibens (1971) reported a 51% continued use rate; Shepherd and Ruzicka (1991) reported a 50% rate; and Allen (1971) reported a 43% rate. Factors that were reported to contribute to continued use are education, commitment, and involving the patient in the orthotic decision-making process (Knox, Engel, & Seibens, 1971); the ability to don the orthosis easily (Allen, 1971); and adequate training, acceptance, internal motivation, and strong functional or vocational goals (Shepherd & Ruzicka, 1991). In these same studies, reasons for orthotic discontinuation were stated by subjects to be improvement in muscle strength, use of alternative methods or equipment to perform tasks previously done with the WDWHO, poor fit, bulk, and the orthosis taking too long to put on.

Prevent Contractures or Modify Tone

Careful attention to positioning in the presence of wound healing, muscle imbalance, abnormal muscle tone due to stroke or brain injury, or motor disorders such as cerebral palsy is critical in the prevention of loss of range of motion, which can lead to functional or skin hygiene problems. Many of the static splints, casts, and orthoses previously mentioned for immobilization, stabilization, or substitution can be used for this purpose. Examples of these include acute burn immobilization splints to pre-

Figure 16-75 Commercial inflatable pressure splint.

vent wrist and digital contractures, wrist extension splints to prevent contractures caused by wrist drop, thumb abduction splints to prevent thumb adduction contractures, and lumbrical bar splints to prevent MCP hyperextension and IP flexion contractures.

Ideally, these splints should not limit function, exert excessive stress to soft tissues, or interfere with movement of uninvolved joints. If splints are not required for functional use, often it is possible for patients to wear static positioning splints at night only. In addition to the prevention of contractures, splints may be used to prevent shortening of the muscle-tendon unit. For example, a volar thermoplastic or plaster splint worn at night to position the wrist and fingers in maximum composite extension can help to prevent tightness of the long finger flexors (Tribuzi, 2002).

Lapboards, arm troughs, and suspension arm slings can help to position the upper extremities properly. Bivalved plaster casts or anteroposterior splints (Fig. 16-48) can be used to maintain range of motion, especially in the presence of increased tone. *Care must be taken to avoid pressure problems by ensuring that casts are properly padded and the skin is closely monitored.*

An inflatable pressure splint (Fig. 16-75), originally designed as an emergency immobilizer for the limbs, has been adopted for use in patients with abnormal tone. When inflated, it provides deep pressure and warmth, and depending on how it is used, it can either reduce tone in hypertonic extremities or increase tone in hypotonic extremities. It may be worn as a precursor to movement therapy or during weight-bearing activities to help position the limb. A study of 18 patients with CVA who wore the splint for 30 minutes a day, 5 days per week, for 3 weeks found no significant difference in upper extremity sensation, pain, and motor function between the splinted and control groups, leading the authors to suggest further study as to the long-term effects that inflatable splints may have on tone (Poole et al., 1990).

The use of thermoplastic splinting in the modification of tone in the wrist and hand continues to be controversial in the literature and in practice. A survey of occupational therapists clearly demonstrated the conflicting practices in splinting (Neuhaus et al., 1981). Opponents of splinting argue that splinting may lead to

increased muscle tone, joint stiffness, and muscle atrophy and may interfere with treatment aimed at facilitation and functional use. Proponents of splinting contend that splinting can reduce tone (McPherson, Becker, & Franszczak, 1985; Neuhaus et al., 1981). In a systematic review of hand splinting to prevent contracture and reduce spasticity following stroke, Lannin and Herbert (2003) found insufficient evidence to either support or refute its effectiveness.

Literature regarding optimal thermoplastic splint designs and wearing times shows no consensus. Static designs may be volar or dorsal, and comparative studies have been done in attempts to determine quantitatively which design is more effective in tone reduction. A study by McPherson et al. (1982) demonstrated no significant difference between the two basic splint designs and encouraged therapists to reexamine the amount of wearing time prescribed so that tonal reduction occurs without unwarranted secondary stiffness.

A design clinically studied by McPherson (1981) used a dorsal forearm base, volar finger and thumb pans, and finger abductors to position the wrist in 30° of extension, the MCPs in 45° of flexion, the IPs in full extension, the fingers fully abducted, and the thumb in extension and abduction. McPherson reported that splint wearing resulted in a reduction of tone related to the length of time that subjects wore the splint and that the effects of splint wearing were not necessarily permanent.

Common static splint designs include resting pan splints, finger spreaders or abduction splints, and cone splints (Coppard & Lohman, 2001; Jacobs & Austin, 2003). Several pre-formed splints are commercially available (Figs. 16-76 and 16-77), but no clinical studies have been done to establish their fit and effectiveness.

Dynamic splint designs have also been developed to reduce tone in the wrist and hand. In a study of eight subjects, the finding was a greater reduction in hypertonus using a dynamic splint as compared with static splints and passive range of motion (McPherson, Becker, & Franszczak, 1985). Scherling and Johnson (1989) studied the effects of their dynamic splint design on 18 subjects, with all subjects achieving varying degrees of tone reduction with a minimum of 4 hours of splint use per day.

Soft splints made of neoprene can be custom fabricated (Casey & Kratz, 1988) or purchased commercially. A hand-based thumb loop can be used to decrease tone and position the thumb out of the palm for function (Fig. 16-78). To position the forearm, a long neoprene strap can be added to the hand splint.

A thermoplastic hand-based inhibitive weight-bearing splint described in the treatment of children with increased flexor tone (Coppard & Lohman, 2001; Kinghorn & Roberts, 1996) can also be used with adult patients having hypertonicity. This volar splint is custom fabricated to hold the fingers in extension and thumb in ra-

Figure 16-76 Rolyan® Anti-Spasticity Ball Splint with Slot and Loop Strapping.

dial abduction to enable the hand to be in an optimum position for upper extremity weight-bearing activities (Fig. 16-79).

Splinting may be an effective means of providing a low-cost, noninvasive method for decreasing tone in some patients but may not be effective in others (Langlois, Pederson, & Mackinnon, 1991). Continued research on the long-term effectiveness of splinting for tone reduction and the key patient variables that contribute to that effectiveness is needed. Meanwhile, therapists must carefully decide on splint use and monitor outcomes patient by patient.

SPECIALIZED PERMANENT FUNCTIONAL ORTHOSES

Permanent functional orthoses represent a great investment of time, cost, expertise, and commitment to fabrication, fit, training, and use by the patient-therapist-orthotist team. Proper fit, training, and successful func-

Figure 16-77 Progress™ Dorsal Anti-Spasticity Splint.

tional use are accomplished only through close collaboration and communication among all who participate in the process. As with all orthoses, this process should begin with careful consideration of functional needs, achievable goals, and education of the patient and significant others in orthotic purpose and selection. Providing the patient with opportunities to interact with experienced users of similar equipment can be quite helpful to the patient, both before the prescription and during training.

A permanent orthosis that is useful to the patient must be valued, accepted, and incorporated into the patient's body image. A prime prerequisite to acceptance is that the orthosis allows the patient to do something meaningful that cannot otherwise be done without it (Long & Shutt, 1986; Yasuda, Bowman, & Hsu, 1986). Since the orthosis will be used over the long term, the patient and caregivers must also be told whom to contact should problems arise after the therapy program has ended.

The principles of orthotic training are similar to those of prosthetics. They include testing of fit and mechanics; teaching the patient the names and functions of component parts; care of the orthosis; donning and doffing of the orthosis; controls training; and functional use training. Intensive practice under various conditions to encourage independent problem solving by the patient and skilled spontaneous use is a key element of training. Following is a closer look at two commonly used permanent functional orthoses.

Mobile Arm Supports

As described earlier in this chapter, the MAS (Figs. 16-59 and 16-60) is a mechanical device prescribed to support the weight of an arm and assist weak proximal muscles for function.

Figure 16-78 Rolyan® Thumb Loop.

Patient and Caregiver Education

If the patient has been actively involved in the decision making, a brief review of the MAS's purpose and capabilities should be sufficient. The patient and caregiver should be oriented to key component names and how they operate. Finally, they should know how to care for and maintain the orthosis.

Assembling and Balancing

Procedures for Practice 16-3 has instructions on how to assemble and balance the standard MAS assembly.

Training and Adjusting

Adaptive equipment or a WHO is commonly used in conjunction with the MAS, and these should be integrated during all phases of MAS training and adjusting. Once the

patient is proficient with basic movement patterns, MAS training with all of the activities that the patient is interested in performing should be done. Any of these activities may require various fine component adjustments before final MAS adjustments are completed. Periodic follow-up may be required, especially with a growing child. Procedures for Practice 16-3 has information related to MAS training and adjusting.

Orthotic Checkout

Once final adjustments have been completed, bolts and screws should be checked for a secure fit. A MAS appraisal form (Fig. 16-80) can be used to ensure that all important details are assessed.

Wrist-Driven Wrist-Hand Orthosis

A WDWHO (Fig. 16-74), as previously described, is used to enhance hand function in the presence of distal muscle weakness by using wrist extensor power to enable prehension.

Orthotic Checkout

The therapist must begin with a careful inspection of the orthosis both on and off the patient. Optimal fit is crucial for maximum function. Ensuring smooth operation of mechanical parts, proper positioning of the digits for pad to pad prehension, and proper location of splint joint axes at the wrist and second MCP is essential. The strength of pinch should be assessed, and the length of the transfer bar should be changed by the orthotist to increase pinch strength as needed.

Straps should facilitate independent application and removal of the orthosis. Loops added to the ends of

Figure 16-79 Custom thermoplastic hand-based weight-bearing splint.

Occupational Therapy Department

MOBILE ARM SUPPORT APPRAISAL

Patient's Name _____

Type of MAS (L) _____

Date Fitted _____

Type of MAS (R) _____

I. PATIENT'S POSITION IN WHEELCHAIR

YES	NO	N/A	Are hips well back in wheelchair?
YES	NO	N/A	Is spine in good vertical alignment?
YES	NO	N/A	Does patient have lateral trunk stability?
YES	NO	N/A	Is wheelchair set-up providing adequate comfort and stability?
YES	NO	N/A	Is patient sitting in maximum upright position possible?
YES	NO	N/A	Does patient have needed hand splints on?
YES	NO	N/A	Does patient meet requirements for passive range of motion?

II. MECHANICAL CHECKOUT

YES	NO	N/A	Are all screws tight?
YES	NO	N/A	Is bracket tightly secured on wheelchair?
YES	NO	N/A	Are all MAS arms and joints freely movable?
YES	NO	N/A	Is proximal arm inserted completely in bracket bearing tube?
YES	NO	N/A	Is distal arm inserted completely in proximal arm bearing tube?
YES	NO	N/A	Is bracket at proper height so shoulder is not forced into elevation?
YES	NO	N/A	Does elbow dial clear lapboard when trough is in "up" position?
YES	NO	N/A	Is patient's hand (in "up" position) as close to mouth as possible?
YES	NO	N/A	Can patient obtain maximum active reach?
YES	NO	N/A	Is patient's arm secured in trough?
YES	NO	N/A	Is trough long enough to give maximum support to forearm?
YES	NO	N/A	Is trough short enough to allow wrist flexion if desired?
YES	NO	N/A	Are trough edges rolled so that they do not contact forearm?
YES	NO	N/A	Is elbow secure and comfortable in elbow dial?
YES	NO	N/A	Is trough balanced correctly?
YES	NO	N/A	During vertical motion, is elbow dial free of distal arm?
YES	NO	N/A	Are vertical stops correctly placed for both up and down motions?
YES	NO	N/A	Are rubber band hooks secured?
YES	NO	N/A	Are rubber bands securely attached?

Figure 16-80 Mobile Arm Support Appraisal Form.

III. CONTROL CHECKOUT

YES	NO	N/A	Can patient control motion of proximal arm from either extreme?
YES	NO	N/A	Can patient control motion of distal arm from either extreme?
YES	NO	N/A	Can patient control vertical motion from either extreme?
YES	NO	N/A	Have stops been applied to limit motion, if necessary?
YES	NO	N/A	Does patient accomplish maximum horizontal reach in front of body?
YES	NO	N/A	Can patient easily reach mouth?
YES	NO	N/A	Can patient easily reach tabletop?
YES	NO	N/A	Can patient horizontally adduct arm sufficiently to clear doorways?
YES	NO	N/A	Is performance consistent from day to day?

IV. USE CHECKOUT

YES	NO	N/A	Are fine adjustments necessary to enable patient to perform different activities?
YES	NO	N/A	Are there some tasks that patient can perform better without MAS?
YES	NO	N/A	Is patient able to instruct caregivers in how to assemble MAS components?
YES	NO	N/A	Have patient and caregivers been instructed in care of MAS?

Figure 16-80 (continued).

the straps enable the patient to use the thumb of the other hand to fasten and unfasten them with increased ease.

The patient's ability to don and doff the orthosis is strongly related to independence in activities and to the patient's ultimate acceptance of the device. This is true especially if the patient must remove the orthosis to perform other activities such as propulsion of a wheelchair. Removal of the WDWHO is typically easier than application of it. With training, donning the orthosis can be accomplished in less than a minute (Clark, Waters, & Baumgarten, 1997). Initially, the orthosis should be placed on the patient for no more than 30 minutes. Upon removal, the skin should be carefully checked for any areas of redness. These red areas should be reassessed in half an hour, and if they are still present, the orthosis requires adjustment before the patient can use it. Once pressure problems have been resolved, wearing time can be gradually increased.

Patient and Caregiver Education

A brief review of the WDWHO's purpose and capabilities should be provided. The patient and caregivers should be

instructed in the importance of skin inspection to prevent excessive pressure and skin breakdown. Accordingly, they should also be taught wearing tolerance and the schedule. They should be oriented to key component names and how the components operate prior to orthotic controls training. Finally, they should know how to care for and maintain the orthosis. Education in these areas should be reinforced throughout the orthotic training process.

Controls Training and Functional Use Training

Procedures for Practice 16-4 shows WDWHO controls training and use training.

EFFICACY AND OUTCOMES

The state of best evidence about upper extremity orthoses is limited at best (Evidence Table 16-1). Most published materials are anecdotal, based on clinical experience, or of varying study quality. Further research is needed to enhance our knowledge of splinting efficacy and variables that lead to optimum outcomes.

Evidence Table 16-1

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Hand splinting to prevent contracture and reduce spasticity following stroke	Different types of splints and splint designs.	230 patients.	Splint wear for unknown time up to 11 weeks, various wearing patterns.	Meta-analysis of 21 studies.	Insufficient evidence to either support or refute the effectiveness of hand splinting for adults following stroke.	Heterogeneity of study design, methods, splint design and regimen, and outcomes prevented the pooling of data to determine effect size.	Lannin & Herbert, 2003
Splinting for lateral epicondylitis	6 splint designs.	362 participants (277 patients and 85 normal subjects).	Splint wear for test session up to 4 weeks.	Systematic review of 11 studies.	Yes. Early positive, but not conclusive, effectiveness of splinting.	Not reported.	Borkholder et al., 2004
Splinting for carpal tunnel syndrome	Different types of splints and various angles of immobilization.	197 patients (242 hands).	Splint wear for 1–12 weeks, night only or night and day.	Systematic review of 6 studies.	Yes. Significant benefits from splinting across different splint types and wrist angles.	Not reported.	Muller et al., 2004

<p>Splinting for pain relief in thumb arthritis</p>	<p>Soft, pre-fabricated CMC/MP splint vs. rigid custom-made CMC splint.</p>	<p>25 patients with stage I or II osteoarthritis of the first CMC.</p>	<p>Randomly assigned to wear one splint for 1 week, followed by the other splint for 1 week.</p>	<p>Randomized controlled trial. IB1b</p>	<p>Yes. Significant decrease in pain. Greater reduction in pain when wearing soft splint. Pinch strength greater wearing soft splint. Higher satisfaction with soft vs. rigid splint. Problematic ADL easier to do using the soft splint.</p>	<p>$p \leq 0.001$, $Z = 3.09$, $r = 0.62$ $p = 0.019$, $Z = 2.075$, $r = 0.41$ $p = 0.012$, $Z = 2.26$, $r = 0.45$ $p \leq 0.001$, $Z = 3.09$, $r = 0.62$; 72% vs. 20% preferred soft splint 48% vs. 26% reported activities easier to do with soft splint</p>	<p>Weiss et al., 2004</p>
<p>Compliance-enhancing approach to resting hand splint wear</p>	<p>Approach emphasizing learning principles, sharing of expectations, positive affect and behaviors by therapist (therapeutic rapport), and patient assumption of responsibility vs. standard approach.</p>	<p>40 outpatients with rheumatoid arthritis and no prior referral for resting hand splints; mean age = 48.8 years.</p>	<p>Initial treatment session plus follow-up call at ~2 weeks. Splint wear for 28–56 days.</p>	<p>Randomized controlled trial. IB1b</p>	<p>Yes. The treated group showed greater compliance with splint wear vs. other group.</p>	<p>$t_{(38)} = -1.97$, $p = 0.056$, $r = 0.30$</p>	<p>Feinberg, 1992</p>

CASE

EXAMPLE

Orthotic Intervention in a Patient with Peripheral Nerve Injury

Occupational Therapy Intervention Process

Clinical Reasoning Process

	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information Ms. N., a 22-year-old woman 8 weeks post motor vehicle collision, was referred to outpatient occupational therapy for evaluation and splinting of her left arm. She had a brachial plexus traction injury and a humeral fracture, treated with a closed reduction and fracture brace (purpose: to immobilize for healing). Prior to her injury, she was right-hand dominant and employed full time as a secretary.</p> <p>On initial assessment, the following problems were identified as related to her left upper extremity: (1) poor positioning of the entire arm, with Ms. N. using her right arm to help and support the left arm; (2) absent motor function and impaired sensation throughout; (3) limited passive range of motion of the shoulder in all planes, forearm supination, MCP flexion, and thumb abduction; (4) traction pain in the shoulder; and (5) lack of functional use for any activities.</p>	<p>Appreciate the context</p> <p>Develop intervention hypotheses</p> <p>Select an intervention approach</p> <p>Reflect on competence</p>	<p>“Ms. N. is dealing with a significant injury with an enormous impact on her life. I am concerned not only about the status of her left arm, but also about the disruption of her routines and roles. She is obviously frustrated about not being able to work and having to ask her mother to help with most tasks. I need to help her feel empowered and instill hope for her future.”</p> <p>“I think that poor left arm positioning is the factor contributing most to her lack of occupational functioning. If I can free up her right arm for function, I believe this will go a long way in helping her cope with her injury.”</p> <p>“Orthoses will be an integral part of Ms. N.’s treatment and will need to be carefully selected based on her clinical and functional status. From reviewing the literature, I know that collaborating with the patient closely throughout the splinting process is crucial to a successful outcome. I also understand that recovery may occur at a slow rate and orthoses will need to be durable.”</p> <p>“I have treated patients having similar peripheral nerve injuries in the past and have seen good functional recovery occur in many cases. These past experiences have also taught me that I have to do what I can to help Ms. N. be patient since recovery time with these types of injury can be frustratingly slow.”</p>
<p>Summary of Short-Term Goals and Progress Ms. N. was fitted with a standard pouch sling that was easy to don and doff and supported the weight of her arm with the goals of pain relief and freeing her right arm for functional use (purposes: to support a painful joint and to protect tissues); she was also fitted with a custom-fabricated static wrist extension–thumb abduction splint to prevent the loss of wrist extension and to regain MCP flexion and thumb abduction range of motion (purposes: to prevent contractures and to restore mobility).</p>	<p>Assess the patient’s comprehension</p> <p>Understand what he or she is doing</p> <p>Ascertain the patient’s endorsement of plan</p> <p>Compare actual to expected performance</p> <p>Know the person</p> <p>Appreciate the context</p>	<p>“I think it is important to begin with an intensive program that will quickly address Ms. N.’s clinical and functional needs. Even though they have to travel a good distance from home, Ms. N. and her mother understand the importance of early therapy intervention to improve the prognosis for recovery. I acknowledge the hardship this causes for them, so I promise to minimize the therapy visits as much as possible.”</p>

Next Steps

As Ms. N.'s neuromuscular recovery progressed, the following orthoses were used in response to new problems and functional potential identified:

Week 11: The sling was discontinued, as shoulder and elbow strength had improved to 3 to 3+ and traction pain had resolved. Ms. N. continued to use the wrist extension–thumb abduction splint during the day. At night, Ms. N. wore a custom-fabricated composite wrist and finger extension static splint to prevent long flexor tightness from unopposed finger flexors that had regained 3+ strength (purpose: to prevent contractures).

Week 17: At night, Ms. N. wore a custom-fabricated serial static elbow extension splint to regain elbow extension range of motion lost to initial positioning from the sling, an ineffective home range-of-motion program, and return of unopposed 3+ elbow flexor strength (purpose: to restore mobility).

Week 21: A Colditz radial nerve splint was fabricated to substitute for weak muscles supplied by the radial nerve and to enhance hand function as long finger flexors and wrist flexors recovered to sufficient strength of 3+. Ms. N. wore this splint during the day to allow functional use of the hand during light tasks (purpose: to substitute for weak or absent muscles).

Week 26: The Colditz radial nerve splint was discontinued, as wrist and long finger extensors had regained 3+ strength. A custom-fabricated thermoplastic lumbrical bar splint for the ring and small fingers was issued to address residual weakness of intrinsic muscles innervated by the ulnar nerve, leading to clawing. Ms. N. wore this splint during the day to assist with hand opening and prevent IP flexion contractures (purposes: to restrict unwanted motion and to prevent contractures).

Week 28: A dynamic forearm rotation splint was fabricated from a commercial kit; Ms. N. wore it at night to regain full supination range of motion initially lost from positioning and an imbalance of forearm rotator muscle strength (purpose: to restore mobility).

Week 36: No further splinting was required, as Ms. N. had full neuromuscular recovery. Ms. N. was able to return to her previous employment with full functional use of her left arm.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if she should continue or discontinue therapy and/or return in the future

"I need to be ready to respond to Ms. N.'s unique needs. I need to closely monitor for changes in range of motion, motor function, and sensory function, and be on the lookout for development of deformity that may occur from muscle imbalance. I want to optimize her ability to use her left arm as soon as her clinical status allows. To enable an optimum functional and clinical outcome, I need to discontinue orthoses as soon as they become unnecessary and implement new orthoses as different needs arise."

"It is important to continuously educate Ms. N. on her status so she can see her recovery progressing and understand how important the various orthoses are to optimize her functional outcome."

"I also need to give Ms. N. the opportunity to voice her questions, concerns, and preferences so that we can work together to select the most appropriate orthoses and design optimal wearing schedules."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Selecting the Most Appropriate Orthoses for a Patient

Ms. N. is a young, socially active woman who was living independently. What would the therapist anticipate to be Ms. N.'s primary concerns in orthotic selection? How could the therapist best engage her in the orthotic selection process while determining priorities for her orthotic needs? What are the clinical and functional components that must be closely monitored to determine specific orthotic needs?

SUMMARY REVIEW QUESTIONS

1. What is the role of the occupational therapist in orthotic rehabilitation?
2. Define orthosis.
3. Name the purposes for which splinting may be used.
4. What are key factors for selecting an orthosis for a particular patient?
5. Discuss factors that may enhance splint wearing and those that may interfere with it.
6. Discuss why a static splint may be chosen and the precautions related to such splints.
7. Describe two dynamic splints and the purposes for which they are used.
8. Select an orthosis to decrease an elbow flexion contracture, discuss the reasons for your choice, and state the principle or principles that it implements.
9. Discuss two types of finger or hand orthoses that assist in restoring function while stabilizing a joint.
10. For which type of patient would you choose a wrist-driven wrist–hand orthosis?
11. Name the basic components of a standard MAS and two diagnostic categories of candidates who may benefit from its use.
12. Describe a treatment session to improve a patient’s hand-to-mouth and hand-to-table control of a MAS and basic adjustments that can be made to the MAS to facilitate these motions.
13. What are the pros and cons of various orthoses designed to modify tone?

ACKNOWLEDGMENTS

I thank Y. Lynn Yasuda, MSED, OTR, FAOTA, and Maura Walsh, OTR/L, CHT, for sharing their clinical expertise and advice; Michele Berro, MA, OTR/L, for assisting with obtaining photographs; Paul Weinreich (in memoriam), former Medical Photographer at Rancho Los Amigos National Rehabilitation Center, for his photography and technical support; and the colleagues and patients who inspire and teach me daily.

I acknowledge the following contributions:

CHAPTER 17

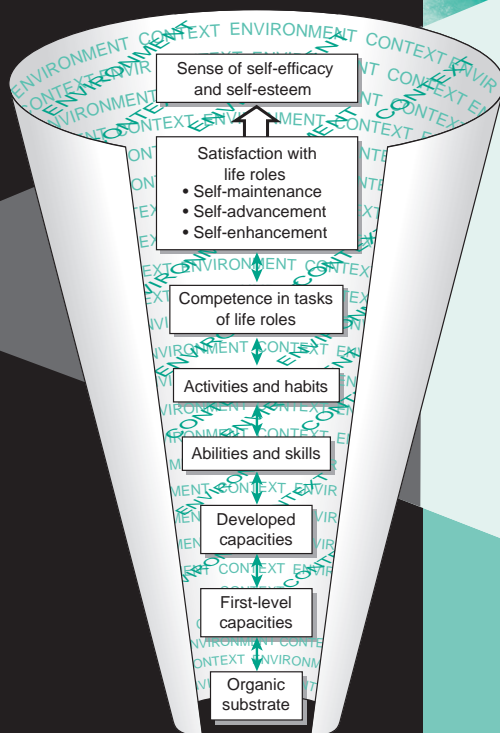

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the anatomical, bio-mechanical, and mechanical principles applied to splint construction.
2. Identify the properties, benefits, and limitations of various splinting materials.
3. Recognize factors affecting splint wear compliance.
4. Explain design, pattern making, and construction for three splints.
5. Describe the components of a splint checkout.

Construction of Hand Splints

Nancy Callinan

Glossary

Dual obliquity—Variance between the length and height of the metacarpals, with the radial side longer and higher than the ulnar side. These relationships must be considered when splinting the hand.

Dynamic splint—A splint that applies a mobile force in one direction while allowing active motion in the opposite direction. The mobile force is applied with rubber bands, elastic thread, or springs.

Fibroblastic phase—Stage of wound healing that follows the inflammatory phase, during which fibroblasts proliferate and initiate collagen production in the healing of tissues.

Haldex gauge—A spring gauge that precisely measures the grams of force for rubber band dynamic traction or torque angle curves.

Inflammatory phase—Phase of wound healing immediately following injury or surgery; characterized by edema and infiltration of leukocytes and macrophages to begin healing of the injured tissues.

Maturation phase—Stage of wound healing that follows the fibroblastic phase; characterized by wound contraction, remodeling, and maturation of the healed tissues.

Serial static splint—A splint with no moving parts designed to be remolded as a contracture improves.

Splint—A device applied to the body to provide protection, positioning, immobilization, restriction, correction, or prevention of deformity for the splinted part; an orthosis.

Static progressive splint—A splint designed to stretch contractures through the application of incrementally adjusted static force to promote lengthening of contracted tissues.

The hand is an incredible tool. Through a carefully orchestrated integration of muscles working together, the hand executes a range of functions from picking a delicate flower to firmly gripping a hammer. If disease or injury disrupts this balance and harmony of muscle power, the hand loses its remarkable skills. This impairment can be treated by splinting to maximize function and return the individual to meaningful occupational performance.

The art and science of occupational therapy are clearly evident in splint construction. In the design and construction of a **splint**, the therapist uses creativity combined with knowledge of the complex anatomy and biomechanics of the hand. An understanding of pertinent mechanical principles is necessary because a poorly designed splint can cause discomfort and further dysfunction of the hand. A thorough understanding of the patient's functional needs and clinical condition is also necessary to ensure that the splint meets the treatment goals. The therapist benefits from appreciation of a variety of splinting materials and their properties in the design and construction of splints.

Splints can have a significant effect on healing tissues and can greatly influence the remodeling of scar tissue. Applying the proper splint at the appropriate stage in healing can significantly influence functional outcome. The therapist must thoroughly evaluate the patient and the clinical condition to identify the appropriate splint in the course of rehabilitation.

Splinting is used in conjunction with other treatment strategies to enhance occupational performance; the splint, however, may also interfere with functional performance. The therapist must evaluate the effect of the completed splint on the patient during functional activities within the context of the patient's environment to

determine whether the splint contributes to the goals of treatment. A splint that impairs performance by causing poor compensatory patterns of movement may necessitate modification of the splint or the wearing schedule. Purposes of splinting are reviewed in Definition 17-1.

ANATOMICAL AND BIOMECHANICAL CONSIDERATIONS IN SPLINTING

The construction of hand splints must take into consideration certain anatomical facts and biomechanical principles.

Anatomical Considerations

Therapists apply a thorough knowledge of anatomy of the hand to their construction of hand splints. The creases of the hand provide landmarks for splint fabrication

DEFINITION 17-1

Purposes of Splinting

- Protection of structure at risk of injury
- Positioning for function
- Immobilization for healing
- Restriction of undesired motion
- Correction or prevention of deformity
- Substitution for absent or weak muscles

(Coppard & Lohman, 1996). These creases identify the axis of motion for the corresponding joint. The distal edge of a splint must not extend beyond a crease if motion at that joint is desired (Fig. 17-1). Bony prominences of the hand and wrist (Fig. 17-2) can create pressure points if the splint does not adequately conform to these areas. Potential pressure points are common on the dorsum of the hand and wrist. The arches of the hand (Fig. 17-3)—the distal transverse (metacarpal) arch, the proximal transverse (carpal) arch, and the longitudinal arch—ensure optimal hand function (Coppard & Lohman, 1996; Tubiana, Thomine, & Mackin, 1996). The splint must conform to these arches to support the functional position of the hand.

The functional position of the hand is 15–30° of wrist dorsiflexion, neutral to slight ulnar deviation, 15–20° of metacarpophalangeal (MCP) flexion, 10° of flexion at the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints, palmar abduction of the thumb, and extension of the metacarpophalangeal (MP) and interphalangeal (IP) joints of the thumb (Coppard & Lohman, 1996). This position places the muscles, tendons, and ligaments at a resting length and in position for grasp and prehension (Fig. 17-4). The web space of the thumb allows maximal abduction of the thumb for grasp. Every effort is made to preserve the maximum web space because the size of the object that can be grasped depends on the mobility of the thumb web space (Tubiana, Thomine, & Mackin, 1996).

Figure 17-2 Bony prominences can lead to pressure points, especially over the back of the hand. Careful contouring of the splinting material can minimize this problem.

Figure 17-1 Creases of the hand provide landmarks for the distal ends of the splint. For a wrist support splint, the distal end of the splint should not block the thenar eminence or distal palmar crease.

Figure 17-3 Arches of the hand must be supported in splinting.

Figure 17-4 Functional position of the hand.

The fingers vary in length and height, with the fingers on the radial side being longer than those on the ulnar side of the hand when the hand is open. The metacarpophalangeal joints on the radial side are higher than those on the ulnar side of the hand when the hand is closed. The therapist must apply this concept of **dual obliquity** to the construction of a splint (Fig. 17-5). That is, the splint must be longer and higher on the radial side of the hand (Fess & Philips, 1987).

The therapist should evaluate sensibility, mobility, motor function, edema, and tone prior to splint design and construction. Sensory deficit in the hand creates a concern: the patient may not be able to feel pressure points or areas of irritation from the splint, which can

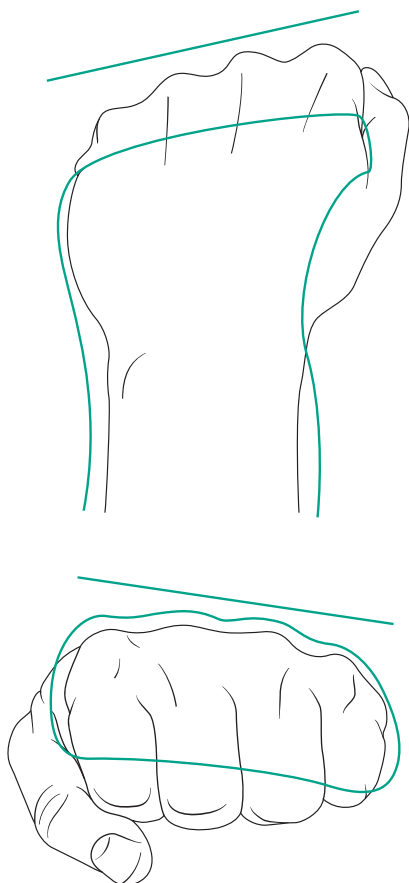

Figure 17-5 Concept of dual obliquity applied to splinting.

lead to skin breakdown or injury. In the case of hypersensitivity, the use of a splint can protect the fingertip or hand from unpleasant stimuli. Edema may also indicate the need for close monitoring of splint fit and comfort. As edema diminishes, the splint requires modification or remolding to maintain proper fit. Deficits in mobility may change during the course of splinting, so the splint may have to be modified. Weakness may indicate the need for a dynamic assist splint to prevent muscle imbalance or deformity. As muscle strength improves, the force of the dynamic assist should be adjusted to the patient's needs. Increased or decreased tone may indicate the need for splinting to maintain balance and prevent contracture. As tone changes, the therapist should modify the splint as necessary to meet the goals of treatment. Ongoing assessment helps the therapist identify any need for changes in the splint.

In designing a splint, the therapist must be aware of the natural postures of the hand that affect function. When the hand is held in supination, the wrist is held in neutral to slight radial deviation. When the hand is held in pronation, the wrist assumes a more ulnarly deviated posture. These considerations affect fit: if a splint is fitted in supination for a patient who will be using the hand primarily in pronation, the splint may not fit comfortably. Another consideration is that, normally during flexion, the fingers converge toward the scaphoid bone (Fig. 17-6). Therefore, the application of dynamic or static progressive assists to finger flexion splints must have the direction of pull toward the radial border of the wrist.

In designing a splint that includes functional positioning of the thumb, the therapist notes the position of the thumb for prehension to the index and middle finger. Typically, the thumb is held in palmar abduction and opposition to these fingers for effective prehension. While forming the splint, the therapist may have the patient

Figure 17-6 Fingers flex toward the scaphoid.

hold a pen or other object in the hand to test the ability of the thumb to achieve functional prehension. When designing a splint for the patient with carpal tunnel syndrome, the therapist should be aware of the position of the wrist that produces the lowest pressure in the carpal canal. The ideal position for the wrist is close to neutral, with $2 \pm 9^\circ$ of dorsiflexion and $2 \pm 6^\circ$ of ulnar deviation (Weiss et al., 1995).

Biomechanical Considerations

Biomechanical considerations include the effects of healing tissue on the biomechanics of hand use and mechanical principles that affect the design of the splint.

Position of Safe Immobilization

Following injury the hand may stiffen in a nonfunctional position. This position typically includes wrist flexion, MCP extension, and PIP and DIP flexion in a claw position (Bunnell, 1996). The distal transverse arch is flattened. If this position is maintained for long, the hand becomes nonfunctional as a result of shortening of the collateral ligaments. The position of safe immobilization (Fig. 17-7) prevents ligamentous shortening and contracture following injury. This position maintains the length of the collateral ligaments by holding the MCP joints in flexion and the PIP and DIP joints in extension while keeping the wrist in dorsiflexion. Specifically, the wrist is held in $30\text{--}40^\circ$ of extension, and the MCP joints are positioned in $70\text{--}90^\circ$ of flexion with full extension of PIP and DIP joints (Coppard & Lohman, 1996; Boscheinen-Morrin & Connolly, 2001). This position is also called intrinsic plus or safe positioning.

Tissue Healing

The therapist should be aware of the phases of wound healing when selecting the splint design for the patient with an injured hand. Splinting applies gentle stress to healing tissues to influence change (Fess & McCollum, 1998). During the **inflammatory phase**, the therapist may use a splint to immobilize and protect the healing tissues. During the **fibroblastic phase** of healing,

Figure 17-7 Position of safe immobilization.

splints may be used to mobilize healing tissues while protecting them. As the strength of the healing tissues increases and the scar tissue matures in the **maturation phase**, low load force may be applied with splinting. As maturation progresses, the tissues can tolerate an increased amount of stress (Schultz-Johnson, 1996). A splinting program must recognize these changes in healing tissues with appropriate changes in the splint as needed. Exercise programs and functional activity must begin simultaneously with splinting to maximize the benefit.

Influence of Splinting on Scar Remodeling

When mobility is lost to immobilization from casting, injury, or a neurological condition, collagen fibers develop increased intermolecular bonds, which result in dense tissue with relatively little mobility (Bell-Krotoski & Figarola, 1995). This response causes tissues to adapt and shorten, resulting in contracture. Such a limitation in mobility may be treated with splinting. There is some controversy regarding how splinting creates changes in soft tissues (Fess & McCollum, 1998). Is it by stretching existing tissue or the actual production of new tissue? The mechanism of stretching was initially thought to be creep, the elongation of tissues under a prolonged stress over time (Bell-Krotoski & Figarola, 1995; Fess & Philips, 1987). If tissues are stretched excessively, however, they rupture or produce an inflammatory response. Research suggests that ideal tissue remodeling occurs with gentle elongation of tissues. Tissues lengthen and grow if gentle stress is applied. This process is not stretching but rather growth of new tissues to accommodate the stress placed on them (Bell-Krotoski & Figarola, 1995; Brand, 2002). **Dynamic splinting, serial static splinting,** and casting are based on this mechanism.

The total end range time (TERT) theory suggests that the amount of increase in passive range of motion of a stiff joint is directly proportional to the amount of time the joint is held at the end of its range (Flowers & LaStayo, 1994). TERT theory states that if a joint is held at the end of its range, the dense connective tissue around the joint grows. This lengthening of tissues increases range of motion. The longer the joint is positioned at its end range, the greater is the gain in mobility. One study (Glasgow, Wilton, & Tooth, 2003) reported that a TERT of 6 hours or more per day resulted in a more effective reduction of contracture at a faster rate than a daily TERT of less than 6 hours over 4 weeks of splinting. Serial static splinting or casting is often used in the application of TERT theory in splinting.

Another theory employs stress relaxation, or static progressive stretch therapy, in splinting (Bonutti et al., 1994). This approach elongates tissues through progressive incremental stretch. The static progressive stretch approach applies 30-minute sessions of splint wear with stretch

increased every 5 minutes to the patient's tolerance to increase range of motion. **Static progressive splints** apply this theory by applying a low-load force that can be adjusted incrementally. These splints use methods such as MERiT (maximum end range time) components for gradual advancement of the static stress on the splinted part (King, 1993; Schultz-Johnson, 1996).

Torque angle curves provide a consistent method for measuring changes in soft tissues to determine whether splinting is overcoming joint stiffness (Brand, 2002; Breger-Lee et al., 1993). By using a goniometer and a **Haldex gauge** and plotting the data on a graph, a therapist can evaluate the effectiveness of splinting intervention. The Haldex gauge allows the therapist to apply a precise amount of torque for each measurement (Breger-Lee, Bell-Krotoski, & Brandsma, 1990). The graph displays the joint's response to the force applied with progressive torque on the vertical axis and the range of motion on the horizontal axis. A steep slope of the curve indicates that the joint is less responsive to splinting than a gradually sloped curve (Flowers & Pheasant, 1988).

Flowers (2002) proposed a model for assisting therapists' choice of static, dynamic, or static progressive splinting for a stiff joint based on a formula of the *Modified Weeks Test (MWT)*. Applying this model, the patient's stiff joint is first tested using standard goniometry. Then the therapist places the patient's involved extremity in a heat modality for 20 minutes. Following heat, stretch is applied for 10 minutes to patient tolerance. A second goniometric reading is taken of the stiff joint and then compared to the first reading. A gain in motion is an indicator of the responsiveness of the joint to stretch. If the gain is 20°, no splint is recommended. If the gain is 15°, a static splint at end range is recommended. If the gain is approximately 10°, a dynamic splint is appropriate, and if the gain is only 5° or less, a static progressive splint is most helpful. The *MWT* provides a useful model for guiding splint selection of any stiff joint.

Casting with plaster of Paris or Quickcast (Sammons Preston Rolyan) is another highly effective method in mobilizing stiff joints. Casting is useful in reducing joint, muscle, or skin tightness and may be used in therapy to enhance tendon glide (Colditz, 2002). Due to its uniform circumferential fit, it is usually well tolerated by the patient and, in addition, can reduce edema.

Mechanical Principles of Splint Design

The following principles concerning force distribution guide splint design.

Increase the Area of Force Application to Disperse Pressure

Splints apply external forces to the splinted part. Pressure is equal to the amount of force divided by the area of force application (Fess & Philips, 1987; Fess, 1995b). The clinical

applications of this principle are: (1) a wide, long splint is more comfortable than a narrow, short one; and (2) contoured pressure over a bone or bony prominence is preferable to uneven or point pressure over the prominence. The therapist must be cautious when padding a splint because it may actually increase a point of pressure if the splint is not well molded to the area.

Increase the Mechanical Advantage to Reduce Pressure and Increase Comfort

The mechanical advantage is the application of parallel force systems with the joint as the axis (A), the distal part splinted as the resistance (R), and the proximal part as the force (F), with the splint acting as a first-class lever much like a balanced teeter-totter (Fess & Philips, 1987; Fess, 1995b). Given a constant resistance, the amount of force in the lever system can be decreased by increasing the length of the force arm. In the case of a wrist support splint, the forearm trough is the force arm (FA), and the metacarpal bar serves as the resistance arm (RA) (Fig. 17-8). A longer forearm trough will decrease any pressure caused by the transferred weight of the hand. Mechanical advantage is equal to the FA divided by the RA. In accordance with this principle, the recommended length of the forearm trough is usually two thirds the length of the forearm (Fig. 17-8), although the forearm trough should not be so long as to impede elbow motion.

Ensure Three Points of Pressure

The three parallel forces in a first-class lever system, such as a splint, are in equilibrium. The splint acts as a counterforce proximally and distally to the forces of the forearm and hand, respectively. A strap securing the splint at the axis position provides a reciprocal middle force. These parallel reciprocal forces create the three points of pressure (Fess & Philips, 1987; Fess, 1995b). The concept of three points of pressure guides splint design and directs placement of straps for proper force application (Fig. 17-9).

Add Strength through Contouring

When a force is applied to a flat piece of material, the material bends. If the same material is molded into a curve, the material can withstand the force more effectively. Contour mechanically increases the material's strength. The splint should follow the contour and extend midway around the part being splinted for maximum comfort and strength (Fess & Philips, 1987). In addition, rounded edges are more comfortable and increase the splint's durability. Curved and contoured edges are preferable to angled or squared edges to conform to the finger lengths, which form a curve, and the other curves throughout the hand, wrist, and forearm.

Figure 17-8 Increase the mechanical advantage of the splint by increasing the length of the forearm trough. A, axis; FA, force arm; RA, resistance arm.

Perpendicular Traction for Dynamic or Static Progressive Splinting

To mobilize a joint through dynamic or static progressive splinting, the line of pull must be perpendicular to the long axis of the bone being mobilized. Whether using finger loops with an extension outrigger or nail hooks with a flexion pulley, the therapist must maintain a 90° angle of pull to provide the most effective application of force (Fig. 17-10). The perpendicular force application prevents shearing stress and unwanted traction on the joint. As mobility improves, the therapist must make changes in the outrigger to maintain the 90° angle of pull (Fess & Philips, 1987).

Acceptable Pressure for Dynamic Splinting

Forces in dynamic splinting may be applied with rubber bands, elastic thread, or springs (Gyovai & Howell, 1992). The force must not exceed acceptable limits. Low-load forces of 100–300 g are recommended for dynamic splinting of fingers (Fess, 1995b). Therapists may use lighter forces for the acute stages and heavier forces for treatment of chronic joint contractures (Fess & McCollum, 1998). The therapist must consider the patient's size, condition, and stage of recovery when determining the proper force application. The length and width of the rubber band determine the force of tension. A Haldex gauge (see Resources 17-1) can be used in the clinic to determine the

Figure 17-9 Three points of pressure in a wrist support splint.

Figure 17-10 Perpendicular angle of pull for dynamic traction: **A.** Correct. **B.** Incorrect.

exact amount of pressure (force) applied by splinting. Eagerness to achieve results quickly may cause the therapist to use excessive force, which may injure tissue. Effective dynamic splinting of a contracture produces a gain of only 10° per week (Brand, 2002). If dynamic splinting is not enough to remodel tissues or if greater pressure is required, serial casting may be preferable. Serial casts contour intimately to the limb and disperse pressure throughout a larger surface area (Bell-Krotoski & Figarola, 1995).

High- Versus Low-Profile Outriggers

High- and low-profile outriggers are similar in their effects. Some authors, however, believed that, as improvement occurred, high-profile outriggers generally required fewer adjustments to maintain the 90° angle of pull than the low-profile ones (Fess, 1995a, 1995b). A study by Austin et al. (2004), which analyzed the need for adjustment in high- and low-profile outriggers, failed to support these beliefs. The authors found that the high-profile outrigger was not significantly more adjustable and that mechanical differences between high- and low-profile designs were minimal. One author suggests that the high-profile outrigger may require less force to initiate the allowed motion than a low-profile outrigger (Boozer et al., 1994). A high-profile outrigger, however, may be cumbersome to the patient returning to work or daily living activities. If a patient has adequate strength of the opposing muscles and can be seen in the clinic for periodic splint adjustment, a low-profile outrigger may be preferable.

OTHER CONSIDERATIONS IN SPLINTING

Despite the most beautifully designed and constructed hand splint, the effectiveness of a splinting program depends on two other factors: compliance and education.

Compliance

Even the most expertly designed and constructed splint will not benefit the patient if the patient does not wear it. Compliance can have a profound influence on the effectiveness of the intervention. Patients' perception of the effectiveness of the splint in achieving the goals of rehabilitation can influence their willingness to wear it (Groth & Wulf, 1995). Comfort is also an important consideration in ensuring compliance with splint wear. One study showed that patients with rheumatoid arthritis were more compliant with a soft splint than a hard thermoplastic resting splint (Callinan & Mathiowetz, 1996). Comfort means different things to different people. One patient may prefer a lightweight thermoplastic splint, while another is more comfortable with a softly padded splint. The therapist must be attentive to the patient's needs and requests while designing the splint. These considerations should be combined with the therapist's knowledge of the optimal splint design. It is helpful to collaborate with the patient to identify effective options that are acceptable to the patient. Many factors related to design and fabrication can be adjusted to facilitate compliance. Procedures for Practice 17-1 has strategies to increase splint wear compliance.

PROCEDURES FOR PRACTICE 17-1

Strategies to Increase Splint Wear Compliance

- Offer splint options to the patient if possible.
- Teach the patient about the benefits of splint wear.
- Provide for easy application and removal of the splint.
- Make the splint comfortable.
- Use a lightweight material if possible.
- Immobilize only the joints being treated.
- Make the splint cosmetically pleasing to the patient.
- If feasible, collaborate with the patient on a wearing schedule.

Education

The therapist must provide adequate instruction to the patient regarding wear and care to ensure proper use of the splint. Patients should be taught the goal and purpose of splinting. It may also be helpful to inform the

patients of the consequences of failing to comply with splint wear. Provide written instructions on wear and care. If necessary, provide a diagram of proper application. If the patient is a child or has a cognitive deficit, be sure to instruct a caregiver in the proper application of the splint. Include precautions for the patient or caregiver to watch for, including pressure points, edema, and dynamic tension that is too tight. Offer suggestions on adjusting the splint if feasible. Teach the patient how to clean the splint and to keep thermoplastic splints away from heat lest they lose their shape. Make a follow-up visit if you anticipate a change in the patient’s status that will necessitate splint modification.

SPLINT CONSTRUCTION

Methods to construct splints from thermoplastic materials are described here. Figures 17-11A and 17-12 to 17-20 pertain to a resting splint. Figures 17-11B and 17-21 to 17-23 pertain to a hand-based thumb splint. Figures 17-11C and 17-24 to 17-31 pertain to a wrist splint serving as a

base for a dynamic finger extension outrigger. (See Procedures for Practice 17-2.)

Splint Design

Determine the type of splint design by assessing the patient and the clinical condition in reference to the physician's splint order. Consider the goals and purpose of the splint. You can combine this information with an understanding of the patient and any factors that may affect compliance. Also consider relevant cost factors related to custom splint construction. If there is a commercial splint that achieves the same purpose, it may be more cost effective to provide the commercial splint. When time and materials are added up, the custom-made splint is usually more expensive than the commercial splint, but other factors must be considered in this decision and cost should not be the only consideration if effectiveness is an issue. Procedures for Practice 17-3 lists questions to ask when designing the splint.

PROCEDURES FOR PRACTICE 17-2

Steps of Splint Construction

1. Design splint
2. Select material
3. Make pattern
4. Cut splinting material
5. Heat splinting material
6. Form splint
7. Finish edges
8. Apply straps, padding, and attachments
9. Evaluate the splint for fit and comfort

Figure 17-31 Finished dynamic extension splint with commercial outrigger components—overhead view.

Material Selection

Selecting the proper material for the splint can be a challenge. It is helpful to become familiar with the properties of various thermoplastics so as to apply the most suitable material for the needs of the patient and the purpose of the splint. You may become biased toward certain materials that are relatively easy to work with, but with experience, you will learn to appreciate a variety of materials, each with its own benefits and limitations. Low-temperature thermoplastics have plastic, plastic-like, rubber, or rubber-like bases that give the splinting material its individual characteristics (Breger-Lee, 1995; Breger-Lee & Buford, 1992). Materials with a plastic (polycaprolactone) base, such as Polyform (Sammons Preston Rolyan) and NCM Clinic (North Coast Medical)

PROCEDURES FOR PRACTICE 17-3

Selecting the Splint Design

- How many joints must be immobilized or mobilized?
- What is the best application? Should the splint be volar or dorsal; ulnar, radial, or circumferential; static, static progressive, or dynamic?
- Should the splint be based on the forearm, hand, finger, or thumb to provide the necessary support for the splinted part?
- Is there a cost-effective commercial splint that achieves the goals?
- Will the patient be able to apply and wear the splint as recommended?
- Which material is best to achieve the purpose of the splint? Does the material affect the design of the splint?

may have fillers that affect their drape and durability. Materials with a rubber (polyisoprene) base, such as Orthoplast (North Coast Medical), have less drape and require firmer handling. See Resources 17-1 for locations of all suppliers.

An assessment of properties such as rigidity, drape, conformability, surface texture, memory, color, thickness, and perforations helps determine the best material for the splint (Jacobs & Austin, 2003). The degree of conformability of the splint material determines the handling techniques required (McKee & Morgan, 1998). A material with a high degree of conformability or drape molds easily to the contours of the hand. A material with high conformability is suitable when an intimate contour is desired; a material with less drape is preferable in constructing a long arm splint or a splint requiring firm handling techniques. For example, a resting splint for a patient with spasticity may require a high degree of rigidity with low degree of drape. A material with a rubber-like base, such as Ezeform (Sammons Preston Rolyan) provides the necessary rigidity without drape, allowing the therapist to use firm handling techniques for fabrication.

The surface texture may also be an important consideration. Some materials have a shiny, smooth surface, while others have texture. Some materials are susceptible to fingerprints. Usually the therapist can control fingerprints by using a smooth, gentle, stroking technique during molding. Some materials have a coating on the surface that resists adhesion. This coating must be removed with a solvent or by scraping the surface before attaching straps or other permanent attachments.

Some materials have memory that allows them to stretch and return to their original shape with reheating. These materials are usually translucent and become transparent when heated to the desired temperature. One example is Aquaplast (Sammons Preston Rolyan), which also comes in bright colors.

Many splinting materials are available in a variety of colors. This may be beneficial for ensuring compliance with splint wear in children and teenagers. Allowing patients to select their splint color may improve compliance. Not everybody likes colored splints, however. Many patients prefer a neutral tone. Flesh-tone colors are available in various shades of beige, brown, and black.

Splint materials are also available in a variety of thicknesses. The most commonly used thicknesses are 1/8 inch and 1/16 inch. The 1/8-inch material is preferred for rigid forearm-based splints, while the 1/16-inch material is best suited for hand-based and finger-based splints and circumferential designs. Thinner materials produce lighter weight splints, which may be better tolerated by some patients. Perforations also affect the weight and rigidity of a splint (McKee & Morgan, 1998). Perforations also provide ventilation, which is especially beneficial in warm weather.

Perforations range from microperforation to maxiperforation in some thermoplastics.

Soft lightweight splint materials are also available. The disadvantages of these splints may be their bulk, lack of rigidity, and relatively short durability (Breger-Lee & Buford, 1991). Soft materials, such as leather, elasticized fabric (Schultz-Johnson, 1996), neoprene (Clark, 1997; Fillion, 2004; Weiss et al., 2004; Willey, 2004), silicone rubber (Canelon, 1995; Canelon & Karus, 1995), soft padded fabric with a thermoplastic insert (Callinan & Mathiowetz, 1996), and strapping material (Byron, 1994), may be used for splinting. These materials provide light restriction, which may be desirable for patients who do not tolerate hard thermoplastic splints or for musicians and athletes attempting to reduce harmful motion while continuing to play. The therapist should consider the patient's tolerance to any material being used in splinting. Sensitivity to various materials, such as an allergic contact dermatitis to neoprene (Stern et al., 1998), has been reported in the literature.

High-temperature thermoplastics are also available for rigid splinting. They require use of a band saw for cutting and an oven for heating (Fess & Philips, 1987). These high-temperature thermoplastics have high-impact strength and rigidity but do not contour well, which makes them generally not suitable for hand splinting.

Recent technological advances have allowed engineers to incorporate an antimicrobial agent into several splinting materials. Since splints are often worn continuously against the skin, a moist environment can lead to bacteria and an unpleasant smell over time. This antimicrobial protection may make it easier to clean and maintain splints that are worn continuously.

Pattern Making

Once you have decided on the appropriate splint design and material, you will make a pattern. This is an important step because a well-designed splint pattern usually leads to a well-fitting splint. The pattern provides a two-dimensional guide for the three-dimensional splint. The pattern also helps to minimize waste of splint material. Patterns for many commonly prescribed splints are available in splinting textbooks and from splint material manufacturers. Three commonly prescribed splint patterns are demonstrated here (Fig. 17-11). Paper toweling provides an excellent moldable pattern, but any type of paper can be used for the pattern. Place the patient's hand directly on the paper and mark the anatomical landmarks according to the design being used (Fig. 17-12). The pattern must extend beyond the lateral borders of the hand and forearm to allow the splint to form a shallow trough, which will extend halfway around the

surface being splinted for adequate support. Extend the forearm trough two thirds of the length of the forearm. Once the pattern is drawn, cut it out and place it on the patient in the design of the splint (see Fig. 17-13 for the resting pan splint, Fig. 17-21 for the thumb splint, and Fig. 17-24 for the dynamic finger extension outrigger splint). If it fits perfectly, transfer it to the splinting material. If it needs modification, modify it by cutting the pattern down or adding a piece of paper for extra length or width as needed. Check the pattern on the patient to see if it blocks any joints unnecessarily. The splint pattern can be cut back to reduce this restriction if necessary. If the patient is unable to lay the hand flat for pattern drawing because of deformity or spasticity, use the uninvolved hand for pattern making and flip the pattern over for the contralateral side. You can adjust the pattern for edema or any other variation before transferring the pattern.

Transfer the pattern to the splinting material by tracing it onto the plastic (Fig. 17-14). A wax pencil is easy to see and erases from the plastic. An awl can also be used to scratch the pattern onto the plastic. If using a pen or pencil, cut away the marks as you cut out the splint.

Cutting

With a full sheet of splinting material, it is best to cut it to a size that will fit the pattern. Cut the full sheet with a utility knife by scoring it and bending it, then turning the sheet over and scoring it again from the other side. This provides a manageable sheet of thermoplastic. Heat the thermoplastic once the splint pattern is marked (Fig. 17-15). When the material is soft, cut the splint out with sharp straight-edge scissors (Fig. 17-16). By cutting the material after heating, you eliminate the rough edges, which saves time in the finishing step. Hold the material horizontally while cutting to avoid overstretching it. Excessive handling of material can cause fingerprinting. To minimize this problem, lightly hold the material on the edges that will be cut away. Curved scissors may help in cutting out hard-to-reach curved areas.

Pre-cut splinting blanks are available for commonly used patterns. Considering the time it takes to trace and cut the pattern out of a full sheet of splinting material and the potential for wasting material, pre-cut materials may be cost effective.

Heating Splinting Material

Electric fry pans, splint pans, and hydrocollators can be used to heat the thermoplastic material (Fig. 17-15). It is recommended that the water be at least 1 inch deep if us-

ing a fry pan. If using a hydrocollator, be careful not to let the material overstretch or drop to the bottom. Heat pan liners may be helpful with a hydrocollator. The recommended temperature varies among materials. It is usually best to keep the water at 150–160°F for most materials. Consult the manufacturer's recommendations for specific materials. Use a thermometer in the water to ensure consistent temperature. The heating time for most materials is about 1 minute. The therapist should check the material to make sure it is heated uniformly before forming the splint on the patient. The working time for splinting materials also varies. Some of the thinner thermoplastics (1/16 inch) cool in 1–2 minutes. Most of the thicker materials (1/8 inch) have a 3- to 6-minute working time. Since heat guns do not uniformly soften splinting material, they are recommended only for spot heating, minor adjustments, and edge finishing.

Forming the Splint

Once the entire piece of thermoplastic is heated, carefully remove it from the water with a spatula or tongs. The entire piece should feel soft and easily moldable. Lay the material on a towel to dry briefly. If you are rolling the edges to finish them, do so before forming the splint on the patient. Check the temperature of the plastic before placing it on the patient. If the material is too hot, let it cool slightly for the patient's tolerance and comfort. After placing the patient's hand in the desired position, place the splint material on the patient (Figs. 17-17, 17-22, and 17-25). When using a material with draping qualities, it is best to let gravity assist the positioning. If the splint is based on the volar surface, position the hand in supination or a neutral posture. If the splint is dorsal, place the hand in pronation. Since the wrist posture changes slightly in pronation and supination, check the fit of the splint in both these postures before it cools completely. Using smooth and gentle strokes, contour the splint over the arches and bony prominences of the hand. Try not to grip or squeeze the thermoplastic. Materials with a high degree of drape and conformability, such as Polyform, Polyflex II (Sammons Preston Rolyan), NCM Preferred, and Contour (North Coast Medical), require relatively little handling. Materials with controlled stretch, such as Omega (North Coast Medical), Ezeform, and Synergy (Sammons Preston Rolyan), require a firmer pressure to create contours and maintain their shape. If making a splint on a spastic extremity or an uncooperative patient, you can use an elastic bandage to assist in holding the splint in place while molding.

When splinting the thumb to allow functional use, it is helpful to have the patient hold a pen lightly or hold the thumb in prehension while the splint is being formed (Fig.

17-22). This ensures functional positioning. At this time, it is important to check for any motion that may be unnecessarily restricted. Changes can be made while the splint is forming to reduce any restriction. This is also a good time to check bony prominences for any pressure areas. Light finger pressure can push the material out away from the prominence by rounding out these areas and creating more space for the ulnar styloid or other areas of pressure. You may wish to place a small piece of putty or foam over prominences before splint molding to allow for this enlargement.

While the splint is on the patient, mark the lateral borders if additional material is to be cut away. While the splint is still slightly warm, use your fingernail to mark the trough of the splint so that it extends midway around the forearm. You can also mark distal and proximal edges in this manner and cut away the excess while the material is slightly warm (Fig. 17-18). The warmth facilitates cutting and leaves a nicely finished edge. Flare the proximal edge of the splint away from the skin to prevent a pressure point during wear.

Edge Finishing

Smooth edges are important to prevent pressure points. Cutting the material at the required temperature allows the edges to seal smoothly and not require additional attention. With some perforated materials or rough-cut thermoplastics, however, it may be necessary to smooth the edges. You can achieve a smooth edge by dipping the edge of the splint into the hot water and cutting it to produce a smooth edge or by smoothing it lightly with fingertip pressure after heating it with the heat gun briefly. *The heat gun produces a very hot stream of dry heat. It should never be directed toward the patient's skin.* Remember to set the heat gun on a cool setting before turning it off to avoid damage to the motor. You can eliminate the edge finishing step by cutting the edges so they seal or by rolling edges back after heating the thermoplastic before applying it to the patient. If edges remain slightly rough, you can apply a thin piece of moleskin along the edge to seal it for comfort.

Application of Straps

Straps attach the splint to the patient. Their location must be carefully planned to maintain the best contact with the splint and to provide three-point pressure. Apply adhesive-hook Velcro to the splint and attach the soft-brush Velcro or other foam strapping material to hold the splint securely on the patient. Hook Velcro adheres most effectively if the surface of the splint is prepared for adhesion. Remove the non-stick finish on the

thermoplastic by applying a solvent or by scraping the plastic with the sharp edge of the scissors. Then briefly spot heat the surface of the splint and the sticky side of the Velcro with a heat gun (Fig. 17-19). It is best to place a full piece of sticky-back Velcro on the splint rather than two small pieces on the edges because repeated pull on the pieces during release of the strap may cause them to peel off. Strapping materials include colored Velcro, durable foam, neoprene, and elastic strapping in a variety of widths. Choose the strapping that best secures the splint to the patient comfortably. It is best to round the corners of the strapping material to avoid bending and dog ears (Fig. 17-20).

Padding

To enhance wearing tolerance, you can pad the splint. When padding a splint, allow extra space at the design and molding phases to contour over a bony prominence, avoiding additional pressure in this area. Some padding is applied before forming the splint, and some is applied afterward. If the padding is applied to the splinting material before heating, the excess water should be squeezed out before applying the material to the patient. Some thermoplastic material is available with a layer of padding already bonded to it. You can use stockinette liners instead of padding if light protection is desired. Prefabricated cotton or synthetic liners are available commercially. The patient may appreciate use of a light, washable stockinette under the splint to absorb perspiration. Sticky-back moleskin is also available for a thin, soft padding material. Padding, however, should never substitute for a well-fitting splint. Silicone gel can be used in splints to reduce slippage and to enhance scar remodeling.

Attachments

Outriggers and pulleys can be attached to splints when the splint base is complete. An outrigger provides a base for positioning the 90° angle of pull for dynamic splints or for directing a static progressive force. It can be made by rolling thermoplastic into a tube (Fig. 17-26), by using prefabricated tubes, or by bending wire to the desired position (Coppard & Lohman, 1996). Commercial outriggers are available in high- and low-profile designs. The therapist should consider the requirements of the outrigger for high or low profile, single or multiple finger, static progressive, or dynamic. Safety pins and paper clips can also be used for finger outriggers or pulleys (Byron, 1997; Saleeba, 2003). Outriggers have also been used for applying traction to a joint (Chinchalkar & Gan, 2003). When attaching an outrigger or pulley, prepare the surface of the splint first for optimal adhesion by scraping the surface or

applying solvent. The outrigger or pulley attachment points should be treated similarly. Using dry heat with a heat gun, heat the surfaces and press them together (Fig. 17-27). They must be held together briefly to ensure adequate bonding. They should not be moved at this time unless repositioning is desired. If the pieces need additional reinforcement, heat another piece of thermoplastic and apply it over the outrigger base attachment. Again, prepare surfaces with dry heat and press them together for effective bonding. Some commercial outriggers can be attached with specially designed thumbscrews (Figs. 17-30 and 17-31).

Dynamic splints may be prone to slide distally because of the traction on the splint. You can control this migration by applying a friction surface on the splint that is in contact with the skin. Silicone gel or Microfoam tape (available through Sammons Preston Rolyan), which has a soft padded surface, provides light traction to keep the splint in place.

The tension of a dynamic splint is provided by rubber bands, coil springs, or elastic thread. You can attach these to the splint with Velcro tabs, hooks, thumbscrews, or knobs placed proximal to the outrigger on the splint base. Pulleys or line guides can redirect the line of pull as needed for dynamic or static progressive flexion splinting. Monofilament (fishing line) attached to the rubber band creates a smooth excursion for the rubber band tension as it pulls over the outrigger or under the pulley for dynamic splinting. The monofilament attaches to a finger sling (Figs. 17-28 and 17-30) or fingernail hook or tab to provide the appropriate tension and 90° angle of pull. Dynamic splints may incorporate hinges, which provide a movable axis at a joint. Hinges are available commercially or can be made from rivets (Byron, 1994), crimped thermoplastic tubing, or brass fasteners (Dennys, Hurst, & Cox, 1992). Static progressive splints use locking hinges and various types of inelastic components such as Velcro strips, monofilament line, MERiT components, and ClickStrips (Vazquez, 2002). Hinges and turn screws may also be used for static progressive splinting to provide adjustable positioning of stiff joints in the optimal position tolerated by the patient. These components then allow adjustments as the patient achieves increased mobility (Schultz-Johnson, 2002).

Evaluating Splint Fit and Comfort

After the splint is finished, have the patient wear it for about 20 minutes and remove it to check for any redness.

PROCEDURES FOR PRACTICE 17-4

Splint Checkout

Review the splint using these questions as guidelines:

- Does the splint achieve the purpose?
- Does the splint maintain the proper position of the joints? Check angles with a goniometer if necessary.
- Does the splint fit the contours of the hand, the arches, and bony prominences?
- Does the splint restrict or immobilize any joint unnecessarily?
- Is the splint long enough to support the splinted part?
- Are all edges smooth and all possible pressure points relieved?
- Does the splint allow functional use of the hand if allowed?
- Can the patient apply and remove the splint?
- Does the patient understand wear and care instructions?
- Is the splint cosmetically acceptable to the patient?

Redness or blanching of the skin may be an indication that the pressure of the splint is too much (Brand, 1995). Modify the splint if signs of redness or excessive pressure are present. Then reevaluate fit and comfort (Procedures for Practice 17-4).

Orthotic intervention requires a client-centered approach by a skilled therapist. Splinting is not merely the application of a device, but rather it is an important component in the rehabilitation process to meet the occupational performance goals of the patient. McKee and Rivard (2004) suggest that the successful use of this intervention demands the skills of a therapist working closely together with the patient to meet the needs of comfort, cosmesis, and convenience that will ensure wearability of the splint and optimal outcomes.

Technology is changing rapidly. New materials offer new possibilities for the splinting therapist. By combining skill and creativity with knowledge of new technology and the patient's needs, the therapist can meet the challenges of the future by applying principles of splinting to meet the goals of rehabilitation.

CASE

EXAMPLE # 1

Construction of a Resting Splint for a Patient with Hemiparesis

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information Mr. J is an outpatient who sustained a left cerebral vascular accident (CVA) 3 weeks ago with resulting right hemiparesis. Patient is medically stable. Hypertonicity of finger flexors limit grasp and release of right hand. Limited in full extension passive range of motion (PROM) of fingers due to mild flexor hypertonicity.</p>	<p>Obtain information about the patient</p>	<p>“Hemiparesis may limit patient’s full strength and dexterity of right hand, but functional grasp is possible. However, hypertonicity of flexors will affect ability to release objects held in hand.”</p> <p>“The patient is highly motivated to retain his current hobbies, though both require functional grasp and release.”</p>
<p>Interview: Mr. J. is a 67-year-old right-hand–dominant man who is retired but remains active with hobbies, including golf and bridge. He is married and lives with his wife in their two-story home.</p>	<p>Evaluate to identify the problem(s)</p>	<p>“Mr. J values his role as an independent person, friend and sportsman. His hobbies allow continued socialization and self esteem.”</p>
<p>Interview: Mr. J. plays golf and bridge with a supportive group of friends who encourage his continued involvement and independence. In addition to his role as independent person, Mr. J. values self enhancement roles in his hobbies.</p>	<p>Implement the intervention</p>	<p>“He will need to use a resting splint to maintain full extension to counteract the effect of the hypertonic finger flexors.”</p> <p>“I will need to monitor splint tolerance as Mr. J. continues to gain strength. Modifications in the splint may be necessary.”</p>
<p>Assessment: The therapist measured Mr. J’s grip strength with dynamometer at 10# on right compared to 70# on left. He exhibits slightly increased flexor tone with difficulty fully extending fingers following grip. Passive extension of fingers was only slightly limited, but tone prevented full active extension. Sensation was normal for the right hand. He was able to grasp a golf club and hold cards in his right hand but has difficulty with release.</p>	<p>Evaluate the result</p>	<p>“The splint helped to maintain a balance of the flexor spasticity and the weak extensors during the initial stages post-CVA. He used it at night initially, and it didn’t seem to interfere with his sleep so he was happy to continue wearing it. He discontinued splint use at 6 months post CVA when he didn’t need it anymore.”</p>
<p>During occupational therapy, a custom fabricated resting splint from 1/8" Ezeform was made for Mr. J. He tolerated splint wear without difficulty and was instructed in a nighttime wearing schedule.</p>		
<p>Mr. J. gained grip strength on the right to 43# with slight hypertonicity of the finger flexors. He also gained strength in active finger extension. He regained full PROM of fingers. He resumed golf and card playing successfully.</p>		

CASE

EXAMPLE # 2

Construction of a Hand-Based Thumb Splint for a Patient with CMC Osteoarthritis

Occupational Therapy Intervention Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
<p>Diagnosis: Mrs. O. is an outpatient with carpometacarpal (CMC) osteoarthritis of the right trapeziometacarpal joint of the right hand.</p> <p>Interview: Mrs. O. is a 55-year-old, right-hand-dominant woman who is employed part time as a librarian. She is independent in all ADLs but reports pain when grasping books, writing, and turning a key. She also has pain when gardening. She lives alone in her home. She prefers sedentary activities including reading and gardening in her small flower garden.</p> <p>Interview: In addition to her role as an independent person, Mrs. O. has the self advancement and self enhancement roles of worker and gardener.</p> <p>Mrs. O.'s employer at the library is willing to make some changes to help Mrs. O. reduce pain during work if necessary. She is a valued employee, and they have suggested she do less of the shelving and spend more time on check-outs.</p> <p>Mrs. O. loves to garden. She often spends long hours on her projects in the garden on her days off.</p> <p>During occupational therapy, Mrs. O. is fitted with a custom-fabricated hand-based thumb splint made from 1/16" Orfit thermoplastic. She is also instructed in gentle active range-of-motion and strengthening exercises for the thumb. Joint protection instruction is provided.</p> <p>Mrs. O. tolerates the splint well. She wears the splint as needed during the day. She is able to write, work at the library, and garden with the splint on.</p> <p>She understands the exercise program and is compliant. She enthusiastically applies the joint protection strategies and feels they help her pain.</p>	<p>Obtain information about the patient</p> <p>Evaluate to identify the problem(s)</p> <p>Implement the intervention</p> <p>Evaluate the result</p>	<p>"She can reduce pain by applying joint protection principles, using a hand-based thumb splint, and modifying her activities."</p> <p>"Mrs. O. values all her roles. She is highly motivated to make changes that will allow her to continue in these roles."</p> <p>"Mrs. O. needs to work with her employer to find ways to manage her demands at work, by rotating tasks and taking mini-breaks during the day."</p> <p>"Mrs. O. gets so involved in her gardening that she forgets about her thumb pain until it is quite severe. She may need to find ways to adapt her gardening and manage the time she spends in the garden."</p> <p>"She will benefit from use of the splint during her work day and as needed in the garden. She will try to modify her work day by taking mini-breaks for stretches and alternating tasks that may be more stressful to her thumbs. She would also benefit from setting a timer while in the garden so she remembers to take breaks and listen to her body for any signs of pain. Adaptations like easy-grip pruners may also be helpful in the garden. She will benefit from being shown various methods of joint protection in handling books and writing. She may also want to try a soft pen grip."</p> <p>"She may need splint adjustments over time if changes occur in splint fit or comfort. She was given a clinic number to call if problems arise."</p>

CASE

EXAMPLE # 3

Construction of Dynamic MCP Extension Assist Splint

Occupational Therapy Intervention Process

Clinical Reasoning Process

Objectives

Examples of Therapist’s Internal Dialogue

Mrs. D. is a 41-year-old, right-hand–dominant woman who underwent MCP arthroplasties of the left hand for ulnar drift. She has a 12-year history of rheumatoid arthritis with ulnar drift and subluxation of the MCP joints on the left. This deformity has progressed over the past 3 years, and Mrs. D. reports significant loss of function and inability to lay her hand flat, to wash her face, or put her hand in her pocket. She works as a receptionist part time and has significant difficulty using her computer at work. She also experiences difficulty using keys, opening doors, and using a knife in meal preparation. She has become frustrated with her difficulty performing cooking tasks, because cooking is one of her hobbies. She lives in a two-story home with her husband and 3 teenage daughters.

Her surgeon performed MCP arthroplasties with rebalancing of the extensor tendons on the left. She is referred to occupational therapy at 5 days post-op for splinting and ADL modifications.

Interview: In addition to her roles as an independent person and mother, Mrs. D. identifies the self-advancement and self-enhancement roles of worker and cook.

Mrs. D hopes to resume her job, but her leave of absence will allow her to focus on her rehabilitation.

Mrs. D enjoys cooking and baking for her family and hopes to resume these activities. In the meantime, her teenage daughters will help with these tasks at home.

Assessment: The surgeon has told Mrs. D. that light ADLs can be resumed with the dynamic splint at 3 weeks after surgery.

Mrs. D. is able to flex fingers in the dynamic splint, and then the rubber bands return her fingers to the extended position.

Obtain information about the patient

“Initially Mrs. D. will need assistance with ADLs. She will be limited in use of her left hand. She will need to learn one-hand ADLs and may need to recruit more assistance from her husband and daughters at home. She has taken a medical leave from work to devote the next month to therapy. The surgeon was pleased with surgical result and wants her to follow his standard protocol. She should do well.”

Evaluate to identify the problem(s)

“Mrs. D. values her roles as independent person, mother, worker, and friend. She wants to retain all those roles.”

“As she gets further along in her recovery, her job will be reviewed, and modifications will be suggested at that time.”

“Mrs. D. will need review of joint protection and may benefit from adaptations for the kitchen.”

“She will need to wear the dynamic splint during the day and the resting splint at night per post-operative protocol.”

The therapist fabricates a dynamic extension outrigger splint for daytime wear and a resting splint for night use. Mrs. D. is instructed to perform active MCP flexion exercises in the splint 10 times hourly during the day, allowing the rubber bands to return her fingers to full extension. She wears the dynamic splint for 4 weeks. During this time, the therapist also instructs her in joint protection principles and offers suggestions for assistive devices to facilitate occupational performance. She adapts her doorknobs, uses a key holder, and purchases cutlery with enlarged handles. She also enlists her daughters' help in the kitchen.

Implement inter-
vention

“Mrs. D. will follow a standard protocol for post-operative MCP arthroplasty.”

“Mrs. D. needs review of joint protection and assistive devices. She will be quite open to these suggestions.”

Mrs. D. returns to work 4 weeks after surgery to answer phones with the use of a headset. She gradually resumes full duties at 6 weeks after surgery. She continues to use the resting splint at night for 3 months. Mrs. D. achieves an excellent outcome postoperatively. She also achieves a higher level of independence in her occupational performance because of improved hand function and increased awareness of modifications in her daily activities.

Evaluate the result

“Mrs. D. has had a highly successful post-operative recovery and an excellent outcome.”

SUMMARY REVIEW QUESTIONS

1. Name the steps of splint making in order.
2. Name the creases of the hand and describe their importance in splint construction.
3. What is the difference between the functional position of the hand and the position of safe immobilization in splinting? Give an example of when you would use each.
4. Describe the concept of dual obliquity as applied to splinting.
5. What does mechanical advantage mean in splinting? How does it apply to the length of the forearm trough?
6. What are some strategies to enhance compliance with splint wear?
7. Which material would be a good choice for a hand-based thumb splint? Why?
8. What does a splint checkout include?

ACKNOWLEDGMENTS

I would like to thank my husband, my family, and my colleagues for their inspiration, support, and encouragement while writing this chapter. I also want to acknowledge my patients who have been my teachers through the years, challenging me in the art and science of splinting.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the factors that should be considered in wheelchair selection and explain how they inter-relate.
2. Describe the three basic types of wheelchairs and reasons for each to be chosen.
3. Specify measurements typically taken to determine wheelchair and related seating system configurations for a particular individual.
4. Demonstrate knowledge of the components common to many wheelchairs and describe why each merits consideration in wheelchair selection.
5. Discuss the roles and responsibilities of the occupational therapist in wheelchair selection.
6. Suggest how the occupational therapist can facilitate the user's participation in wheelchair selection.

CHAPTER 18

Wheelchair Selection

Brian J. Dudgeon and Jean C. Deitz

Glossary

Glossary

Angle in space—Angle of the seat back in relation to the true vertical when the seat and back are rotated counterclockwise as a unit. Sometimes called tilt-in-space or orientation, this position may be altered for postural control.

Camber—The amount of angle on the wheels, creating flare-out at the bottom. A 4–6° camber is recommended for push rim convenience and wheelchair width.

Pelvic rotation—Asymmetrical position of the pelvis with forward position of one side, typically due to low back rotation, muscle asymmetry, or spinal deformity.

Pelvic obliquity—Uneven level of anterior superior iliac spines and ischial tuberosities associated with spinal scoliosis, hip abnormality, and pelvic deformity.

Proximity-sensing devices—Devices or systems that remotely sense the position of a body part (e.g., head) and use that position to control the wheelchair without physical contact between the part of the body used for control and the switch.

Scanning—Control option that presents choices one at a time, grouped or singly, until the desired choice is offered for the user to select by switch activation.

Scoliosis—Abnormal spinal curvature, typically with a lateral curve, S-shaped, or C-shaped pattern creating an unlevel shoulder and pelvic position. Scoliosis deformities may be fixed or flexible.

Seat-back angle—The angle of the seat surface relative to the back surface. This angle is typically 90–100°. Backrest angles and seat plane angles may be designated separately.

Sip and puff—A system typically involving a dual-action switch, in which one action is controlled by the user sipping on a tube held in the mouth and the second action is controlled by puffing on the same tube. (In wheelchair operation, the chair functions can be controlled by patterns of switch closures.)

Snap-secured—A locking mechanism on the frame that holds folding frame parts in place for smoother ride with less frame migration and reduced wheel and caster flutter.

Third-party payer—Individual or organization (i.e., insurance company) other than the person receiving services that pays for services or equipment.

“Mobility is a fundamental part of living. Being able to move about, to explore, under one’s volitional control is a keystone of independence.” (Warren, 1990, p. 74)

Mobility is a major part of daily living, facilitating participation in home, work, and community settings. Wheelchairs are a focal point for many people who have mobility challenges. As such, wheelchair selection and training necessitate consideration of the user’s preferences and current and anticipated performance needs, capacities, and environments. The process of evaluating and choosing a wheelchair system as part of functional mobility involves the user, an interdisciplinary team, and equipment suppliers or vendors. Also, family members, primary care providers, and others from the user’s work and leisure environments may contribute important information useful in choosing an appropriate wheelchair system to meet needs for mobility within and between environments.

Wheelchair selection has a functional orientation and involves multiple factors including the user’s (1) needs and goals; (2) home, work, recreational, and other community environments; (3) physical and mental status and anticipated course of impairments; (4) financial and community resources; (5) views about appearance and social acceptability; and (6) needs for interface of the wheelchair system with other assistive technology. A selection process includes issues such as current and changing needs of the

user and family, training needs for use and maintenance, and anticipated changes in technology. A wide range of wheelchair options are available, yet funding and community-based resources for training and servicing of mobility devices often limit choices.

Some individuals use wheelchairs only occasionally to meet brief transportation needs, while others use them continuously to meet most day-to-day positioning and mobility demands. Especially in the latter case, the events that lead to the need for a wheelchair may be dramatic. For some, acquiring a wheelchair system may create stress or confusion, and this can hinder their contributions to the assessment of needs and selection of a system. Others view the acquisition of a wheelchair as a positive move toward greater independence and freedom, and they make substantial efforts to become informed about choices. In either case, the needs of the user are central to the overall process of selection, prescription, and training, with the wheelchair viewed not just as a means for mobility but as a highly personal device to be chosen with care and precision (Steins, 1998).

In contributing to the selection process, the occupational therapist must have a thorough understanding of the user’s medical needs and personal profile, including environment, daily routines, and goals related to activities and participation. In addition, the therapist should understand the seating and positioning needs of the individual, and wheelchair types, control mechanisms, features,

and accessories. Knowledge of product resources and local area vendors is also critical in creating device choice options. Although this information is presented as components, all of these factors inter-relate in comprehensive planning for functional mobility through a clinical reasoning process.

EVALUATION OF THE INDIVIDUAL

During evaluation, primary attention is given to user and family goals for use of the wheelchair as part of a functional mobility system. Further, the therapist evaluates

the skills of the user, the user's ability to develop new skills, and changes expected from the diagnosis (e.g., declining sensorimotor skills). How the user plans to transport the system is also an important consideration. Evaluation of needs should include interview, observation, and examination. Trials with seating simulators, trial seating systems, self-propulsion methods, and/or other control systems are often needed to confirm appropriate prescription of these systems. Figure 18-1 outlines evaluation needs; patient-specific information relates to Case Example 1.

The evaluation typically involves both sitting posture and mobility needs. The therapist can best assist in seating and wheelchair selection by understanding the client's personal and medical profiles (Behrman, 1990).

Sample Wheelchair Evaluation: Needs of the Individual

Client information: Lisa, 17-year-old high-school senior with recent C7 level tetraplegia from traumatic SCI in MVC. Attends evaluation with mother. Inpatient stay in acute rehabilitation unit.

Functional Needs and Goals

Environments of use (home, school, work, community at large): Full-time at home, at school, and in other community locations. Has interest in athletics, high school programs.

Seating needs (time, pressure relief, transfers): Postural support needs for trunk and thighs, cushioning for neurogenic skin. Able to perform push-up pressure relief and independent transfers to/from wheelchair.

Control or propulsion methods (attendant, manual needs, power controls): With postural support and seat belt, self-propels using friction push rims and wheel brakes. May benefit from grade aids for propelling up inclines.

Methods of wheelchair transport (car, van, truck; ground travel, air travel): Family owns full-sized truck and minivan. Lisa has driver's license but has not yet explored or been oriented to adaptive driving.

Physical Examination

Head control: No limitations in mobility when trunk is stabilized.

Sitting balance and spinal deformity: Now using TLSO.

Pelvic rotation or obliquity: Symmetrical at this time, mobile pelvis, lumbar support through TLSO.

Lower limb mobility: Full PROM, flaccid at rest with periodic spasms into hip adduction, knee extension and ankle plantarflexion. Neurogenic skin below C8 level.

Upper limb mobility: Full PROM, good to normal strength in shoulder, elbow flexion 5/5, extension 4/5, forearm rotation 4/5, wrist extension 4/5, flexion 3/5, finger extension 3/5. Neurogenic skin lateral hand, 4th and 5th fingers.

Sitting and Balance Needs

Postural support: Now using TLSO for stability, lateral trunk supports for midline positioning. Seat belt and chest harness necessary for support and safety. Explore back cushion contouring when/if TLSO is discontinued.

Cushioning: Solid base of support needed with cushion contour. Tried low-profile Roho and Jay Cushion. Lisa preferred latter for balance, good cushioning effects.

Wheelchair Training Needs

Control or propulsion: Manual propulsion with seating components in place. Enlarged and rubberized friction rim tried and preferred over plain rim or knobs. Wheel camber may assist in hand placement. Needs training for propulsion on level surfaces, maneuvering corners and doorways, all outdoor settings.

Transfers to and from wheelchair and chair, bed, toilet, bathing tub or shower, floor, car: Is beginning transfer training wheelchair to bed using sliding board. Removable armrests and swing-away footrests will enable independence. Will need car transfer training, tub transfer, and floor to wheelchair instruction later.

Wheelchair Maintenance Resources

Lisa expresses interest in learning maintenance routine; father willing to assist as reported by Lisa and her mother. Wheelchair vendor within 15 miles of family home.

Figure 18-1 Evaluation overview. Clinicians address these issues by interview, observation, and physical examination. SCI, spinal cord injury; MVC, motor vehicle collision; TLSO, thoraco-lumbar-sacral orthosis; PROM, passive range of motion.

wheelchair use may be planned. Therapists should recognize that uses of adapted mobility systems often conflict with personal spaces and public accessibility. Public accessibility is based in part on human-factors design in which the typical wheelchair user sits at a 19-inch height and propels a manual wheelchair through a 32-inch wide opening and turns around in a 5-foot clear floor space. Many people are served well by environments that accommodate this type of user, but others continue to be constrained by the environment and need individual guidance about making appropriate accommodations. For example, some power mobility devices have a larger turning radius or excessive weight that limits the user's access to some buildings and/or transportation systems.

Medical Profile

A user's medical profile includes review of medical history and physical assessment. The therapist should be aware of the user's diagnosis and prognosis, that is, whether the medical condition is temporary, stable, or progressive. Such factors influence choices related to complexity of options and need for adjustment as well as preferences for rental, lease, or purchase. For example, if a condition is temporary, a chair may be selected with greater concern for cost factors. In contrast, if a client's condition is chronic and stable and necessitates full-time use of a wheelchair, durability and individualization to meet needs are priorities. If a condition is progressive, a chair that permits a range of adjustments for both seating and wheelchair control may be indicated. The physical assessment should focus on neuromuscular status (e.g., muscle tone, postural control, reflexes, and coordination), musculoskeletal status (e.g., range of motion, deformity, strength, and endurance), sensory status (e.g., anesthetic skin and skin integrity), and physiological status (e.g., temperature regulation, respiration, and cardiopulmonary needs).

Total cost over the life of the wheelchair is a consideration for users with chronic disability and everyday use. For manual users, some ultralight models appear to have the greatest longevity, or greater years of expected use, in comparison with standard wheelchairs or other lightweight models (Cooper, Boninger, & Rentschler, 1999).

In recent years, wheelchair products have been evaluated using standards promulgated by the American National Standards Institute (ANSI) and Rehabilitation Engineering and Assistive Technology Society of North America (RESNA), an interdisciplinary association for the advancement of rehabilitation and assistive technologies, and by direct product comparisons regarding features such as stability, safety, durability, and cost (Cooper et al., 1997). These standards are changing and bring new terminology as well as design elements that impact choices regarding seating, wheelchair frame styles, and attachment options.

Personal Profile

The client's personal profile includes factors such as age and stature, developmental status, living environment, educational or work routines and plans, recreational pursuits, other assistive technology needs or uses, and future anticipated needs. Special attention is given to seating and operation of the chair in both private and public environments. Specifically, the therapist should consider factors such as floor surfaces, outdoor terrain, climate, doorways, hall spaces, restroom dimensions, workspace design, transportability, and parking. If a client has already used an adaptive mobility device before, it is important for the therapist to determine the user's assessment of pros and cons regarding that mobility method or system. A blending of walking aids and

SEATING AND POSITIONING

Critical to selection of a wheelchair system is the attention given to seating and posture needs of the user. Seating systems have a significant effect on the ability of the user to perform functional activities and on basic decisions about choice of mobility base types and components. Effective seating has several broad goals, including: (1) enhancing posture, comfort, physiological maintenance, and skin protection; (2) preventing injury; (3) accommodating existing deformity; (4) enabling vision readiness and upper limb function; and (5) attending to cosmetic appearance and social acceptance. Evaluation and intervention related to positioning often entail participation by team members such as physical therapists to address postural supports, speech therapists to address augmentative communication, and family members and others to address daily routines and schedules. Occupational therapists may coordinate these concerns by incorporating the needs and goals of the user and family with medical care concerns in making recommendations and by analysis of functional issues so that recommendations optimize the individual's access to activities and participation in various environments. The role of team members varies somewhat in different locations and organizations.

Seating Principles: Solid Base of Support

Seating strategies and particular techniques are both age and diagnosis specific (Letts, 1991), although some principles can be applied to meet a variety of needs (Garber & Krouskop, 1997). One such principle is the need to provide the individual with a solid base of support that begins with appropriate pelvic positioning. The sling seat,

common to folding and unlocked wheelchair cross-brace frames, is the seating element most often criticized because it tends to promote pelvic instability and malalignment of the thighs and is often the primary component of seating modification (Krasilovsky, 1993). A solid seating base is accomplished by stabilizing the pelvis on a firm surface with pressure distributed throughout the buttocks and the full length of each thigh.

Postural Supports

Postural control is influenced by the seat and back contact surfaces and by orientation adjustments to the **seat-back angle** and the **angle in space** (Fig. 18-2). There are three commonly used seating position features. First is a sitting position with 90° hip, knee, and ankle positions. Second is a slight anterior tilt to the pelvis to distribute weight through the buttocks and thighs and, for some individuals, to inhibit abnormal reflexive responses (Fig. 18-3). Third is a 95° seat-back angle with a 3–5° angle-in-space recline. Hardware that secures the modular seat and the back components to the frame are often used to adjust these positions.

Seat Surfaces and Cushioning

The seat and back contact surfaces can be planar, pre-contoured, or custom contoured. Single-plane or flat surfaces are appropriate only for those who need little or no postural support and those who can easily reposition themselves to maintain balance and comfort. Contoured designs are used to provide added contact for postural support and distribution of pressure. Custom contouring is often necessary for individuals who need accommodation for deformity of the pelvis or spine, those with abnormal muscle tone, and those who have discomfort

Figure 18-2 Adjustment of seat-back angle and angle in space helps to support posture and provide appropriate pressure distribution.

Figure 18-3 Pelvic positioning with slight anterior tilt helps to distribute tissue pressure throughout the buttock and thigh.

from lack of support at the lumbar spine. These cushions are individually fabricated by bead-seat molding, foam-in-place techniques, or other shape-sensing technology (Cooper, 1998).

Cushions are used to reduce peak pressures associated with bony landmarks and to distribute pressure evenly over a large area of skin contact. Shearing forces that compromise circulation also can be reduced by appropriately shaped cushions. Although cushioning relieves skin and soft tissue pressures, factors including postural stability and control, ease of transfers, ability to accommodate deformity, moisture, and maintenance may be as important for some users. Cushioning of the seat and back may call for use of one or more materials such as variable-density foams, gels, air, and honeycomb-shaped plastics. Custom contouring and alternating pressure systems also may be considered. Table 18-1 lists advantages, disadvantages, and examples of each. Selection of cushion coverings also should take into account factors such as heat and moisture, friction, durability, and cosmetic appearance.

Skin should be monitored closely for tolerance when use of any new seat cushion is started. Progressive sitting time schedules along with ongoing skin inspection routines are essential because no cushion provides sufficient pressure relief during regular use. Properties of materials vary, yet no cushion is considered sufficient in relieving

pressure enough to preserve capillary blood flow to compressed tissues while a person is seated. Pressure on sitting surfaces is greatest during manual propulsion (Kernozek & Lewin, 1998), and users should be informed about dynamic factors that may threaten the health of skin tissues. Although cushions help to reduce skin pressures (Pellow, 1999), other means of pressure relief are necessary. Assisted or user-performed wheelchair push-ups, side leans, or forward leans may be used for pressure relief needs every 15–30 minutes as required. Alternatively, technologies for pressure relief include tilt-in-space mechanisms, use of alternating pressure cushions that continuously cycle high- and low-pressure segments of a cushion (Burns & Betz, 1999), and custom contouring of cushions (Fig. 18-4). The latter show some promise for reducing static seating pressures (Rosenthal et al., 1996).

Adding Seating System Components

A seatbelt is often recommended because it serves an important role in stabilizing the pelvis as part of a therapeutic positioning in the seating system. This anterior support is typically mounted on the wheelchair frame so that it pulls on the pelvis at a 45° angle to the base of the seat back, fitting just under the anterior superior iliac spines. Additional seating supports should be used as needed to improve posture, restrict abnormal movements, and promote head control and voluntary use of the limbs. For example, if sitting balance and abnormal postures are problematic, lateral trunk and thigh supports may be suggested. In addition, use of anterior supports may be necessary across the upper trunk, knee, or ankle for balance and stabilization. Neck and head supports are used to promote head and neck alignment and are sometimes recommended for safety. Upper extremity positioning also may be a concern, in which case specialized armrests or lap trays can be recommended.

Justification of Seating Systems

Since sitting is a dynamic rather than a static state, seating devices should allow some element of pressure relief and freedom of movement. The principle of *less is more* is recommended when applying specialized seating systems because as more seating apparatuses are used, freedom of movement tends to diminish. Therefore, only components that maximize individuals' abilities to function, correct their positions, and maintain comfort should be applied.

Expense justification with the **third-party payer** must relate to medical necessity. Inappropriate seating and mobility base selection can exacerbate complications and accelerate decline for the user. Functional accessibility and

Table 18-1. Cushion Types and Examples

Classification	Advantages	Disadvantages	Example
Foam	Lightweight	Uneven pressure relief	T-Foam by Alimed
	Easily sized, shaped	Poor durability	
	Low cost	Hard to clean	
Gel-filled	Self-contouring	Heavy to move	Jay Cushion by Jay Medical
	Posture control	Temperature sensitive	
	Sitting balance	Leaking, maintenance	
Air-filled	Lightweight	Reduced control/balance	High or Low Profile by Roho
	Even pressure relief	Requires attention to air-pressure tending	
	Little shear	Potentially requires repair of puncture/air leaking	
Honeycomb	Lightweight	Uneven pressure relief	Supracor Stimulite Contoured
	Easy to clean	Difficult to shape	
	Low maintenance	Excessive thickness	
Custom-contoured foam	Surface area coverage	Expense	Contour U, Pindot by Invacare
	Reduced shearing	Longevity with change	
	Better postural control	Reduced weight shift	
Alternating pressure systems	Scheduled relief cycle	Cost and availability	Dynamic Seating System by Talley Medical
	Reduces user effort	Uneven pressure relief	
	Self contouring	Unsteady sitting balance

protection of the user from secondary complications that come with immobility or physiological risks with seating may be cited as part of insurance justifications.

To justify specialized seating with users and families, the experienced therapist can employ clinical observation and literature reviews. Improved motor skills, comfort and participation, physiological supports, and functional independence are widely hoped for as part of specialized seating and wheelchair selection. Some goals should be viewed cautiously, however, because wheelchair and seating configurations can be considered specific to certain diagnostic groups and mostly provide a prosthetic effect, meaning that these benefits are largely limited to the time that the person spends in the seating system. Reid, Laliberte-Rudman, and Hebert (2002) reviewed 46 seating interventions studies with adults and concluded that, although some performance skills and factors have been partially addressed, research has not adequately attended to engagement in occupations and psychosocial issues. Others have reviewed seating needs of specific clinical populations, such as those with spinal cord injury (Krey & Calhoun, 2004; Minkel, 2000) and identify support for

some seating strategies while emphasizing the need for more explicit study of outcomes. Although more wheelchair seating research is now being conducted, methodology challenges and studies with small samples have led to calls for a more focused research effort. Geyer et al. (2003) assembled a variety of stakeholders who reviewed existing work addressing wheelchair seating and called for future research efforts aimed to address wheelchair transportation, postural control, comfort, and tissue integrity. See Evidence Table 18-1, which is related to the case examples.

WHEELCHAIR TYPES: MOBILITY BASES

Once the therapist has a full understanding of the user's personal and medical profile and seating needs, it is important to understand the types and uses of wheelchair systems. Wheelchairs used in everyday activity can be divided into three general categories: (1) attendant-propelled chairs, (2) manual chairs, and (3) power mobility devices (Hobson, 1990). Special-use chairs and attachments to standard mobility bases for participation in recreation and sports also can be considered.

Attendant-Propelled Chairs

Attendant-propelled chairs are designed to be pushed by another individual because of the user's inability to propel or operate a wheelchair in a functional or safe manner. This may be necessary for some users on a temporary or circumstantial basis, for example as a means to be mobile as part of community outings. Attendant assistance also may be a full-time need for individuals who have diminished cognitive capacities, severe judgment difficulties, or restricted physical capacities. These chairs may be full size (e.g., those used in skilled nursing facilities) or may be smaller and created for use in limited spaces (e.g., folding stroller types). Attendant-propelled chairs also are used as a substitute for power mobility when the individual's typical mobility system is being repaired or when space constraints preclude power mobility use. When assisting a user in selecting an attendant-propelled chair, it is necessary to consider not only the fit and comfort of the chair for the person who will be seated, but also the sizing needs of the person most likely to be pushing it. As with all wheelchairs, attention to transportation of the user and the wheelchair device between environments needs attention and planning. Besides chairs specifically designed to be attendant propelled, many manual wheelchairs (described next) can be propelled by an attendant.

Manual Chairs

Manual wheelchairs are for those who can propel and brake using the upper limbs (Fig. 18-5). These chairs have a variety of frame types, weights, and transport features. In general, manual wheelchairs have rigid or box frames or folding frames; folding frames are either free or **snap-secured**. Quick-release wheels can also be selected. Folding, snap-secured frames with quick-release wheels and detachable front rigging may offer the greatest flexibility for transporting the wheelchair. Although rigid-frame chairs may provide greater energy efficiency with propulsion, they may be awkward for loading into automobiles.

The conventional manual wheelchair frame has large rear wheels, which are used to propel the chair, with smaller caster wheels in the front. Wheelchairs of this design are highly maneuverable and easy to propel, and they allow freedom for tilting, which is necessary when ascending or descending curbs. Standard designs, sometimes called depot or institutional wheelchairs (Cooper, 1998) weigh at least 50 pounds without specialized seating systems. A distinction can be made between multiuser chairs, often found in health care settings, and single-user or rehabilitation chairs, sometimes designated as lightweight and ultralight chairs. In recent years, sturdy lightweight metals and designs have been adapted from sport wheelchairs, resulting in lightweight and ultra-lightweight wheelchairs ranging from less than 25 pounds to 40 pounds. Lightweight chairs are often used on a full-time basis. Many new designs allow adjustable wheel positions and seat heights, making it possible to optimize biomechanical efficiency for the user (Masse, Lamontagne, & O'Riain, 1992). Along with reduced weight, these changes can enhance propulsion and ease transport (Brubaker, 1990; Parziale, 1991).

Other types of manual wheelchair designs include the amputee frame for the person with loss of or severely reduced weight of the lower limbs. In this design, the rear axle is offset farther behind the seat back than is standard. This concentrates a person's weight farther in front of the rear axle, reducing the risk of the chair tipping backward. Another type of manual wheelchair, although not commonly recommended, is the indoor frame. It has large front wheels, which are used for propulsion, with smaller casters in back. Although this design rolls easily over door sills and rug edges, larger barriers such as curbs are difficult to traverse, and transfers may be awkward because of the forward placement of the large wheels.

Manual propulsion is typically accomplished through hand rims attached to the outside of the large wheels. Optimally, the user is seated so that, with shoulders slightly extended and elbows partially flexed, each hand rests at the 12 o'clock position of each hand rim (Brubaker, 1990). Contact with rims generally occurs between the 11 and 2 o'clock positions on each side. Circular

Evidence Table 18-1 Best Evidence for Occupational Therapy Practice Regarding Wheelchair Selection Based on Case Examples

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Manual wheelchair testing using ANSI/RESNA standards	Selected ultralightweight wheelchairs were tested and compared to lightweight wheelchairs.	12 models of ultralight wheelchairs; 4 models receiving greater analysis.	ANSI/RESNA tolerance standards.	Randomization of product testing. IC2b; machine tested vs. consumer use.	Specific products (by Invacare and Kuschall) had better durability characteristics (i.e., life-cycle value).	$p < 0.05$	Cooper, Boninger, & Rentschler, 1999
Pressure distribution using wheelchair seat cushions	Mean and peak pressure mapping with 4 cushion materials/products.	7 adult participants with disability that included scoliosis .	Talley pressure monitoring of mean and peak pressures.	Product testing in single-session use by participants. IIIc2b	All cushions relieved peak pressure, although only foam products reduced the mean pressure ratio.	$p < 0.05$	Apatsidis, Solomonidis, & Michael, 2002
Dynamic sitting and reaching by wheelchair users with paraplegia	Displacement of center of pressure (COP) when performing reaching tasks while seated on three types of cushions.	9 adult wheelchair users with SCI.	Reach and COP displaced on air, flat foam, and generically contoured seat cushions.	Trials using different cushion types. IC1b	Generically contoured foam resulted in greater reach distance and speed with increased stability.	$p < 0.01$	Aissaoui et al., 2001
Survey completed by individuals with ALS about preferences for use of mobility	Survey about experiences with use of wheelchairs.	42 adult patients with ALS (mean age = 54 years) observed in a neuromuscular clinic who used manual (n = 20) or power (n = 22) wheelchairs.	Naturally occurring accommodations used by individuals.	Survey about clinical course of treatment and change. IIIb3b	Wheelchair use permitted greater community interaction. Focused on comfort and ease of maneuvering. Either manual or motorized beneficial.	Powered wheelchair use had benefit to activity ($p < 0.05$).	Trail et al., 2001

SCI, spinal cord injury; ALS, amyotrophic lateral sclerosis; NA, not applicable.

steel tube hand rims are common. For users who have difficulty with grip, hand rims can be covered with vinyl coating; knobs or other projections can be added to the rims so that grip is not required; and/or gloves or mitts can be worn to improve traction. Gloves and mitts also protect the hands. Hand rims vary in size. Small hand rims, often used on racing chairs, result in a slower and more difficult start but provide for a high top speed that is sustainable with relatively little effort (Ragnarsson, 1990).

Manual propulsion by a person with hemiplegia or unilateral upper limb use necessitates additional adaptations. Commonly, the person with hemiplegia uses the more capable side for the hand rim and the leg and foot to steer and provide additional propulsion and braking. This requires removal of the unused footrest and usually requires lowering the seat height or using small-diameter wheels to optimize foot contact with the floor. For the user who plans to propel the wheelchair using only one arm, a chair can be ordered with both hand rims on one side so that each wheel can be controlled independently or together. Learning to maneuver two hand rims on the same side can be perceptually and mechanically difficult. Another option for unilateral control is the single-lever drive. This

rare device uses a forward-and-backward motion to propel the chair and rotation of the lever to turn the chair.

Augmentation of manual propulsion and braking systems is available. As an aid to propelling on inclines, hill climbers or grade aid devices restrict the rearward movement of wheels through a friction stop engaged by a lever on each tire. Speed control and braking to a stop simply depend on slowing wheel rotation by use of the arms or legs. New devices that augment propulsion through electrical or mechanical means now also can be considered. Such devices provide supplemental power from an electric motor to amplify the user's effort (e.g., iGlide™ and Superwheel™ electric wheelchair) or mechanical advantage through a two-gear system (e.g., HandMaster™ and Magic Wheels™)

Brakes are used on each large wheel and are engaged through a variable-length single- or dual-action lever, depending on reach and force abilities. Such levers press on the tire to resist rolling and require that tires be fully inflated with periodic tightening after tire wear. Brakes restrict wheel turning when the chair is parked but are not typically recommended for slowing or stopping. In addition, anti-rotation locks also can be used on casters.

Figure 18-5 Conventional manual wheelchair with component parts.

Power Mobility Devices: Motorized Wheelchairs

Power mobility devices are used by individuals (1) who cannot propel a chair using either the hands or the feet, (2) for whom the energy expenditure required to walk or propel a manual chair is contraindicated, (3) who have musculoskeletal complications, such as arthritis, in upper limb joints, (4) who are prone to repetitive stress injury, and/or (5) who have neuromuscular dysfunction that may cause associated reactions in the lower extremities when the upper extremities are used for manual wheelchair propulsion. There are a number of types of power mobility devices. Selection of power mobility can be a complex task due to the variety of user needs and the many options for wheels, controls, and environmental designs (Field, 1999).

Power Wheelchairs

Most new power wheelchairs have a power-base design so that the wheels are, in effect, independent of the seating components. Such bases may have front-, mid-, or rear-wheel drive, with a variety of wheel diameters. For each type of design, the wheels may be coupled to motors through exposed or concealed chains or gear systems. Mid-wheel-drive chairs generally have a smaller turning radius, which improves maneuverability. Power-base wheelchair designs are noted for being sturdy and appropriate for the full-time user both indoors and outdoors. These designs generally allow for ease in changing seating dimensions, such as for a growing child or for an individual with changing seating system needs.

Several power-base chairs have options that enable the user to change seat height or elevate toward a standing position independently. Similarly, some manual wheelchairs have manual lever systems that allow the user to rise to a near standing position. These allow the person greater vertical flexibility in environmental accessibility, enabling face-to-face communication and easing performance in reaching books in a library, working in a shop using power equipment, and accessing a high counter.

The primary disadvantages of power wheelchairs are that (1) they can be large and heavy and may be difficult to maneuver in small spaces and transport from one place to another; and (2) a 5 × 5-foot turning space, as part of standard barrier-free design, may not be sufficient for some power wheelchairs. Typically, van or bus transport of the individual sitting in a power mobility device requires special lifts or ramp devices, and the size of some chairs necessitates a raised roof in these vehicles. Alternatively, the user can transfer into the vehicle and an attendant can load the chair separately by use of a lift or by breakdown into components. Some lightweight power wheelchairs are designed to be taken apart for automobile transport. Some of these chairs are built on folding

frames and/or have low-powered motors, making hill climbing and use on uneven surfaces more challenging. Assistance with taking apart and reassembling the chair often is required.

Manual Wheelchair with Add-On Power Unit

Another option for power mobility is the use of an add-on unit on a manual wheelchair to provide power assistance. Such systems can be engaged and disengaged to switch between manual and power mobility. Since a significant amount of weight is added to the chair and units are not easily taken on and off the frame, this option is most commonly suggested as a trial for a transition to a regular power wheelchair. As previously described, pushrim-activated power-assisted devices (e.g., iGlide™) have also been used to reduce energy demands and the biomechanical strain of manual propulsion (Algood et al., 2004), especially in environmental conditions such as inclined ramps, uneven surfaces, and thick carpet (Algood et al., 2005).

Scooter

A popular type of power mobility device is the scooter. Scooters typically have three wheels, although four-wheeled designs are available, and may have either rear- or front-wheel drive. Most of these designs are characterized by tiller control, wherein users steer the scooter by rotating the front wheel while using a lever-style switch for forward and reverse power. This type of chair is appropriate for the marginal walker and is often used to compensate for a person's inability to travel comfortably within the community. Scooters are sometimes modular and can be disassembled and loaded in and out of the trunk of a car or the back of a station wagon or van. Steering and control of scooters can be difficult, so individuals with marginal control may be better served by use of a power wheelchair with a variety of control options. Scooters may also not be appropriate for individuals with significant posture control needs because special seating and other components are difficult to attach. In addition, scooters require a larger turning radius and may limit accessibility indoors.

Power Mobility Considerations

Specific factors unique to power mobility require consideration. The therapist should determine whether the device will be used primarily indoors or both indoors and outdoors. A device that is to be used in both settings must have more stability, power, distance capability, and durability than an indoor-only model. In addition, the therapist should consider use and maintenance of the batteries that provide power. Various sizes of deep-cycle lead acid batteries, either wet cell or sealed cell gel types, have different expense, longevity, and needs for maintenance.

Other power wheelchair characteristics to consider include noise, braking systems, ride quality, and portability, including ease of assembly and disassembly if appropriate. If the device can be disassembled, the weight and size of each part should be carefully evaluated for transportability. Non-leaking sealed cell or gel batteries are preferred for added safety in airline transportation.

Selection of appropriate controls for driving is critical. Programmable controls are most common and enable careful selection of torque and speed control based on wheeling surface resistance and safety. Power devices are typically driven using one of two types of options: proportional or discrete control. Most commonly, a proportional joystick is used, in which directions and speeds are linked to angle and magnitude of stick displacement. Proportional control also may be achieved through **proximity-sensing devices** that sense the position of the head. The user moves his or her head as a joystick, and the wheelchair's speed and directional control is proportional to the head displacement. An alternative is discrete micro-switch control activated with a joystick, a multiple-switch array, or a single-switch scan. Each switch activation engages a preset or programmed speed and direction. Micro-switch systems require less skilled movement to achieve control, although control of the wheelchair is often less precise than that provided by proportional control. Also, learning to use micro-switch control is not simple. Each direction may be controlled by activating a micro-switch using a body part (i.e., hand, arm, chin, foot, head, mouth, lips, or tongue), and control may be organized through a combination of special techniques such as **sip and puff**, **scanning**, or switches imbedded in headrests (Fig. 18-6). For instance, breath may be used for forward and reverse control, and proximity-sensing switches may be used to activate turning control. When selecting controls, the therapist should consider adjustment options provided by various systems in relation to the needs of the individual. For example, clients with poor motor control may benefit from adjustment of programmable electronics that enable wheelchair speeds to be automatically restricted when turning or that enable several levels of control to be programmed for new learning and training in various environments.

Power wheelchairs and scooters are electronically braked, meaning that drive wheels do not rotate except under power. Gears are then released by levers that allow the chair to roll freely.

Activity- or Environment-Specific Wheelchairs

For everyday use, attendant-propelled, manual, or power wheelchairs are selected. Many users, however, need mobility to overcome unique barriers or for use in recreation and leisure activities that require activity-specific technology (Axelson, 1998). Special power-wheel configurations can be used for ascending or descending stairs (e.g., the

Figure 18-6 College student uses a power wheelchair controlled with proximity switches in a head array. The display in front of right armrest provides feedback regarding drive selection, environmental unit (ECU) functions, and battery level. A switch on the right side of the head array permits selection of drive and ECU functions. (Courtesy of Adaptive Switch Laboratories, Inc., Spicewood, TX.)

iBOT™). Other special designs for wheelchairs, including those for use at the beach and on other soft and uneven surfaces, are available commercially or may be custom made. For recreation, cycling configurations may be requested. Row cycles are large, low to the ground three-wheeled cycles propelled by a rowing action that activates chain-driven rear wheels. Cycling action also can be added to manual wheelchairs (Fig. 18-7) or be configured as a separate chair for outdoor sport. Sport wheelchairs for racing, basketball, and other competitions are commercially available, but often they require customized sizing and expert instruction. For a thorough review of options

Figure 18-7 A father uses a cycling apparatus attached to his everyday-use manual wheelchair for outdoor activity with his children.

for using activity-specific or sport and recreation chairs, see Cooper (1998).

WHEELCHAIR SIZING AND ERGONOMIC CONSIDERATIONS

Modern wheelchairs are engineered as modular systems and are assembled to match the specific physical dimensions of the user. Measurements of the individual form the basis for determining wheelchair frame size, need for adjustable ranges in component parts, and need for customization to meet special needs.

Sizing

Appropriate size determinations of the wheelchair frame, seat, back, leg rests, and armrests are based on measurements typically taken with the user in an optimally seated position. Alternatively, the therapist can evaluate the individual on a mat in a supine or side-lying position and take careful measurements of distances between key landmarks. These measurements are confirmed for accuracy with the user seated. The user's typical or specialized clothing needs should be considered during measurement. If thoracolumbar bracing or lower limb orthotics and prosthetics are likely to be used in the wheelchair, they should be worn during sizing measurements. Manufacturers of wheelchairs and seating systems have differing standards for measurement and sizing. Typically included are measures of pelvic or hip width; upper and lower leg lengths; mid-back, mid-scapula, and top of shoulder heights; chest and shoulder widths; elbow height; and overall sitting height (Fig. 18-8).

- **Seat width:** The therapist determines the widest point across the hips and thighs and typically adds a total of 5 cm (2 inches) for adequate clearance on the sides. Overall wheelchair width may be dictated by the seat width measure. Wheelchairs should be as narrow as possible while allowing for comfort, easy repositioning, clothing needs, and transfers. For manual users, narrower wheelchairs are likely to improve ease of hand rim propulsion and maneuverability.
- **Seat depth:** The therapist, for both the left and right sides, measures the distance from the most posterior part of the buttocks under the thigh to the popliteal fossa of each knee. About 5 cm (2 inches) is subtracted from the measure. This allows as much weight bearing through the thigh as possible without the front edge of the seat pressing into the back of the knee. Right and left leg length discrepancies can be caused by hip dislocation, **pelvic rotation**, or other anatomical factors. The shorter side may be used to determine seat depth, or if a greater than 1-inch discrepancy is found, the front seat edge may be offset to accommodate the length of each

Figure 18-8 Seating measurements. For B to G, all measurements are taken on both right and left sides. A, Hip and thigh width; B, thigh length; C, leg length; D, back height to below scapula; E, back height to mid-scapula; F, back height to top of shoulder; G, elbow and forearm height; H, chest width; I, shoulder width; and J, sitting height.

side. Individuals who use their feet to propel or steer will need greater front-edge seat clearance.

Selected seat cushion height should be incorporated into further measures of trunk, arm, and leg.

- **Back height and width:** The therapist generally takes three measures from the seat surface upward (1) to the mid-back just under the scapula, (2) to the mid-scapula or axilla, and (3) to the top of the shoulder. Back height is affected by seat cushions, which should be considered in sizing decisions. Height of the chair back is based on the need for postural stability and freedom of arm movements for propulsion or other functions. For those who exclusively self-propel, a chair back height of 2–5 cm (1–2 inches) under the tip of the scapula may be preferred. For sporting activities, the optimal back height may be even lower. By contrast, for power wheelchair users, back heights to mid-scapula or the top of the shoulder may be necessary to allow use of postural supports for the upper trunk and the head. Chest and shoulder width should be measured in cases of deformity or to determine the space requirements for lateral trunk supports or other trunk-positioning devices. Alterations of the standard sling back may be necessary for improving trunk posture by using an adjustable or flexible sling back, curved backs, or additions of lateral trunk supports.
- **Seat height and leg rests:** Seat height is based on positioning of the individual such that footrests have at least a 5-cm (2-inch) clearance from the floor. Use of seat cushions affects this measurement by raising overall seat height. Seat height is determined with the individual's knees and ankles positioned at about 90°.

Measurements are taken from under the distal thigh to the heel of the individual's commonly used footwear or shoe. Several inches of adjustment are typically available in leg rest lengths. Unusual leg lengths or hip or knee deformity may necessitate special ordering.

- **Armrest height:** The therapist measures from under each elbow to the cushioned seating surface with the shoulder in neutral, the arms hanging at the sides, and the elbows flexed to 90°. Armrests must provide forearm support with neutral shoulder position but should not obstruct reach to hand rims for propulsion or to brake locks.

Common Components

In addition to overall sizing and seat and back surface, the team and user should consider selection of head and neck rests, armrests, leg rests, and other options. Table 18-2 lists options for head, neck, arm, leg, and foot support. Users should consider armrest stability for performing wheelchair push-ups for pressure release. Detachable or swing-away styles may allow greater ease in sliding board and other sideways transfers and improve access to tables and desks. Guards can be used on armrests to keep clothes from coming in contact with wheels. Attachment of lap trays may require use of full-length armrests or other specialized hardware. The front rigging consists of leg rests and foot plates. Options are selected according to needs for elevation of the calf and foot, ankle position, and stabilization of the leg. Flip-down footplates or platforms are common and popular because they can reduce the overall length of the chair. Swing-away or detachable front rigging may enable easy transfers and transportability of the wheelchair in and out of vehicles.

Tires can be either pneumatic (air filled), semi-pneumatic (airless foam inserts), or solid-core rubber and are mounted on spoke or molded wheels. Air-filled tires are lightweight with low rolling resistance, providing a well-cushioned ride and shock absorber function that tends to

improve comfort and prolong the life of the chair, but they do require regular maintenance. Semi-pneumatics provide good cushioning and less maintenance, but tire wear may be more of a problem. Solid-core tires are noted for minimal maintenance and approach the weight and low rolling resistance of high-pressure pneumatic tires.

Casters, as either front or rear wheels, vary in diameter, and small ones usually facilitate maneuverability. Pneumatic and semi-pneumatic caster tires provide some shock absorption for use outdoors and on rough surfaces. Solid-core caster tires are best for use indoors and on smooth surfaces. Special designs (e.g., Frog Legs™) for manual wheelchairs and power wheelchairs are promoted for shock absorption and enhanced maneuverability.

Placement of the rear axles can be fixed or adjustable on most manual wheelchairs, especially newer manual lightweight and ultralight styles. Backward placement of the axle tends to increase stability; by contrast, forward placement of the axle decreases stability but increases maneuverability and shortens turning radius. Sometimes rear wheels have a **camber** adjustment. This orients the hand rim for easier propulsion and may slightly widen the wheel base for better stability. Anti-tipping extensions can be used on a wheelchair to prevent the chair from tipping backward or forward. Typically used on the back, these fixed or adjustable extensions can improve safety, particularly during mobility training.

Seatbelts, safety vests, and harnesses vary in design and are used for both safety and positioning. These devices should be considered for individuals who have severe neuromuscular impairments and need control for posture and safety. Restraints may be considered with individuals who have poor judgment, but these should be avoided whenever possible and be regarded separately from seating postural needs. In general, restraint reduction efforts in long-term care facilities are often enhanced by use of appropriate and comfortable seating (Stinnett, 1997).

Frame and upholstery color and material options are numerous. Users can personalize their chair through selections of colors and other styling. Durability, cleaning,

Table 18-2. Head, Arm, and Leg Supports

Component	Attachment to Frame	Adjustment	Style
Head and neck supports	Fixed or removable	Height, depth, and rotation	Flat, winged, lateral, occipital, or wedged
Armrests	Fixed, swing away, and/or removable	Same height or adjustable height	Full length or desk length, rigid or padded
Leg rests	Fixed rigid, swing away, and/or detachable	Fixed or telescoping length	Fixed angle or elevating
Calf pad and foot plate	Rigid or flip up, flip away	Variable sizes in pads or straps	Plate, tubular, rigid, or padded

ease of repair, and compatibility of materials with temperature regulation, friction, moisture, and skin protection also require careful planning.

Recline and tilt-in-space options enable postural changes for rest and pressure relief. In attendant-propelled wheelchairs semi-reclining up to 30° from upright or full reclining up to 90° from upright can be considered. In tilt-in-space systems, the seat and back assembly pivot together. This feature makes the use of postural seating components more stable because the angle between the seat and the back remains unchanged, reducing or eliminating the problem of shear. Power recline systems can be used with conventional or power-base designs. Such systems may involve tilt-in-space and/or low-shear back recline, both of which provide pressure relief and rest positioning (Hobson, 1992). Tilt-in-space chairs that go back 45–60° achieve effective pressure relief under the buttock and thigh and may have other physiological benefits, such as improved respiration (Chan & Heck, 1999). These systems, however, may add costs and increase wheelchair size and weight.

Narrowing devices are available for some non-secured folding frame manual chairs to reduce chair width temporarily for fitting through doorways. These devices mount on one side of the seat and narrow the chair when a crank is turned to shorten a belt wrapped around the frame to narrow the chair.

Other considerations are accessories that optimize use and performance. Lap trays can be used for postural support of the upper limbs and serve a variety of purposes related to function. Other accessories include mounting bags or baskets for storage and carrying, cup or bottle holders for taking fluids, and storage attachments for reacher or walking aids to enhance access and mobility. Some wheelchair users also need other assistive technology, such as communication devices or environmental controls. These devices may be mounted on the wheelchair and operated independently of wheelchair controls or can be integrated with power wheelchair controllers.

MOBILITY TRAINING

Mobility training with the wheelchair system is essential and often involves interdisciplinary team members, such as the physical therapist. Most users benefit from instruction and practice beyond the training provided by vendors. Once the chair has been provided, a check should be conducted, and appropriate training of the user and attendants should commence. This includes review of the user's goals for mobility along with a check of the device for fit and adjustment. Instruction also should be provided regarding (1) use of the chair indoors and outdoors and on a variety of surfaces (e.g., level, carpeted, incline, and uneven); (2) transfers (e.g., bed, toilet, and car); (3) transport of the wheelchair

(e.g., cars, trucks, vans, and buses); and (4) maintenance of the wheelchair (e.g., cleaning the chair, lubricating moving parts, monitoring tire pressure and wear, adjusting brakes, and caring for batteries). Troubleshooting with the wheelchair system ultimately becomes the responsibility of the user and equipment supplier or vendor, but the therapist may advise about problem-solving strategies and organization of maintenance routines and schedules. Throughout training, the therapist emphasizes safety issues because accidents during day-to-day wheelchair use, although infrequent, do occur, and some appear to be preventable (Calder & Kirby, 1990).

Manual wheelchair users also benefit from instruction about propelling, braking, and transport. Particular attention to hand placement and trunk lean for effective and efficient wheeling can be explored. General consumer use guidelines are available for the user and trainer (Axelson et al., 1998). Power wheelchair users also need guidance about power functions such as controllers, batteries, and accessory devices. With all wheelchair users, the therapist should provide initial checks; periodic follow-up to address safety issues, fit, and adjustment; and updated information about new options to meet the changing needs of the user.

Transportability of the wheelchair system between environments can be especially challenging. Loading and unloading should be trialed with the vehicle most likely to be used. As noted, car transfers of the user and loading and unloading of the wheelchair need careful planning. Breakdown of the wheelchair for portability or the addition of special lift accessories to vehicles should be considered during selection. Weight of the wheelchair and component parts may be limiting to users as well as care providers who assist with vehicle transfers. Lifts are often used with vans or buses. In these vehicles, wheelchair tie-downs are necessary as safety mechanisms to keep chairs stabilized when traveling. The necessary style may be determined by wheelchair design. Such devices secure the wheelchair to the base of the vehicle; the individual is independently secured in the wheelchair seat or in another seating device within the vehicle.

WHEELED MOBILITY AND PARTICIPATION

As part of the wheelchair selection process, impact of devices on the users' roles and participation needs to be considered relative to home, work, and community contexts. Functionally matching to the environment in terms of access within and between settings, speed of mobility, and positioning may impact interactions. Different routes of travel may be necessary that could detract from feelings of inclusion. Speed of mobility may hinder shopping trips within and between stores or with

movements at work. Armrest or other features of the wheelchair may preclude positioning with peers at dinner or meeting room tables. Professional rating tools that address needs (Miller et al., 2004) and consumer rating tools that address satisfaction with wheeled mobility devices are being proposed and address issues and interactions between the person, the technology, and the environment (Mills et al., 2002).

Greater successes in matching devices with environments of participation is needed. Although wheelchair mobility can lead to successful independence, challenges continue regarding integration of wheelchair users in various settings. For example, data on disability and workplace accommodation (http://www.infouse.com/disabilitydata/workdisability/2_1.php) reveal that less than 25% of wheelchair users are employed. Studies involving wheelchair users often indicate that obstacles created by use of wheeled mobility devices are seen as a major reason for lack of community participation and as a source of frustration (Chaves et al., 2004; Hoenig et al., 2003; Reid et al., 2003). Nevertheless, use of wheelchairs, and powered mobility devices in particular, is often credited with enhancing occupational performance and participation (Brandt, Iwarsson, & Stahle, 2004; Buning, Angelo, & Schmeler, 2001; Davies, DeSouza, & Frank, 2003). Although the built environment is a major reason for obstacles, attention also should be given to associated factors such as wheelchair user fitness and health, use of assistants and other assistive technologies, and social interactions in the community (Meyers et al., 2002).

FINAL DETERMINATION

In making a final determination regarding seating components, style, size, and control systems, the user and team take a comprehensive and functional view, simultaneously considering the current and future needs, desires, and resources of the user; environments of participation; and anticipated changes in technology (Batavia, Batavia, & Friedman, 2001).

Decision Making and Justification

Costs and related funding issues are critical components of the decision-making process. Expensive technology and options should not be ordered unless justifiable for increased function, health (e.g., skin protection), user satisfaction, or safety. When expensive choices are being considered, it is important to rule out the feasibility of using less costly alternatives. For example, before selecting power mobility, it is important to rule out the feasibility of using a manual chair because the cost of providing and maintaining a powered system is estimated to be approxi-

mately three times that required for a manual system (Warren, 1990). In such cases, appropriate justification must be clearly delineated for users and third-party payers. Some users decide to purchase devices or features on their own or seek funding through other sources.

A comprehensive functional mobility system for an individual often includes more than one means of mobility and selective use in different environments (Hoenig et al., 2002). For example, an individual may use limited walking skills within settings and benefit from a manual chair for traveling short distances, such as at home, and a power chair for traveling longer distances in the community and at work. Funding sources may pay for only one of these options, but with mobility being unique to different activities, negotiation of options may be explored with health insurance as well as educational and vocational support programs.

The Clinician's Responsibilities

Technology design and products are changing rapidly. Therefore, it is a continual challenge for occupational therapists to remain current. Therapists have a responsibility to keep abreast of new technology, new products, and new product evaluation research. They must be able to provide users with current information on the advantages and disadvantages of various wheelchairs, components, and features. In addition, they must have current knowledge of issues related to availability, serviceability, and performance of various wheelchairs and options (Behrman, 1990). Professional and consumer sources of information about wheelchairs, related options, and manufacturers of mobility systems, controls, and seating systems are useful for product information (see Resources 18-1).

Therapists also are encouraged to explore wheelchair standards developed by the American National Standards Institute (ANSI) and Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) and the International Standards Organization (ISO) (<http://www.wheelchairstandards.pitt.edu/>). These voluntary standards for wheelchair developers and manufacturers provide guidelines for product specifications based on uniform measurements and testing. Use of these standards facilitates product comparisons. Besides being aware of wheelchair standards, the therapist also is responsible, along with the interdisciplinary team, to develop relationships with appropriate vendors of seating and wheelchair systems.

Wheelchairs, selected through a user-led team, can facilitate participation in multiple environments. Selection of an appropriate wheelchair system results from a clinical reasoning process that considers multiple variables, particularly best fit, function, and the user's preferences. Consumers' satisfaction with seating and mobility systems is critical to program evaluation that addresses out-

CASE

EXAMPLE # 1

Wheelchair Selection for a Student Who Has Tetraplegia

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information Lisa is a 17-year-old high school senior with C7-level tetraplegia from a traumatic spinal cord injury (SCI) that she experienced in an automobile crash. She is expected to be a long-term wheelchair user, and in the hospital, she demonstrates the ability to propel a manual ultralight wheelchair using coated push rims. Lisa previously was active in soccer and other sports and would like to match her school colors with her wheelchair frame. She was intrigued to learn about competitive wheelchair sports but is inexperienced with independent mobility.</p>	<p>Appreciate the context</p>	<p>(See Chapter 43 for review of spinal cord injury rehabilitation).</p>
	<p>Develop intervention hypotheses</p>	<p>“Lisa may not endorse her need for long-term use of a wheelchair but may agree to the interim reality and specific wheelchair choices related to return to home and school.”</p> <p>“Ultralight wheelchair styles have good longevity and can be customized in various ways for her size and needs.”</p> <p>“A vendor and options for wheelchair choices from such a vendor should be introduced to Lisa and her family.”</p>
	<p>Select an intervention approach</p>	<p>“A rehabilitative approach matches her adaptive capacities and skills with training for use of appropriate assistive technology, environmental accommodations, and care providers.”</p>
	<p>Reflect on competence</p>	<p>“My own knowledge of wheelchair needs is strong, but my awareness of currently available products will be augmented through the vendor and product representatives. Accessibility needs at home, in school, and in the community will need to be explored specifically for Lisa and her support network.”</p>
<p>Recommendations The care team is preparing a wheelchair prescription and considering these features:</p> <p>Wheelchair</p> <ul style="list-style-type: none"> • Manual ultralight cross-brace folding frame • Purple frame with black upholstery • Adjustable axle position with camber control 	<p>Consider the patient’s appraisal of performance</p>	<p>“Lisa may regard the wheelchair as a short-term versus a long-term strategy but seems interested in resuming independent mobility, as seen in her use of a loaner wheelchair. Helping her learn about customization of size, cushioning, colors and other features may encourage her use of the wheelchair.”</p>
	<p>Consider what will occur in therapy, how often, and for how long</p>	

- Lift-off desk-length tubular armrests
- Swing-away fixed-angle foot rests with heel loops on flip-up foot plates
- Vinyl-coated push rims with pneumatic tires and non-pneumatic front casters
- Grade aids and standard rubber-coated brake levers

Seating

- Cloth-covered Jay seat cushion with flexible sling back, mid-scapular height
- Seat belt and chest strap

Ascertain the patient’s endorsement of plan

“Her new wheelchair may not be available until after inpatient hospital discharge.”

“Options to review with her for selection of chair include frame type, cushioning, armrest and leg rest features, frame and upholstery color, and a variety of hand rim and brake features.”

“Gel cushion is encouraged for sitting balance and pressure relief. Air demonstrated good pressure relief but can impair sitting balance and necessitates tending to air pressure. Foam or silicone have less even pressure distribution but are lighter weight and do not need regular maintenance. Gel has the precaution of cooling/freezing with low outdoor temperature and could puncture and leak.”

Summary of Short-Term Goals and Progress

A loaner rehabilitation wheelchair has been provided to Lisa and she makes use of this self-propelled device to go to and from therapy and other appointments. When she is with visitors, she is often pushed to other locations on the hospital campus.

Sitting tolerance times have been increasing daily with skin inspection performed by Lisa with nursing or therapy supervision and guidance. Sitting tolerance and travel distances are being staggered and staged to increase time and range of mobility. By discharge, up to 6 hours of wheelchair time is expected before bed-rest relief. Indoor mobility independence is expected including use of doorways and elevators. Outdoor mobility is supervised initially to assure safety with ramps, curb cuts, and cross slopes.

Wheelchair-to-bed transfer training is proceeding with use of a lightweight sliding board and standby supervision for safety. Toilet and tub transfer skills are being introduced, and she currently receives moderate assistance. Independence in wheelchair transfers is expected with standby supervision anticipated.

Assess the patient’s and family’s comprehension

“Trial use of a loaner wheelchair has Lisa experiencing transfers, self-propulsion, and environmental access on hospital grounds. She is taking responsibility to go to and from therapy sessions but is seen being pushed by family and friends at other times.”

Understand what the patient is doing

Staging of wheelchair sitting time is scheduled, and Lisa seems willing to observe this precaution and is accepting of reminders to attempt pressure relief routines. She does not appear to attend to time of day on a regular basis, so she will likely need an external cue of some sort.”

Compare actual to expected performance

Know the person

“Lisa monitors her progress carefully in both occupational and physical therapy with high hopes of regaining strength. Nevertheless, she also is aware of her functional mobility and capacity to self-propel and transfer.”

Appreciate the context

“Self-initiated goals for functional mobility in and around the hospital campus are being suggested by her. These are being encouraged with use of appropriate standby supervision.”

Next Steps

Lisa will be using the wheelchair full time at home, at school, and in other community locations. Her own wheelchair is being ordered and will be available at discharge or soon after her return home. Accessibility at home and school need to be assessed with Lisa and her family.

Anticipate present and future patient concerns

“Lisa has become aware and has concerns about accessibility at home and school where stairs are an issue to enter and move between levels.”

Analyze patient’s comprehension

“An accessibility audit of home and school through interview will be conducted and a home visit with Lisa and family members is anticipated before inpatient discharge. School access may be appraised in conjunction with the school therapist.”

Decide if patient should continue or discontinue therapy and/or return in the future

“Lisa continues to hope that she will again be able to walk, but as weeks progress, she has focused increasingly on her wheelchair skills.”

“Referral to and follow-along in community-based therapy or outpatient visits to the SCI program are anticipated. Goals will be safe mobility and full participation in school and community. Consideration for airline travel and sports participation might be anticipated in coming years.”

? CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Selection of Other Wheelchair Options

Based on Lisa’s functional needs, what else should be considered related to wheelchair selection and mobility training? Consider use of other wheelchair accessories, performance in transfers, transportation with the wheelchair, and maintenance of the wheelchair. Under what circumstances might power mobility be considered? What other kinds of activity-specific mobility aids might interest Lisa?

CASE

EXAMPLE # 2

Dependent Mobility with Amyotrophic Lateral Sclerosis

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information Mr. R. is a 48-year-old husband and father with amyotrophic lateral sclerosis (ALS). He is near the end of his ability to walk safely and has quit driving a car. He teaches in a public school and expects to retire at the end of the month. He coaches his children’s youth baseball teams. He lacks sufficient strength in his arms to self-propel a wheelchair. To address his needs now for mobility at home, at work, and in the community, a prescription for a wheelchair is being written. Family financial resources are limited.</p>	<p>Appreciate the context</p>	<p>(See related assessment and intervention in Chapter 40 regarding adults with neurodegenerative disorders.)</p> <p>“Mr. R.’s walking difficulty with upper limb weakness will necessitate power wheelchair mobility and/or dependent wheelchair use. Use of power mobility in homes is problematic for maneuverability and will likely necessitate a dependent wheelchair for function and care.”</p>
	<p>Develop intervention hypotheses</p>	<p>“Medicare funding would address wheeled mobility for at-home use and perhaps transportation to and from medical appointments. Other community mobility needs should be addressed separately.”</p>
	<p>Select an intervention approach</p>	<p>“A rehabilitative approach will attempt to match devices and environments with abilities to address Mr. R.’s family goals. Wheelchair use will take place along with uses of other assistive devices and environmental accommodations planned for home.”</p>
	<p>Reflect on competence</p>	<p>“As a therapist, I am familiar with dependent mobility devices and need to carefully match size and adjustment options for the client’s home environment. Loaner equipment or used devices are sometimes preferred for cost savings. The ALS Association or other assistive technology recycling programs could be explored.”</p>

Recommendations

To address needs within the home, an attendant-propelled wheelchair is needed. A tilt-in-space manual chair that permits full upright position to 45° recline is selected, along with a foam seat cushion and flexible sling back with a winged headrest. A lap tray is added to enable positioning of the arms and for attachment of communication devices. This chair is requested through health insurance, and once Mr. R. is unable to walk safely, it will be used at home and for attending medical appointments. Community mobility may be served by this device, but other options will need to be explored as well.

Consider the patient's appraisal of performance

"Mr. R. is knowledgeable about his condition but is reluctant to give up walking. Presenting the wheelchair as an option rather than an exclusive device for mobility might be best."

Consider what will occur in therapy, how often, and for how long

"Selecting, fitting, and brief training are specifically needed with the wheelchair device. Operation of brakes, recline mechanism, and other features should be reviewed with Mr. R. and his care providers."

Ascertain the patient's endorsement of plan

"Mr. R. is in agreement but views the wheelchair as being a further indicator of his decline."

Summary of Short-Term Goals and Progress

Mr. R. needs consumer education about wheelchair products and options that he could use. Funding mechanisms need careful review in terms of requirements, dollar allowances, and costs of options.

Client and family training in use of the wheelchair is a service goal, with Mr. R. having informed options about wheelchair use.

Assess the patient's comprehension

"Mr. R. recognizes his mobility needs and is aware of and concerned about costs and access within his home, such as installation of ramps and widening of doorways."

Understand what the patient is doing

"Adjustable cushioning for comfort and function should be devised. Foam cushions are likely the most cost-effective and flexible option, both for seating and transport. He will likely adjust his position easily on his own at first. With more static seating later on, air cushioning could be considered. This will then necessitate adjustment and tending of the cushion relative to air pressure. Gel cushions could be considered, but they are heavy and may make Mr. R.'s own adjustment of his position more challenging."

Compare actual to expected performance

Know the person

"Resting and functional settings at home are likely to include his bed, wheelchair, and another chair or couch location. Transfer training with family care providers should take place soon."

Appreciate the context

Next Steps

Mr. R. obtains and uses the mobility devices, which appear to meet his present needs. Occupational therapy is put on hold, with plans for re-assessment in 6 weeks.

Anticipate present and future patient concerns

"Monitoring of wheelchair operation and use, along with other assistive devices, should occur as part of outpatient follow-up, perhaps every 6 weeks depending on the speed of Mr. R.'s decline. Coordination with home-health or hospice care also may be considered."

Analyze patient's comprehension

Decide if patient should continue or discontinue therapy and/or return in the future

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Selection of Other Mobility Options**

Mr. R. and his family also recognize his need for independent mobility outside of the home. His extended family are discussing pooling their resources to purchase another mobility device he can use outdoors for coaching baseball, shopping, and other activities. Given the progressive decline expected with ALS, what might you suggest in terms of power mobility? If financial resources were not an issue, what kind of comprehensive mobility system would you recommend and why?

comes (Weiss-Lambrou et al., 1999). Ragnarsson (1990) stated, “Ultimately, the most important factor in the success of a wheelchair prescription is the user’s total level of acceptance and satisfaction with [the] chair as it combines looks, comfort, and function” (p. 8).

SUMMARY REVIEW QUESTIONS

1. Who should participate in the wheelchair selection process?
2. What are the three basic types of wheelchairs, and why would each be selected?
3. What factors should be taken into consideration in wheelchair selection?
4. Describe a situation in which the optimal decision for an individual might involve the selection of more than one mobility device.
5. What are the six broad goals of wheelchair seating and positioning?
6. In determining wheelchair and related seating system sizes for a particular individual, what measurements typically are taken?
7. Contrast benefits and limitations of various manual and power mobility frame types.
8. Name and describe two types of controls for power mobility devices. Which would be preferable for a person with cerebral palsy and extremely poor upper extremity control? Why?
9. How can an occupational therapist keep abreast of new product development and research related to these products?
10. How can the occupational therapist facilitate the client’s participation in wheelchair selection?
11. Once the wheelchair and seating system have been selected, what is the role of the occupational therapist?

ACKNOWLEDGEMENTS

We thank and acknowledge the following people for critiquing this manuscript and for contributing their knowledge and expertise: Ken Jelinek, MOT, OTR, Assistive Technology Clinic, University of Washington Hospital and Medical Center, Seattle, WA; and Todd Lefkowitz, Rehab Engr., OTR, Northwest Center, Seattle, WA. We are also grateful to Mike Peterson of Wheelchairs Northwest, Bellevue, WA, for contour seating photographs.

CHAPTER 19

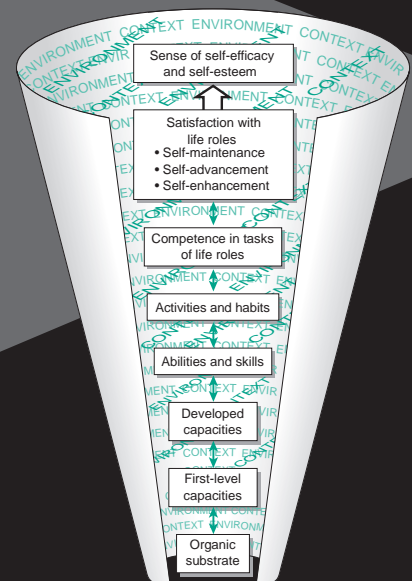

High-Technology Adaptations to Compensate for Disability

Mary Ellen Buning

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Explain the role of assistive technology (AT) as a compensation for loss of occupational function and inability to perform the activities underlying role performance.
2. Describe the basic components of the AT assessment, the participating team members, and the unique contribution of occupational therapy to the process.
3. Use knowledge of unimpaired abilities to determine a client's needed technology interface and ability to use features of AT devices.
4. Recognize an individual who could benefit from an AT evaluation and services and make an appropriate referral.
5. Define primary categories of AT and give examples of AT use to support occupational functioning.

Glossary

Glossary

Augmentative and alternative communication (AAC)—A communication system that requires use of something external to the body. Examples include pen and paper, letter or picture communication boards, and communication devices. Gestures and vocalizations are often used to enhance communication when using an AAC device. Devices may be manual or electronic. AAC devices use a language representation system, e.g., letters grouped into words or picture symbols.

Abbreviation expansion—Software designed to increase typing speed, decrease keystrokes, and decrease errors. For example, OT is the abbreviation for occupational therapy. The abbreviation is entered instead of the words, and the software expands the abbreviation into the word or phrase it represents.

Array—When indirect selection is used, the array is the set of options that are presented in sequence. The user selects from an array by waiting until the desired item is offered and then activating a switch. Some items in an array may branch to a secondary array, for example when a punctuation array is opened from an alphabet array.

Computer-aided design (CAD)—Software used to design, draft, or lay out technical projects ranging from architecture to manufacturing. CAD makes modifications and estimating construction costs much easier.

Electronic aids to daily living (EADL)—Devices that give consumers control of appliances in their environment. This term is favored over the alternative, Environmental Control Unit (ECU), because it stresses the task (i.e., increased independence, safety, communication, and leisure) rather than the thing being controlled (i.e., television, telephone, and lights). EADL accurately describes the technology and has helped funding, both here and in Europe.

E-Tran board—A non-vocal communication device made of acrylic with an open space in the center to allow a clear view of the consumer's eyes. Communication symbols or letters are placed around the frame, and the consumer indicates choice by eye gaze. Both communication partners must be trained in its use.

Infrared (IR)—Light wave outside of (longer than) the spectrum normally detected by the human eye. Sequences of IR code are interpreted as specific instructions by an IR receiver, which executes a command such as volume up or volume down.

Microprocessor—Miniature piece of integrated circuit board that performs a prescribed operation or set of operations and is common in consumer products and AT devices.

Pixel—Smallest unit of visual display on a computer screen; a dot. These dots combine to form words and images. Pixels per square inch is a measure of resolution or pixel density, e.g., 640 × 480. The larger the number, the more information that can be shown on the display.

Pneumatic—Switch activation by increasing, decreasing, or changing the direction of air pressure. Switches that are commonly called sip and puffs are pneumatic switches.

QWERTY layout—Common layout for computer keyboards in which the letters in the top left row are QWERTY. This layout originated with mechanical typewriters when it was important to slow down typists so that the strike arms that printed each letter had time to avoid each other.

Radio frequency (RF)—Signaling technology that uses non-public radio bands to control appliances, open doors, or direct other AT devices.

Scanning—Selection method in which the consumer watches an array and waits for a choice to be offered rather than actively making a choice. Activating a single switch indicates choice.

Speech synthesizer—Computer peripheral (software, hardware, or a combination) that allows a computer to imitate human speech using rules of text pronunciation. Synthesizers are available for many languages.

Ultrasound—Sound outside the frequency detected by the human ear. This signaling technology is occasionally used in AT to control appliances or computer-related devices.

Universal design—Design concept that ensures a built space or a consumer product is accessible or usable by almost all persons. For example, an airport designer considers not only persons using wheelchairs, but also those who are elderly, have visual impairments, or do not speak English.

USB (Universal Serial Bus)—A standard interface updated in 2001 that is commonly used for connections between two or more devices (e.g., mouse, printer, keyboard) connected to a computer. USB II supports high-speed data transfer and works on PC and Apple computers.

Word prediction—Software that uses rules of recency and frequency to anticipate the word the consumer is beginning to type. It is designed to decrease keystrokes and errors but does not increase typing speed. It is used in adaptive word processors and some AAC devices.

Technology, which is now cheaper and more powerful, underlies many of the tasks of modern life. It is difficult to find a school setting or a job that does not use computer-based technology. **Microprocessor** technology controls home appliances, ventilation systems, telecommunications, banking, and transportation. In addition to technology's role in managing the tasks of

daily life, it also has the capacity to support the adaptations or alternate access methods used by persons with disabilities. Technology used in this way is called assistive technology.

The goal of assistive technology (AT) is to compensate for absent or impaired abilities and enable occupational performance. Using the concept of occupation-as-end, AT

enables a consumer with tetraplegia to use a hands-free interface to perform technology-enabled activities like making phone calls, writing letters, or controlling appliances. AT enables consumers with varied limitations to perform daily living tasks, participate in life as they choose, and make choices based on their abilities and the goals and desired roles that motivate them. As stated in Chapter 1, competent role performance leads to life satisfaction, and this is the goal of AT. Occupational therapists interact with the clients to identify desired life roles and the tasks and activities required to perform these roles. They use their knowledge of the limitations of body structure and function to identify categories of AT solutions and customize control interfaces. They analyze the individual's skills and abilities to build on strengths. They recognize the training as well as the human and environmental supports required to learn to use AT and integrate it into the tasks and activities of life roles. AT devices that match consumers' goals and abilities help them assume or return to meaningful lives in the presence of physical, sensory, or cognitive disabilities.

THE HUMAN ACTIVITY ASSISTIVE TECHNOLOGY MODEL

Models serve as analogies or symbolic representations of difficult-to-visualize elements and interactions within a system and are helpful when planning for AT intervention. The Human Activity Assistive Technology Model (Cook & Hussey, 2002) (Fig. 19-1) represents how AT devices help consumers develop or return to occupational functioning.

The Human Activity Assistive Technology (HAAT) Model, which is widely used by AT practitioners, provides a model for considering AT as part of a system driven by the person or the human. In this model, the human varies based on the skill, ability, and experience it has with its intrinsic enablers, which are categorized as sensors, central processor, and effectors. Activity is understood as daily living tasks categorized as self-care, work/school, and leisure/play. The human, activity, and AT all occur within a context that varies on dimensions of the social, cultural, and physical attributes.

The AT portion of the HAAT Model is also a system with four subsections: the human-technology interface, the processor, the activity output, and the environmental interface. The human-technology interface is the means of interaction between the person and the technology device. This information is relayed to the processor via a mechanical or electrical linkage that interprets or responds to create an activity output. The activity output includes actions for which the device is designed such as opening doors or writing text. The environmental interface adjusts

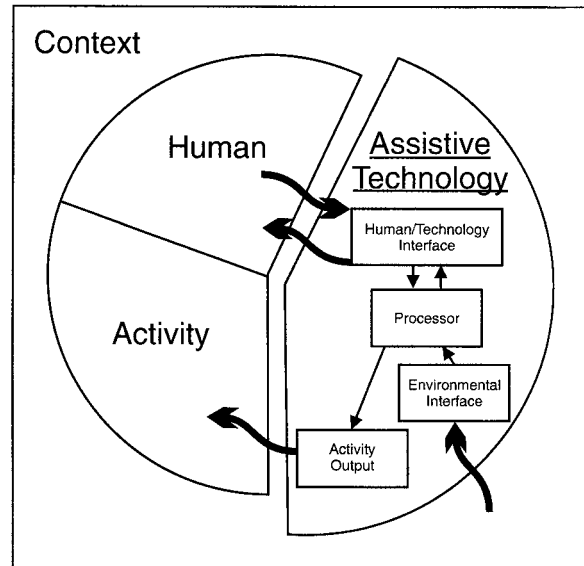

Figure 19-1 The Human Activity Assistive Technology (HAAT) Model shows the interrelationship between components and their interaction with the Assistive Technology System. (Used with permission from Cook, A. M., & Hussey, S. M. [2002]. *Assistive technologies: Principles and practice*, 2nd Ed. Baltimore: Mosby.)

the output of the device in response to input from the environment.

The dynamic nature of the HAAT Model helps identify the needed features of AT devices that will allow them to meet the changing needs of the human. Changing needs occur due to things like progressive impairment, the purpose of activity such as writing for work or for play, and changes in user contexts such as mobility on a sandy beach or on a campus sidewalk. To illustrate, a consumer may choose to take a manual wheelchair and letter board that cannot be damaged by wind and sand to the beach but choose to take a power wheelchair and voice output augmentative communication (AAC) device to a fully accessible college classroom.

AREAS OF AT APPLICATION

Just as occupation infuses all parts of consumers' lives, so also can AT enable accomplishing the activities and tasks of occupations and roles. AT can support self-maintenance, self-advancement, and self-enhancement roles.

Self-Maintenance Roles

Enabling activities of daily living (ADL) performance is a familiar reason for occupational therapy. Technologies such as electric toothbrushes, WaterPics, and electric

shavers can increase competence with personal care ADL tasks. However, instrumental activities of daily living (IADLs) clearly benefit from AT. Text telephones (TTY; formerly called telecommunication device for the deaf [TDD]) and hands-free or adapted telephones enable

calling paratransit organizations, shopping for groceries, and ordering from catalogs over the telephone (Research Note 19-1). Closed-circuit televisions (CCTV) that enlarge objects help with paying bills and balancing checkbooks for clients with low vision. Even more IADLs are supported with computers, such as banking, shopping, online bill paying, and e-mail, and ATM machines are now equipped with headphone jacks and Braille labels.

Consumers with significant disabilities can manage their personal space (i.e., control lights, fans, or the volume on a TV or stereo) through the use of **electronic aids to daily living (EADLs)**. These devices modify the typical user interface so that a client can control many devices in the home environment. The signaling technologies used by EADLs are the same as those used in typical controllers: **radio frequency (RF)**, **ultrasound**, and **infrared (IR)** light. Figure 19-2 describes how both simple and complex EADLs may be used.

Mobility is a basic form of self-maintenance that clients give high ratings as a necessity in everyday life (Verbrugge et al., 1997). Self-initiated mobility not only communicates curiosity, interest in participating, or the wish to be alone, but it also gives independent access to basic ADLs like eating, toileting, and bathing. It has been shown to support the activities of role performance, although having access to accessible environments is a key requirement (Buning, Angelo, & Schmeler, 2001). Home modification is usually necessary for using a wheelchair to cook a meal in a kitchen or approach a toilet in the bathroom. **Universal design**, an inclusive design concept, considers the needs of a broad range of users creating people-friendly spaces that are safer and easily modified for more severe impairment (The Center for Universal Design, 1997).

Augmentative and alternative communication (AAC) devices substitute synthetic or digitized speech when consumers are unable to speak or be understood by vocal communication. Some AAC devices provide the capacity to carry on typical conversations; others only relay a few messages. AAC devices allow consumers who have been taught to use them to socialize, call for assistance, direct caregivers, inform health care providers about health issues, initiate plans for activities, and make food and clothing choices.

Self-Advancement Roles: Work, School, or Community Volunteer

Assistive technology can enable self-advancement roles that range from retirees participating in volunteer activities to employees working at jobs or students attending school. Wheelchairs and scooters allow travel on ramped neighborhood sidewalks, commuting on public transportation, and access to schools, stores, and workplaces with level, accessible entrances. Four-wheel drive wheelchairs give mobility on farms, ranches, and the back woods.

RESEARCH NOTE 19-1

Abstract: Hoenig, H., Taylor, D. H., & Sloan, F. A. (2003). Does assistive technology substitute for personal assistance among the disabled elderly? *American Journal of Public Health, 2, 330–337.*

This study examined whether elders who used AT devices (technological assistance) to compensate for limitations in ADLs associated with their disability used fewer hours of help from another person (personal assistance). The investigators conducted a cross-sectional study of 2368 community-living adults older than 65 years who had one or more limitations in basic ADLs. The participants had previously responded to the 1994 National Long-Term Care Survey. The participants were asked further questions to uncover the relationship between technological assistance and personal assistance. Statistical regression was used to locate significant relationships among variables. Findings clearly supported the hypothesis that technological assistance may substitute for at least some personal assistance in coping with disability. Those who did not use equipment reported about 4 more hours of help per week compared with those who did use equipment. Providing personal assistance was associated with increased dependence, whereas use of equipment may have acted to preserve physical conditioning by maintaining a greater level of physical activity, or it may have allowed self-care tasks to be performed more efficiently and, therefore, reduced the need for assistance.

Implications for Practice

- AT device use appears related to maintaining independence or increasing the efficiency in completing ADL tasks and could help elders age in place.
- Through interview, explore the particular value an individual places on independent completion of instrumental ADLs activities.
- Determine which of those activities are associated with meaningful goals or return to a previous environment or life role.
- Determine which AT devices may be most helpful to that individual in compensating for the limitations due to their functional limitations.
- Refer the elder to community AT resources, such as the State Tech Act Project, for more information on AT devices or trial use of AT devices from AT-lending libraries for more specialized devices.

Simple EADLs

Each device uses one type of signaling technology or controls a separate type of appliance.

X-10 Boxes

controlled by X-10 Controller, TASH Ultra 1 and 4, AAC device.

IR Sender:

controlled by large button remote, scanning remote, Relax II, AAC device.

Bed:

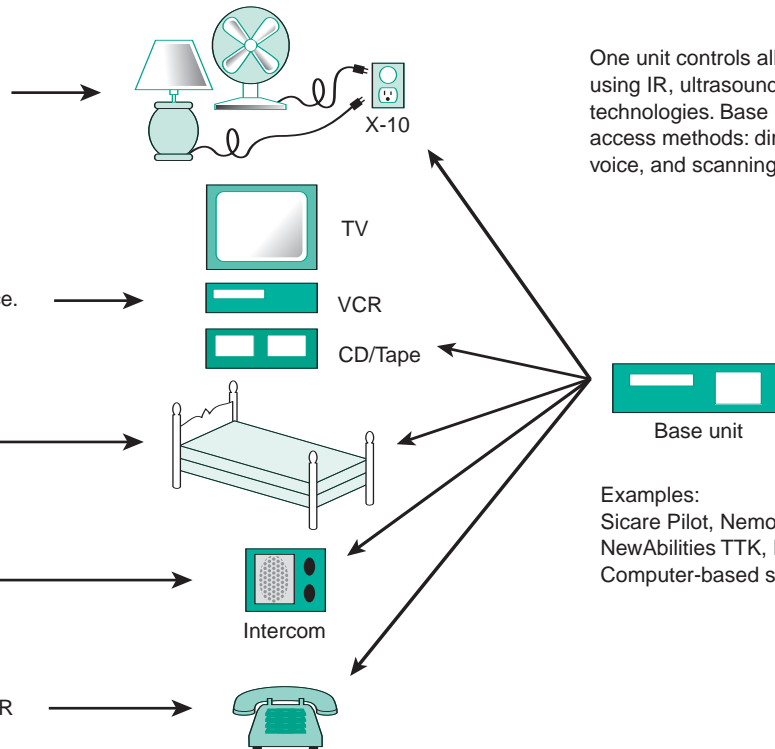

controlled by remote or switch interface.

Intercom:

controlled by remote or wall unit.

Telephone:

controlled by computer phone dialer software, switch activated phone, or IR phone dialing device.

Complex EADLs

One base unit controls many kinds of appliances.

One unit controls all of these appliances using IR, ultrasound, and RF signaling technologies. Base units offer many access methods: direct selection, voice, and scanning.

Examples:
Sicare Pilot, Nemo, MasterVoice,
NewAbilities TTK, Proxi, AAC Devices,
Computer-based systems, etc.

Figure 19-2 Simple and complex EADLs.

Today's communication technologies make information exchange easier and faster for everyone. When clients with sensory, motor, and language impairments also have access to these technologies they reap huge benefits. Adapted computers enable listening to text, writing, accounting, managing databases, desktop publishing, computer-aided design, searching the Internet, phoning, faxing, and printing. Real-time closed-captioning of a speaker's words, videophones for sign language communication, and captioned multi-media and distance learning software include students and workers with sensory impairment.

AAC devices are an essential part of communication at school and in the workplace. Making choices, demonstrating knowledge, asking questions, forming peer relationships, and getting the job done all occur because of communication.

Self-Enhancement Roles: Recreation and Leisure

Recreational choices often have symbolic meaning and clearly reveal our interests and our tolerance for challenge

(Kielhofner, 1997). Recreational choices made for their intrinsic and symbolic qualities allow individuals to take on valued images of self as adventurer, connoisseur, or creator (see Chapter 34). Assistive technology enables activities ranging from alternate controls for video games to adapted reels for one-handed fishing. Recreational AT includes wheelchairs designed for beaches, tennis courts, or mountain trails. Water sit-skis and adaptive snow skis like monoskis allow skill and agility in mainstream recreations.

Children's play is enabled by AT, too. Adaptive mobility devices introduced early to children with motor impairments enable independent play and exploration. Switch-adapted toys teach cause and effect and help children improve their motor control and cognitive skills for more advanced technologies. Video games, whether played on units connected to a TV or a computer, can be controlled with switches as alternatives for triggers. Using EADLs to control home entertainment systems—music, TV, and video—is also a common leisure activity.

Many Americans enjoy using home computers for leisure. Adapted computer access allows browsing sites on the Internet, pursuing interests like genealogy or collecting, and engaging in creative art activities and puzzles. The

Internet allows previewing destinations, finding accessible accommodations, and renting accessible vans. With so many accessible facilities, even traveling is now a form of recreation and play.

THE AT ASSESSMENT PROCESS

The contribution made by a well-chosen and fully used AT device is remarkable. Assistive technology's contribution is the result of a skilled, thoughtful, and thorough assessment. A discussion of the elements of this process follows. (Figure 19-3 is an overview of the AT assessment and intervention sequence.)

Assessments are driven by the consumer's goals and needs (Bain & Leger, 1997; Cook & Hussey, 2002). Family members or caregivers, speaking on behalf of a consumer with communication impairment, may also identify goals and needs. The AT team attempts to understand and address the stated reasons for and expectations of the assessment. It is important to clear up any misunderstandings about the capabilities of the AT team and the types of AT devices available. Clarifying these issues before beginning the assessment creates more realistic expectations for the contribution of AT devices and prevents disappointment.

Consumers, family members, and caregivers come to the assessment with various needs and motivations. For example, a young adult may be transitioning to college and need new computer technology and training to more

efficiently complete assignments, search the Internet, participate in online class discussion, and exchange class notes. Parents may be ready to consider powered mobility for their young child while looking for reassurance that they will not inhibit the development of walking with their action. An adult with a newly acquired disability that prevents returning to previous employment may be looking for AT devices to enable retooling for a new type of work or employment.

In addition to their goals and priorities, the assessment focuses on consumer and family attitudes toward AT. Some people easily adopt technology and incorporate it into tasks and routines. Others resist and even fear it. Some consumers feel that the latest high-technology equipment is not necessary and prefer simpler, more familiar devices. Consumers' religious and cultural background and personal tastes will also influence their choice of devices. Devices that fit within the personal and cultural context of the consumer and his or her family are more likely to be used than the latest technology innovation that is outside the realm of the consumer's comfort zone. Putting aside personal values, the AT team concentrates on addressing the consumer's goals and preferences.

Team Members

The team consists of a variety of experts and stakeholders. The consumer, family, and caregivers have the key role because they will interact with or use the equipment on a daily basis. Professionals on the team vary according to the consumer's needs.

- The seating and mobility expert may be an occupational or physical therapist who is focused on maximizing function in the seated position. With the consumer's activities in mind, this expert assesses posture and range of motion and specifies seat, back and foot support angles, and cushion type (e.g., support or pressure relief or accommodation to abnormal posture). If the consumer has mobility impairment, assessment includes a review of needs and trial with an appropriate type of wheelchair. The decision to use a manual or powered wheelchair will affect selection and use of other AT devices. See Chapter 18 for information on wheelchairs and assessment.
- The access specialist, typically an occupational therapist, is focused on finding the best possible methods for controlling AT devices including a power wheelchair. The access specialist may work with another team member who knows more about specific devices that might be controlled such as computers, AAC devices, and EADLs.
- The teacher or special educator, if the consumer is a student, describes schoolwork tasks and helps formu-

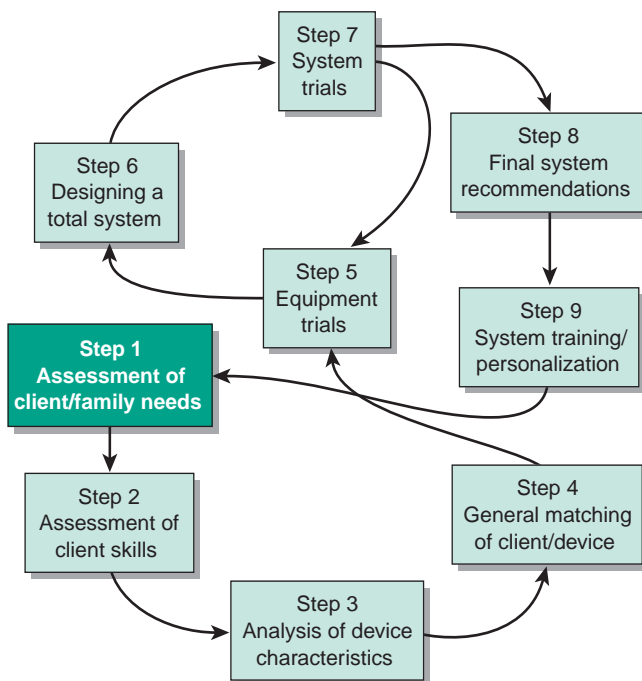

Figure 19-3 Nine steps in the assessment process for AT.

late solutions to support educational tasks and school participation.

- A vocational rehabilitation counselor, if the consumer works or is preparing for work, will approve AT solutions and help with funding.
- A speech-language pathologist (SLP) with expertise in AAC directs the team when communication is the focus. The SLP evaluates the consumer's verbal and written communication potential, helps determine the types of symbol sets (alphabet, pictures, etc.) that will be most effective, and works closely with the access specialist.
- A rehabilitation engineer may be on the team if the consumer has complex needs and off-the-shelf solutions are not likely to be effective. The engineer may integrate several types of AT when consumers have few options for control. For example, a consumer with reliable control of only a finger would need an integrated control system that allows this small movement to drive a wheelchair, operate a computer, and control an AAC device.
- A social worker may help locate funding sources or provide counseling as consumers and significant others come to terms with disability.
- Rehabilitation technology suppliers (RTSs; previously known as vendors) are the equipment experts. An RTS who sells a device may be able to provide a demo model for the evaluation. The RTS knows product features and can help with selection of components and adjust the product after delivery. Certification for RTS (CRTS) signifies advanced training, expertise with assessment, and commitment to ethical practices.

The AT Assessment

Prior to the AT assessment, the team needs to understand the consumer's goals related to roles and the performance of activities to support roles. This information, captured either through a structured interview or an intake questionnaire (Pollock, 1993), should be coordinated with family members' and caregivers' goals. Once goals are established, the door is open for focusing on a particular area of AT, categories of solutions, and assessing current skills and abilities to determine potential access methods. During this part of the assessment, it is important to gather a realistic picture of the consumer's motor control, social skills, and cognitive and sensory abilities, as well as the environments where the consumer will use the devices. Areas commonly addressed in AT assessments follow.

Seating

Optimal seating is mandatory to achieve the best results during the rest of the assessment. If the client uses a seating system that does not provide adequate support (see

Chapter 18), the performance observed during subsequent AT evaluation activities will not accurately show the consumer's ability.

Sometimes it is not possible to address seating issues before the rest of the assessment. When this happens, a seating simulator can be used. A seating simulator has an adjustable back, sides, armrests, lateral supports, pom-poms, and foot supports and can be set to meet a broad range of postural support needs. The risk is that it may be difficult to duplicate the control the consumer had in the seating simulator. Therefore, whenever possible, the best solution is to assess consumers in their own appropriately fitting seating system and wheelchair.

Another important factor to determine early in the assessment is where and in what positions the consumer spends the most time. Asking these questions at the beginning of the assessment avoids recommending access methods that the consumer can use with accuracy in their wheelchair only to find out that, at home, the consumer spends the most time in bed or a lounge chair. Once seating issues have been resolved, motor control for access is addressed.

Motor Control

Ideally, access methods, such as touch-typing on a keyboard, are effortless. Effortlessness comes after practicing and refining the skill. For a skilled typist, it seems the fingers know the words as they quickly move across the keys. Attention is on the thoughts the typist wishes to enter into the word processor rather than individual keystrokes. To reach effortlessness, it is important to narrow access methods to those that the consumer is able or potentially able to activate consistently and reliably.

To establish physical control of an AT device, the therapist first identifies potential anatomical sites for access by evaluating range of motion and fine motor coordination. Often consumers and their family members and caregivers know the body parts over which the consumer has the most control and can provide this information. Usually the hands and fingers are assessed first, as humans prefer them for interacting with objects (Cook & Hussey, 2002). If the consumer is not accurate or efficient with hands or fingers, head movement may be assessed next. Consumers with limited control over their upper extremities sometimes have excellent control of head movements. If the consumer is only partly successful at using his or her head to indicate a selection, the consumer may have more control over eye movements. The assessment may continue with evaluating the potential for volitional control of the feet, knees, or other sites that can interface with access devices. The best two or three sites should become the focus at this point in the assessment.

Evaluating range of motion helps to determine the range a consumer has for accessing a keyboard, switch, and other input devices. Assessment boards are easily con-

structured and useful when assessing range of motion and coordination (Procedures for Practice 19-1). The therapist, using an assessment board, can quickly assess range and accuracy. Using one body part, the therapist asks the consumer to point to the squares on the board with a finger, hand, head (using a head pointer), or toe depending on which anatomical site is being evaluated. Using a replica of the grid printed on the assessment form, the therapist indicates the squares the consumer should reach. Assessing range helps the therapist get an idea of the types of access devices the consumer can use successfully. For example, if the consumer easily reaches the perimeter of the assessment board grid, a normal computer keyboard may be useful. Conversely, if the consumer can reach only squares in the middle of the grid and close to the midline, the access method will be limited to this area.

To assess coordination, the therapist asks the consumer to point to specific squares on the perimeter and in the middle of one of the assessment boards. Accuracy in point-

ing to specific squares gives the therapist an idea of the consumer's coordination. The board with 1-inch squares is used first. If accuracy is sufficient with one or more of the anatomical sites, the therapist proceeds with the assessment. If the accuracy is poor with all anatomical sites, the test is repeated using the 2-inch grid. If the results do not clearly demonstrate pointing ability with at least one anatomical site, the therapist may ask the consumer to try a head pointer or hand-held pointing device to assist with accuracy.

Once pointing trials with three or four anatomical sites are completed with some consistency, compare the results. Comparisons help determine which anatomical site the consumer uses most consistently and accurately. The therapist asks the consumer to point to the same six squares in the same order using each anatomical site being tested. Keeping all the variables identical except for the anatomical site, the therapist determines which anatomical site offers the consumer the best control. The consumer is asked whether he or she agrees with which site provided the most control. If the consumer feels more comfortable using another body part, the therapist and consumer should discuss this and come to agreement on which site should be the primary access site.

Having said all of this, it seems important to note that speech recognition technology has improved greatly in the last few years. This technology creates the possibility that a consumer may need *no* physical interaction with an input device to achieve control. Depending on the consumer's cognitive abilities, motor control issues, and goals, it may be possible to use this constantly improving technology to reduce the amount of time spent searching for a motor control strategy. Even when speech recognition succeeds, however, it is important to have a non-speech control method as back up.

Direct Versus Indirect Selection Methods

Once the anatomical site has been determined, the types of access devices can be reviewed. This evaluation determines whether the consumer will use direct or indirect selection (Procedures for Practice 19-2). If a consumer effortlessly uses an anatomical site to point, direct selection is appropriate. The therapist may also need to consider factors such as target size, placement, and other characteristics to reduce effort and improve speed and accuracy. If the consumer cannot accurately and consistently point with any of these anatomical sites, however, it is necessary to consider more sophisticated AT alternatives. Other technologies that use direct selection are speech recognition, head pointing using devices that track head movement, mouth controlled joysticks, eye pointing, and tongue touching keys on a keypad worn in the mouth. These devices will be discussed later.

As a last resort and in absence of motor control that will allow a consumer to accurately point to or select from

PROCEDURES FOR PRACTICE 19-1

Preparing Range of Motion and Fine Coordination Assessment Boards

Materials needed:

- Two pieces of poster board measuring approximately 11 × 17 inches each
- Permanent marker
- Ruler
- Clear contact paper

Directions:

- Using the permanent marker and ruler, mark off one of the poster boards into a 2-inch grid.
- Mark the other poster board into a 1-inch grid.
- Number the squares on each poster board sequentially.
- Place clear contact paper over each poster board.

The poster boards are now ready to be used during the assessment. The plastic covering protects the boards against moisture. Also, stickers can be placed and removed repeatedly from the poster boards without damaging them.

Some consumers are motivated to touch specific squares with colorful, eye-catching stickers or small food items, such as Cheerios. Consumers whose cognition is intact can point to requested numbers printed in each square. Duplicating a small version of the grid on an assessment form allows the therapist to shade in the squares on the grid with the locations or numbers that the consumer easily reached. This assessment tool is further described in *Assistive Technology for Rehabilitation Therapists* (Angelo, 1997).

PROCEDURES FOR PRACTICE 19-2

Direct and Indirect Selection

In direct selection, all items in the selection set are available at any time. Examples of direct selections are computer keyboards, telephone keypads, and calculators. The advantage of direct selection is that it is intuitive. If an individual presses a K on the keyboard, he or she can expect to get a K on the visual display. The disadvantage is that direct selection requires coordination and some range of motion, depending on the size of each item in the selection set.

At times, trying to press the right key is too difficult for consumers with limited motor control. For example, the A key on a computer keyboard may be too far away, or the consumer may repeatedly press the Q or Z key when trying for the A key.

With indirect selection or **scanning**, only a subset of all possible choices is available at any given time. An example is setting the time on a digital clock and waiting for the correct number to appear. The advantage is that the consumer needs reliable control over only one movement, such as an eyebrow, one finger, or a toe. The disadvantage is that it is much slower to use and more intellectually demanding than direct selection. It requires the ability to remember and sequence steps with a high level of attention.

a set of selection options (i.e., like a keyboard or a number pad), the evaluation moves toward indirect selection. Indirect selection reduces the size of the “selection set,” and choices are presented one at a time until the one desired is offered. The consumer indicates choice by activating a switch or sending an electronic signal. The goal when assessing indirect selection is to identify anatomical sites that the consumer can control consistently without doing so unintentionally. The type of switch, its orientation to the body, and method of mounting are determined based on the anatomical site, the consumer’s movement patterns, and the durability required. The goal is to ensure optimal accuracy and reliability for the body segment with the best motor control. Table 19-1 describes several commonly used switches along with typical activation methods. As with direct selection, the hands or fingers may be assessed first, followed by the head and other body sites.

Switch Assessment

Switch mounting is critical for success when using single-switch access. Switches must be mounted so they remain in place and in line with the angle of activation. This provides for consistent and reliable switch pressing throughout use. Wheelchair and desk mounts with solid, one-way connections are far more likely to be used correctly than those that are adjustable. A switch mount must also be easily removable so it does not interfere with transfers or eating.

Table 19-1. Common Switches and Activation Method

Category and Specific Switches	Company	Primary Activation Site
<i>No Physical Contact—Requires an external power source (e.g., power wheelchair battery)</i>		
IST switch (infrared)	Words+	Eye blink
Adjustable proximity switch	Adaptive Switch Laboratory	Head, elbow, hand, etc.
Adjustable photoelectric switch	Adaptive Switch Laboratory	Any gross movement capable of interrupting the light beam
<i>Physical Contact, No Pressure</i>		
Pneumatic (also known as sip and puff)	Prentke Romich	Mouth and lips
P-switch	Prentke Romich	Any volitional and consistent muscle contraction
<i>Physical Contact with Pressure</i>		
Single rocking lever	Prentke Romich	Arm, hand, head, foot
Tongue switch	Prentke Romich	Tongue
Wobble	Prentke Romich	Arm, hand, head
Jelly bean switch	Ablenet	Arm, hand, head, foot
Specs switch	Ablenet	Arm, hand, head, foot
Big red	Ablenet	Arm, hand, head, foot
Wobble	Zygo	Arm, hand, head, foot
Bass	Don Johnston	Arm, hand, head, foot

The type of switch depends on the anatomical site chosen to control it. A variety of switches are shown in Figure 19-4. For example, consumers with control over one finger may best use a small, sensitive switch. In contrast, a foot switch mounted on a wheelchair footrest must be rugged to withstand impact from shoes and obstacles when the wheelchair is in motion. For an anatomical site that is bony, such as the back of the hand, a switch with a padded covering is appropriate.

Regardless of the type of switch recommended, it should provide feedback so the consumer knows whether the movement was successful. Usually this feedback is auditory, but it may be visual. Switches activated through head movements should produce quieter auditory feedback because a noisy switch mounted near the ear can be annoying.

Six occupational therapists with expertise in AT participated in a focus group to develop a list of the 10 most important considerations for switch access (Angelo, 2000). In the control category, the therapists indicated that the most important considerations were reliability of response, ability to perform timed responses, ability to activate and deactivate the switch within a given time frame, and endurance (the ability to sustain a force and to apply that force repeatedly over time). In the ease of movement category, therapists said that tasks should be performed volitionally, easily, and efficiently and that past performances with positive outcomes should be considered. Since context was considered important, assessments should occur in the environment where tasks are routinely performed. Finally, switch safety should be considered. Switches should have rounded corners, and all wires should be secured so that they do not become entangled with fingers, pointing devices, or other equipment (Procedures for Practice 19-3).

Cognition

Cognition is usually evaluated informally during AT assessments (Cook & Hussey, 2002). During the assessment

Figure 19-4 Commonly used switches (clockwise from bottom: Soft switch, Jelly Bean, Plate, String, Spec, and Microlite).

PROCEDURES FOR PRACTICE 19-3

Switch Assessment

1. Identify the anatomical sites over which the consumer has most control for switch activation. No timing is involved in this step.
2. Evaluate the consumer's ability to wait a specific length of time before activating the switch. This skill is critical for effectively using indirect selection. Errors in selection occur when the switch is released too soon or too late.
3. Evaluate the consumer's ability to maintain contact with the switch and to release the switch on command. This information will help to identify the best scanning mode, e.g., automatic, inverse, or step scanning.
4. When one or more anatomical sites have been identified for accurate switch pressing, the AT team determines which type of switch is most appropriate and how best to mount the switch. This concept is further described in Cook and Hussey, 2002.

activities and interaction, it is possible to estimate the consumer's attention span, reading level, short- and long-term memory, and ability to follow instructions and sequence tasks. Knowing about these aspects of cognitive functioning helps the AT team determine which devices have the features and performance characteristics that will match the consumer's cognitive ability (see Chapter 9).

Visual Acuity and Visual Perception

Blindness or visual impairment as the primary reason for an AT assessment necessitate a different type of assessment. However, the evaluation team should always consider vision and the possibility of impaired acuity, oculomotor skills, or visual perception. Visual acuity will affect the size of symbols used for communication boards and the size of letters and icons on a computer display. Decreasing the distance from the eye to the display (typically one arm's length) or altering the contrast or magnification helps compensate for poor acuity.

During an AT assessment, eye range of motion, conjugate eye movements, visual field cuts, tracking, and figure-ground discrimination are assessed. Knowing the extent of eye movement and whether the eyes work together is important when consumers are using indirect selection methods. This method requires the eye to track or follow a cursor and scan options to find a specific item. If imbalance is noted, then eye preference should be established and this information used during the assessment and later during equipment set up. Information about a visual field loss helps to determine the location of visual displays and may influence choice of fonts, sizes, or contrast to help compensate.

When the consumer is thought to have a learning disability or cognitive impairment, such as cerebrovascular accident (CVA) or traumatic brain injury (TBI), it may be important to assess visual perception. Knowledge about figure-ground problems helps the team ensure that a visual display is usable. Icons, words, or symbols may need to be placed farther apart or the background simplified to reduce visual stimulation.

Assessments such as the *Motor Free Visual Perception Test* (Colarusso & Hammill, 2002) and the *Test of Visual Perception Skills* (Gardiner, 1993), which directly test visual perception, may help identify the consumer's needs (see Chapter 8). If tracking is impaired, activities to encourage the development of tracking skills, such as simple cause-and-effect software under the control of a single switch, can be helpful.

Finalizing the Match between User and Technology

By this time in the assessment, the AT team has a clear idea of the consumer's motor, cognitive, visual, and visual perception abilities. The AT team should have begun to narrow the range of AT options down to a few AT devices with input method, mounts, and control enhancers that match the consumer's needs and abilities.

Once options have been narrowed to two or three, a more extensive trial of each is conducted. Trials of two to three devices with the control interface and control enhancers allow the consumer to become familiar with the equipment and determine how comfortable he or she feels when using it. As previously mentioned (Angelo, 2000), this trial, if not the entire assessment, should occur in the environment where the consumer will use the equipment. Using the system in the actual or intended environment—home, workplace, or school—uncovers problems that may not emerge during center-based trials. Noise, desks that are too small for devices, tables that are too low for rolling under with a wheelchair, and lights that are too dim or that glare on the display can be addressed and resolved. Trials should occur before making recommendations and submitting a final equipment list because this increases the likelihood that the devices will actually be used and not abandoned. Since the reauthorization of the Tech Act of 1988 now requires each state to develop an AT device-lending library, teams can begin to make use of this resource (United States Congress, 2004). Many states already have such a resource in place.

The AT Intervention Process

The specifics of AT device recommendations are guided by the consumer's skills and abilities, which are broadly guided by their preferences and goals. Broad categories of AT solutions include control enhancers, computer modifications, AAC devices, and EADL, and each of these will be discussed in turn.

Hierarchy of Access

The earlier discussion of the HAAT model established that AT devices are comprised of a user interface, processor, activity output, and environmental interface (see Fig. 19-1) (Cook & Hussey, 2002). Occupational therapists, by their education and interest in human function, are well suited to analyze and recommend solutions for the user interface aspect of this model. When consumers have difficulty with or cannot use standard input devices, a principle called hierarchy of access is used (Schmitt, 1992). When this principle is used, potential solutions are considered based on a range of simple to complex. Solutions that are less complex are also less costly and easier to implement and support. When complexity is reduced, the likelihood for technical conflicts is also reduced. The goal is to create the optimal solution without burdening the consumers with more technology than they need. The following paragraphs will elaborate on this range of solutions.

Control Enhancers

AT devices alone do not usually provide enough support for consumers to engage in the activities of occupational roles. Consumers may also need the help of low-technology aids called control enhancers. The term control enhancer, first used by Cook and Hussey (Cook & Hussey, 1995), refers to aids that enhance or extend a consumer's physical control. Control enhancers include head pointers, hand-held pointing devices (pencils, pointers with built-up handles, and typing sticks), mouth sticks, wrist rests, and arm supports (Fig. 19-5). Control enhancers also include devices that modify placement of user interfaces such as easels, flexible switch mounts, and LCD monitor arms. For example, a lever adjustable keyboard tray can increase keyboarding comfort, or an easel can position a regular keyboard for a consumer using a mouth stick and eliminate the need for a special keyboard. Control enhancers also support using devices efficiently and with reduced fatigue.

Figure 19-5 Control enhancers, such as a mobile forearm support and key guard, improve direct access.

Comparing several control enhancers helps determine the best fit between the consumer and the AT devices.

Adaptive Computer Access

A discussion on methods for adapting computers to allow use by consumers with disabilities should start with a review of the basic parts and functions of a computer (Definition 19-1). The methods for adapting a computer

fall into two categories—modifications to input and to output—based on the two interfaces humans have with computers. Depending on diagnosis or impairment, consumers have difficulty getting information either into or out of computers—and sometimes both.

Any discussion of adapting computers should start with a review of the accessibility options in the computer operating system (OS). Since these options are found on all computers at no additional cost, they are a likely first step in the “hierarchy of access.” Accessibility options, which are found in the control panel, allow any user to modify input and output options like setting the size and speed of the mouse, latching modifier keys on the keyboard to aid one-handed typing, reducing keyboard sensitivity to cut errors due to tremors, increasing the contrast or size of fonts on the menus and icons, and controlling basic computer functions with speech. Both Microsoft and Apple websites offer extensive tutorials and step-by-step guides for using these features.

Input

Specialized software and hardware can modify computer input. Input is the means by which a user gives instructions to the computer, usually using a keyboard or mouse.

ALTERNATIVE KEYBOARDS

Consumers should first try a standard keyboard with an adaptation such as a keyguard to physically reduce unintended key hits. Only then consider alternative keyboards. Most alternative keyboards provide transparent computer access; that is, the computer thinks the input is coming from a standard computer keyboard. Additionally, most of these keyboards are equipped with **USB** connectors so they can be exchanged without rebooting and will work on Windows or Macintosh platforms.

Several commercial products are included in this category. Some are adaptable and can be used in a variety of ways; others have narrow application. One keyboard, Intellikeys (Fig. 19-6), crosses computer platforms. It comes with a set of standard overlays that are instantly detected by the keyboard through bar code readers. The layouts of these overlays range from simple enough for use by early learners to more complex for advanced computer users. Key press acceptance rates are easily adjusted, and keyguards can facilitate key pressing accuracy. The keyboard also allows mouse control to be assumed by arrow keys if the consumer cannot smoothly point with a mouse. Since the keyboard is made from a pressure sensitive membrane rather than mechanical switches, custom overlays with keys that vary in size can easily be created. Additional software designed for this keyboard allows an interface specialist to create overlays for early learning software or beginning writing or to support curriculum modification for students struggling to meet educational objectives.

DEFINITION 19-1 *definition*

Parts of a Computer

Central Processing Unit (CPU)—The hardware including circuit boards, microprocessors, timing clocks, disk drives, and a cooling fan. The speed of the computer, measured in gigahertz, and the computing power of the microprocessor dictate how efficiently a computer can sequence instructions and perform calculations.

Application Software—The software that allows people to be productive with computers. It ranges from drawing and early-learning software for children to advanced statistical and mathematical programs for scientists. Common application software includes word processors, spreadsheets, and databases.

Computer Peripherals—Additions to the CPU that enable the computer to meet the user’s requirements. Flat monitors, telephone and cable modems, page scanners, plotters for creating technical drawings, trackballs and joysticks, digital cameras, speech recognition microphones, printers, and cameras are just a few examples of computer peripherals.

Operating System (OS)—The underlying software that coordinates with hardware and enables the computer to run applications software. Operating systems now use a graphical user interface (GUI, pronounced *gooey*) to make computers easier for non-technical users. GUIs use the analogy of desktop, pages, file folders, and wastebaskets to represent OS tasks. Windows and Macintosh OS are common, and Unix is used by computer information systems (CIS) professionals.

Random Access Memory (RAM)—Memory that is built into the circuit boards and is used for routine computer tasks. The amount of active memory or RAM required varies with the task. When writing a paper, RAM “remembers” the words and pictures in a document until the user saves them. Information stored in RAM is lost if the computer shuts down before work is saved.

Storage—Computers save or store a user’s work so it can be retrieved at another time. Data is stored on floppy disks, internal and external hard drives, remote drives on networks, USB flash drives, memory cards, and read/write optical discs. Digital media (cameras, music, and video) have increased the need for large-capacity storage.

Figure 19-6 Intellikeys stores a user's preferences within the keyboard's memory.

The keyboard is 11×17 inches, so good range of motion is needed to reach all of the keys.

For consumers with limited range of motion, smaller keyboards are helpful. Although it looks like a typical keyboard, the Datalux (Fig. 19-7) offers a smaller footprint and a more compact key layout, making it ideal for small hands or mounting for mouth stick use. A very small keyboard that also uses pressure-sensitive membranes is the TASH Mini, sized at 7.25×4.24 inches. Fingertips or a mouth stick have only a short reach to press all keys. The TASH Mini keyboard is offered in two permanent layouts, either with the most used keys in the center of the keyboard or in a **QWERTY** layout. Keys also control mouse movements.

Another small keyboard is the Magic Wand. The consumer holds a metal stylus like a pencil and touches the appropriate metal key on the keyboard with this stylus. No force is required. The half-QWERTY keyboard offers another approach in which a one-handed consumer with knowledge of touch-typing simply uses the space bar to create access to the mirror image of QWERTY layout. Software helps to teach the concepts and users quickly relearn touch-typing with one hand. A one-handed typist may prefer the concept of a chordic keyboard like the BAT personal keyboard. The hand stays in a home position and uses multiple finger combinations, as in playing chords on a piano, to enter all of the alphanumeric characters. Macros (small programs that run inside an application) can execute special commands and keyboard shortcuts, although a pointing device such as a mouse or trackball is usually also necessary.

TRACKBALLS

Although a mouse is the most common pointing device, a trackball offers some important advantages because the ball remains stationary in a base. A trackball separates the actions of pointing and clicking, allowing more accurate

cursor control and reducing the frustrating movement that can occur when initiating a mouse click. The hand rests on the base of the trackball, thus increasing proximal stability for the fingers. Many consumers with poor coordination who cannot control a mouse can control a trackball. Furthermore, a trackball is sturdy enough for control via elbow or toe movements. Trackballs usually come with software that allows adjusting the ratios between ball movement and cursor speed. Clicks and double clicks can be linked to buttons on the right or left side of the trackball base. Another substitute for mouse use is the 1.5-inch square track pad. Cursor movement happens in response to fingertip movement, and clicks happen in response to finger taps.

TOUCH SCREENS

Like the trackball, a touch screen is a mouse substitute or mouse emulator. Selecting or interacting with a touch screen is as simple as touching an icon to select it or dragging a finger to draw in a paint program. Touch screens are used when the cognitive demands for computer tasks must be kept low, such as when working with young children or adults with cognitive impairments. Touch screens are also commonly used in public kiosks where intuitive use is required.

MOUSE EMULATION

When hands or feet cannot control a mouse or cursor, head movements can be substituted to direct the mouse. Mouse clicks are produced with an external switch or with associated software. One device of this type is HeadMaster Plus, which is worn as a headset. The headset, with its attached **pneumatic** switch that allows clicking and dragging, sends ultrasonic signals to a receiver that sits atop the computer display. The signals are accurately converted into head position and allow the head to precisely direct the mouse. The HeadMaster can be paired with a control box that adds

Figure 19-7 Datalux keyboard has a compact key arrangement and a small footprint.

cordless IR communication to the unit. Infrared allows a consumer with a power wheelchair to independently drive up to a computer and begin to use it without disconnecting wires or headset. Another technology used for head pointing is reflected light. The Tracker Pro, another head mouse, emits light from LEDs around the lens of a 2" × 2" × 3" camera that sits atop the display. Solid-state photo sensors in the camera detect this light when it is returned from a reflective dot worn on the forehead or eyeglasses. An external switch or dwell-activated software is used for mouse clicks. Both of these technologies allow **pixel-to-pixel** accuracy and smooth cursor movement.

Jouse, a joystick mouse operated by mouth, also provides for quick and precise cursor movement. The Jouse sits on an adjustable mount that attaches to the edge of the desktop. Once adjusted, a consumer simply pulls up to the computer and begins computer tasks. A built-in sip/puff switch activates mouse buttons or, in an additional mode, sends Morse code signals. Text entry is achieved via Morse code or through software that creates an on-screen keyboard. All of these head-controlled devices allow use of graphical user interface (GUI)-based programs like computer-assisted drawing (CAD), desktop publishing, and graphic design.

ON-SCREEN KEYBOARDS

To write text with these mouse alternative technologies, consumers need on-screen keyboards. They work with any pointing device and are occasionally used with trackballs. These keyboards are created by software and displayed on the monitor (Fig. 19-8). Virtual keys are activated by clicking on them or by hovering over them with the cursor (called dwell) for a user-defined amount of time. Since the text entry rate is equivalent to one-finger typing, on-screen keyboards are usually packaged with **word prediction** and **abbreviation expansion** software. Word prediction

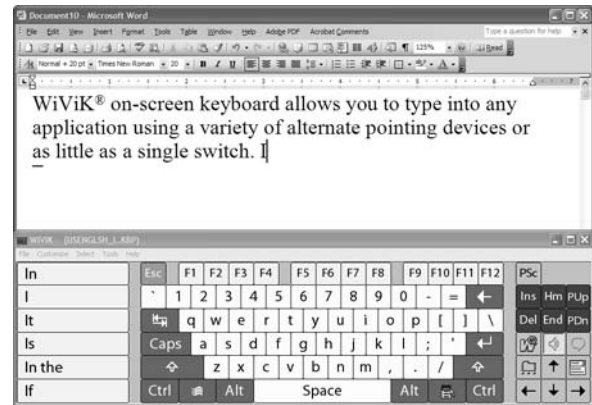

Figure 19-8 WiViK3 is an on-screen keyboard for Windows that allows a consumer to enter text using direct or indirect selection along with word prediction, abbreviation expansion, and synthesized speech feedback.

software uses rules of recency and frequency to guess the word the typist is beginning to spell. Optimally configured, it saves keystrokes. Word prediction works well in this application since the consumer's eyes are already focused on the on-screen keyboard where the predicted words are displayed. A second click or dwell chooses the whole word and enters it into the text document. Abbreviation expansion lets the consumer establish shortcuts to represent frequently used phrases or personal information, such as BTW for "by the way."

SPEECH RECOGNITION

Speech recognition technology has made rapid advances since its development. Originally a tool for data entry in environments where the hands were busy, its usefulness for those with disabilities was quickly recognized. Consumers with significant motor impairments who had speech, even with mild dysarthria, were able to train voice

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

AT Related to Self-Advancement Roles

Eighteen months ago, George had a cervical spinal cord injury at C5–6 secondary to a motor vehicle accident. George's biggest frustration is the limited recovery of motor skills in his hands. He can shrug his shoulders, flex and extend his elbows, and pronate and supinate his forearms. He has limited grasp and release, however, and no independent finger movement. After a significant episode of reactive depression, George is now receptive to ideas about how to manage his limitations. Prior to the injury, he worked as a graphic designer. Currently, he is receiving full disability as a result of the injury. The firm he worked for completely transitioned to **computer-aided design (CAD)** last year. His employer has expressed willingness to make a PC and software available to George at home. The employer's hope is that George might, with adaptations and training, be able to return to his former position at work. George's primary graphics tools will be a computer mouse and digitizing pad. Keyboarding will be used occasionally for correspondence and the textual elements of designs.

1. What AT solutions could help George reengage in computer-aided design?
2. How would control enhancers be useful to George?
3. How much training will be needed to ensure that George will be successful?
4. Where should the training take place?

models and write independently using a computer. Although early versions required that each word be spoken separately, today systems use continuous speech recognition. Sophisticated software and high-performance microphones compare sound input with probable words and phrases. Speech recognition is designed for those with good literacy skills since a user must compare text on the screen to what was intended. At present, its use for hands-free computer control has a steep learning curve. Speech recognition technology has dropped dramatically in price along with faster and more powerful computers. Many people with disabilities have adopted speech recognition technology.

OPTICAL CHARACTER RECOGNITION

Optical character recognition (OCR) is a technology that converts pages of print into computer documents. Originally developed to help secretaries avoid retyping documents, OCR is a mainstream technology that offers adaptation for individuals with disability. OCR uses a flatbed page scanner to capture a page image and software to analyze the image and recognize it as alphanumeric characters or text. A technology that converts print into computer text creates a significant compensation for those with visual impairment or learning disability. Computer text can be spoken, converted to large print, or sent to a Braille printer. OCR is available in stand-alone products like the SARA (scanning and reading appliance) or as a component of a personal computer. Special education programs use OCR technology to convert paper worksheets and tests to digital documents. Students then complete digital worksheet using an adaptive computer access method. Naturally, the accuracy of the recognition process is critical for success, but accuracy rates of 99% are achieved with high-quality printed materials.

EYE GAZE

Some consumers with severe motor impairments, such as those with high-level spinal cord injury or brainstem stroke, can only control their eye movement. This control, however, will allow them to use one of several eye gaze technologies. VisionKey uses a small keyboard on an LCD display attached to eyeglass frames. A small camera directed toward the eye reads its position in relation to characters on that keyboard. By focusing on the desired character for a set amount of time, a selection is made and confirmed with a beep. Using this process, the consumer types or selects characters or commands from the keyboard. These inputs are sent to a computer and viewed on its display by the other eye. The advantage of this solution is that the tiny keyboard moves with the consumer's head, which maintains alignment of eye-to-sensor. Another eye gaze approach uses cameras mounted on a computer display and focused on one eye to interpret the eye's movement in relation to the head. Eye Tech and LC Technology both use this

approach. Software analyzes the eye movement to determine where the consumer is looking and moves the cursor to that point. This technology is paired with onscreen keyboards, and mouse clicks are performed with dwell, a slow eye blink, or a hardware switch. Computer software supports word processing, **speech synthesizers**, and control of EADLs. The consumer's head must be kept stationary so the eye remains in the sensor's field of view. Recalibration is needed if the head moves outside this range. Eye gaze technology was very expensive in the past, but newer products have brought competition and reduced prices.

MORSE CODE

When consumers have few motor control sites, Morse code is an option. Although Morse code brings up images of pre-telephone days, it is a physically simple means of sending encoded data to a computer or other device. Users must have control and endurance at a minimum of one motor site (e.g., a finger or eyebrow) and the cognitive ability to learn and recall codes. One or two switches can be used. Consumers with the motor ability to initiate both long and short signals use one switch. Those unable to time switch closure must use two switches, one for dit and one for dah. Once the code is sent, computer software converts signals into alphanumeric characters, keyboard shortcuts, or operating system macros. Using Morse code, consumers compose text, use spreadsheets, and browse the Internet. Using a body part that can be moved quickly as a switch site, it is possible to type at rates of 30 wpm. No other input method for a person with severe motor limitation allows writing at this rate of speed (Anson, 1997).

TONGUE-TOUCH KEYPAD

Another strategy used when there are few motor control sites is the tongue-touch keypad (TTK). A consumer with good tongue control can use its tip to touch one of nine keys imbedded in an orthodontic appliance worn on the roof of the mouth. A battery-powered ultrasound transmitter in the TTK can send an RF signal to a power wheelchair controller, an EADL, or a computer. Computer software that accompanies the TTK allows total control of the computer operating system and application software. Each switch embedded in the TTK corresponds to a cell in a 3×3 matrix. When one of the nine cells is touched, the computer accepts the input and displays a sub-matrix on the monitor with nine additional choices. In this way, many options are offered with only a small set of keys.

SCANNING

Scanning, or indirect selection, is the input method of last resort. When a consumer lacks the ability to accurately choose one item from a set of all options (e.g., a key on a keyboard or push button phone), an **array** with subsets of options is offered. In an array, the subsets are offered in sequence, and the individual signals choice by activating a

DEFINITION 19-2 *definition*

Basic Scanning Modes

Automatic—The consumer presses the switch to initiate scanning. The cursor highlights items in the selection set one at a time. The consumer presses the switch as the desired item is highlighted.

Inverse—The consumer presses the switch to initiate scanning. The consumer must maintain switch closure for the cursor to move across the selection set. When the desired item is highlighted, the consumer releases the switch, indicating the choice.

Step—The consumer presses the switch to move to the next item in the selection set. The cursor moves to the adjacent item each time the switch is pressed. A selection is made when the cursor dwells on an item and the consumer refrains from pressing the switch.

switch when the desired option is offered. This input method is very inefficient because of the time spent waiting. This delay increases further when the consumer cannot see. In this case, auditory scanning is used, and the consumer listens for an announcement of each choice just before it is available for selection. Scanning arrays can be used to control computers, EADLs, and AAC devices. Information on scanning modes is provided in Definition 19-2.

Output

Once a computer receives input, the central processing unit (CPU) and OS software perform the requested task. CPUs deliver the same output regardless of how the input is delivered to the processor. Output is the result that a computer delivers on the screen, as a printed page or as sound. Output may be a final product, dialog boxes, or alert sounds played as a computer processes data. Individuals with sensory impairment are most affected by computer output because they do not have equal access to it. This leads to the other category of adaptations: adaptations to computer output.

SCREEN

Most computer output is interpreted visually, so most adaptations to output are used by consumers with visual impairments. The range of visual impairments is broad, ranging from field deficits and color blindness to low vision and total inability to perceive light. Thus, there is a broad range of adaptations. Some are as simple as reducing the amount of light coming from the screen, which is accomplished by reversing the screen contrast so that the letters are light on a dark background. This adaptation is possible in the accessibility option in the computer OS. Another simple adaptation is to increase the size of objects

on the screen by reducing the monitor resolution. For example, if a 17-inch monitor capable of displaying 1280×1024 pixels is set to 640×480 , everything displayed on the screen is twice as large.

SCREEN ENLARGEMENT

Screen enlargement software more powerfully accommodates visual impairment by magnifying the screen 2 to 16 times. One product, Zoomtext, shown in Figure 19-9, creates a virtual magnifying glass for a particular section of the screen. The user can move between an area that is greatly magnified and the normal display and thus zoom in to see parts of the screen that are of interest, e.g., a radio button or close box. Most enlargement software offers options such as panning through sentences or highlighting words as a speech synthesizer reads them. Listening along with viewing enlarged text allows listening to support weak visual skills. Screen enlargement software also allows users to set up default colors for text and background, which may enhance their remaining vision.

TEXT-TO-SPEECH

When consumers have no usable vision, they need software to completely substitute for seeing, not just in application software, but also in the OS. Adaptive software, generically called a screen reader (e.g., JAWS, WindowEyes), allows a consumer to direct the cursor around the screen while listening to a speech synthesizer read menu choices, text in dialog boxes, and paragraphs in word-processed documents. The cursor and reading functions are controlled either by the keyboard's number pad or by a separate keypad. Consumers can set up preferences (e.g., pronunciation of special words or speech rate).

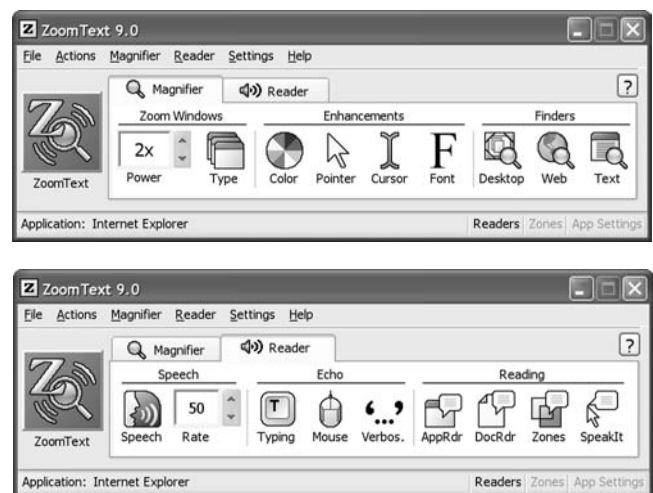

Figure 19-9 Applications now offer both text-to-speech and enlargement of information on the computer monitor. ZoomText control panels are shown.

REFRESHABLE BRAILLE DISPLAY

Braille continues to be an important tool for literacy despite the prevalence of audio recordings and speech synthesizers. Currently only about 12% of school-age children with blindness use Braille as their primary reading medium (Raeder, 2005). This concerns many in the blind community, who know that reading Braille is highly correlated with literacy and academic achievement. Refreshable Braille is an innovative adaptation that overcomes several problems associated with Braille documents, such as the bulk of thick paper and the inability to search the documents quickly or correct errors (Cook & Hussey, 2002).

A refreshable Braille display is created with pins that make tactile dots that rise and fall to show changing computer text. A Braille display sits under and extends beyond the lower edge of a computer keyboard so that a consumer using one easily moves their fingers between the keyboard and the display. A 40-character Braille display shows half of the typical 80-character line of text seen on the computer monitor. The consumer controls the line of text that is displayed in Braille and edits by sending the cursor to the intended Braille cell.

As a means of computer output, a Braille display modifies the output for all computer-based tasks. This means the Braille display presents the text in a web page, the numbers in a column, the text in a table, or the notation in a math formula. Additional information is communicated, and consumers using Braille displays have access to more information than they do when using text-to-speech computer output modifications.

LARGE PRINT

People commonly take away the products of a computer work session in print form. What adaptations are possible if text printed on paper cannot be read? Consumers with low vision often convert documents to large print or modify the font based on its purpose. Serif fonts are considered easier for the eye to recognize (a serif character is ornamented with a small cap or foot) than sans serif text. Yet, sans serif text is more accurately recognized by OCR systems. In most word processing applications, it is easy to select all the text in a document and change the font and size before printing the document.

BRAILLE EMBOSSING

Similarly, instead of sending a word processor document to a conventional printer, a document can be sent to a Braille embosser, which punches Braille characters into heavy paper. Embossers range from those designed for personal use to those that print hundreds of pages a day. Combining embossing with OCR systems to create Braille versions of text documents reduces the work for Braille transcribers who only need to check for errors. Technology makes it easier to produce documents in Braille. New soft-

ware now combines print and embossing to aid others who do not read Braille.

AUDITORY SIGNALS

Hearing impairment also creates a need for modifying computer output. Operating systems offer the option of having the menu bar flash as a substitute for alert sounds. Computers, being highly visual tools, do not usually require other adaptations. As the multimedia capacity of computers has developed, however, it has become important to offer captioning or a text description of a sound feature in educational software and on web pages. This is particularly important when sound is part of conveying the full meaning.

Augmentative and Alternative Communication Devices

AAC intervention is the process of facilitating functional communication across all contexts. Communicating with an AAC device is slow, and it is based on hours of work by the augmented communicator and a team of professionals who provide training and support services (United States Society for Augmentative and Alternative Communication [USSAAC], 2005). AAC methods are multimodal and can be divided into two main groups. Unaided communication systems include sign languages, gestures, facial expressions, and looking up for yes and down for no. Aided communication systems use physical objects like picture and letter boards and high-tech and voice output devices to communicate (USSAAC, 2005). Although both types are needed for effective communication, we will focus on aided communication systems.

Non-Electronic Communication Systems

Aided communication systems can be categorized in several ways, non-electronic or electronic, non-vocal or vocal output, and dedicated or non-dedicated devices. Non-electronic devices include devices that function without batteries or electricity. Examples of non-electronic aids are pencil and paper and alphabet, symbol, or picture boards and books. These aids vary in size from those fitting into a shirt pocket to filling a wheelchair tray. They can be used nearly anywhere, since maintenance is minimal and no electricity is required. These devices do not have storage capability, however, so unique messages cannot be prepared ahead of time. When messages can be prepared ahead of time and stored, as in electronic devices, they can be delivered at the convenience of the consumer and the communication partner. Electronic devices also have the advantage of being able to get the attention of others through a sound or voice output. Their disadvantages are increased weight (anywhere from approximately 0.5 pound to 10 pounds) and the need for regular battery charging.

Synthesized or Digitized

Electronic AAC devices have voice output either as digitized or synthesized speech. Digitized devices can record and store human voice recordings on microchips within the device. Usually speakers of the same gender and age make the recordings so that the device sounds like their own voice might sound. Devices using digitized speech can provide anywhere from a few seconds to a few minutes of voice output. A disadvantage of digitized speech is that it requires a lot of memory for storage and only complete phrases or words can be stored, reducing its usefulness for phrases that may change in grammar.

Synthesized speech is more flexible since it will speak whatever text is presented. Microprocessor-based programs in the device follow rules of pronunciation for the language and convert text to vocal output (synthesized speech) following those rules. Exceptions for things like proper names can be created to meet the user's preference. High-quality speech synthesizers at low cost are available, giving consumers choices in vocal personality and gender. Synthesized speech is available in multiple languages. Although most devices come with some stored words and phrases, they are easy to customize and generally allow the consumer to speak whatever sentence they can create. Customization is accomplished by using the keyboard to enter new words and phrases and following a sequence for storing new vocabulary. Synthesized speech offers independence and flexibility. Consumers can add words and sequence them in any combination.

Static or Dynamic

Visual displays for electronic AAC devices are either static or dynamic. Static displays do not change appearance as the consumer uses them. To give the consumer more communication options on static displays, strategies such as page levels (layers) or visually rich icons with multiple meanings are used. With the level strategy, categories, such as words for mealtime, are grouped on a level. The multiple-meaning icon strategy keeps all communication options on one level. A scheme for associating words or phrases with pictures and the sequence in which they are selected allows a consumer to produce both standard and novel utterances. With static displays, commands and icons remain in the same place. This allows the consumer to develop automatic sequences for messages and increases speed. Because AAC device use is slow, speed in generating speech is very important.

Dynamic displays change in response to anticipated communication needs. Imagine that it is lunchtime and a friend asks the consumer, "Where do you want to go for lunch?" The consumer turns to the device, which provides a menu of topics, such as greetings, mealtime, school, and vacation. The consumer selects the mealtime icon. The screen changes to present a different set of choices: foods

and restaurants. The consumer selects restaurants. Once again, the screen changes and presents a new set of selections, including Dairy Delight, McDonald's, and Pizza Hut. The consumer selects a restaurant for lunch, and the associated stored sentences or words are displayed.

Dynamic displays offer some advantages, since only a smaller set of options that are closer to the theme of a conversation are presented. This is an excellent strategy for presenting words used infrequently in conversation, although core vocabulary—the words and phrases that are part of all speech regardless of the topic—may be left behind on previous pages. Some devices are designed so that this separation is minimized. The cognitive load of retrieving pages can be high. Therefore, groupings of topics or vocabulary should be logical. Figure 19-10 shows the Dynamo, an augmentative communication device with dynamic display capabilities. Most AAC devices now offer a combination of static and dynamic display. In devices that use both types, static icons are used for core vocabulary because this allows the development of automaticity. Dynamic icons are useful for fringe vocabulary, which is less often used and varies among users (Ballandin, Baker, & Hill, 1999).

Figure 19-10 A small communication device with dynamic display can support participation and interaction in many community settings. (Reprinted with permission from Dynavox Technologies, Pittsburgh, PA, 1-800-344-1778.)

Dedicated or Non-Dedicated

AAC devices can be dedicated or non-dedicated. Dedicated devices function solely as communication devices. These devices may or may not produce voiced messages, connect to a computer, or print messages. Non-dedicated devices perform other functions while they also serve as communication aids. Most non-dedicated devices are computers loaded with communication software. The advantage is that the consumer has a fully functioning computer that can be used for word processing and other tasks as well as an AAC device. Separation between dedicated and non-dedicated devices was common in the past, but as micro-processors increase in power and speed and decrease in size, most of the more powerful AAC devices offer computer-like functions. Most control EADL devices through an IR port, and they are often used as keyboards for desktop computers too.

Vocal or Non-Vocal

Devices also vary by whether they have non-vocal or vocal output. As with non-electronic devices, when using non-vocal output aids, the consumer must get the attention of the communication partner before beginning the message. The communication partner must be looking at the communication aid before communication can begin. For some non-vocal output devices, communication cannot take place unless the partner understands the system. Examples of non-vocal output devices include alphabet boards, picture boards, drawings, photographs, symbols, and **E-tran boards**. Vocal aids mean that the device speaks the message. These devices are vocal output communication aids (VOCA). VOCAs include digitized and synthesized speech.

Orthography or Representation

When consumers use the alphabet and spell messages to the partner, the alphabet can be arranged in one of several ways, depending on the need. Typical layout arrangements are alphabetical, QWERTY, and frequency. Alphabetical order is used when the team anticipates that the consumer will continue to use cognitively simple devices and not advance to devices with more options. The QWERTY arrangement, the typical alphanumeric keyboard, is appropriate for consumers familiar with keyboarding or expecting to use a computer.

The third strategy is arranging the letters by frequency of use to maximize efficiency or control. Consumers who point to the letters or scan use this strategy. With pointing, the most frequently used letters are placed where the consumer can most accurately and consistently point. Letters used less frequently are placed in the periphery. Placing the most frequently used letters where the consumer has the best accuracy facilitates use of the device

and the flow of communication. Scanning arrays should be designed so that the commonly used letters or words are offered as the first or second choice.

Symbol systems are used with both vocal and non-vocal output systems. Symbols may be drawings, icons, or figures specifically developed for communication systems and designed to represent concepts. There is little similarity among representational systems, and each approach has its followers and preferred methods for introduction and use. Examples of published symbol sets are Picture Communication Symbols, PicSyms, MinSpeak, and Blissymbolics. Information on these and other symbol sets can be found in *Augmentative and Alternative Communication* (Beukelman & Mirenda, 1992).

Electronic Aids to Daily Living

EADL provide alternative independent control of the electrical devices in an environment, most often at home. The name has recently changed from environmental control unit (ECU) to EADL as a more accurate description of the function of this technology and to improve reimbursement from funding sources by relating its use to functional outcomes (Lange, 2002). The term environmental control unit emphasizes what is being controlled (i.e., television, telephone) rather than an outcome (i.e., increased independence, safety, communication, leisure). EADLs give access to devices such as lights, telephones, audiovisual or home entertainment appliances, beds, intercoms, thermostats, door locks, and window curtains. Consumers without disabilities increasingly use this type of technology. In new home construction, this technology is called home automation and is marketed as a means to create ease or save money by remotely regulating sprinklers, lights, and thermostats.

EADLs can be activated either through direct (pressing a button on a garage door opener) or indirect (scanning) methods. Most direct-access devices were developed for the mass market and therefore are inexpensive and found in electronics stores. If motor impairment prevents direct selection, a specialized AT product must be used. The same criteria used for determining an access method for computer or AAC device apply to choosing an access method for EADL.

Categories of EADL Control Technology

EADL let the consumer control electrical items without having to move to the appliance or interact with its typical controls. Anyone who has used a TV remote recognizes the convenience and ease of controlling an appliance remotely. Occupational therapists recommend EADL devices to consumers who are unable to control devices due to inability to reach or manipulate knobs, dials, and buttons or who are limited by pain or fatigue.

Appliances vary in complexity of the control signals they require. For example, turning a light on or off requires only an on/off signal, but changing the channel on a television set or reshuffling the songs on the CDs in a 5-disc player requires complex control signals. EADL control signals can be transmitted by several methods, such as through the building's electrical wiring; IR, ultrasound, and RF transmitters and receivers; or a combination of these modes. Certain technologies lend themselves to control of specific kinds of appliances.

Using a building's electrical wiring for control of electrical appliances is convenient for appliances such as lights or fans, which require only simple on/off control signals. Such appliances are plugged into a small coded switch module that is plugged into the wall outlet. A control box, also plugged into an electrical outlet somewhere in the consumer's house, sends a signal with the module code and the on/off signal over the wiring system. The receiver module detects the signals and switches electrical power to the plugged-in appliance. The quantity of codes and variety of modules available make it possible to turn electrical devices off and on throughout a home or apartment. The variety of control boxes ranges from simple hardwired push-button switches to sophisticated computer-controlled interfaces. These devices are known collectively as X-10 modules and controllers.

IR light transmitters are also used to generate control signals. IR light control signals are invisible to the human eye. The control signal is interpreted by an IR receiver and translated into the correct function. Television remote controls use this technology, and their invisible light beam must be pointed directly at the television and have a clear line of sight. Various patterns of IR light are coded to direct the appliance to perform specific functions. IR tends to be used in applications that require multiple adjustments, such as television sets, VCRs, and CD players.

An ultrasound controller works in a similar manner, but control signals are transmitted via inaudible, high-frequency sound waves. Since sound waves disburse readily in home environments, ultrasound controllers do not need a line of sight and can travel farther (up to 200 feet), although walls and other obstacles block them. Ultrasound is used in some simple EADL devices that send on/off signals to IR receiver modules.

Radio frequency (RF) signal transmitters are another option. RF signals are less affected by obstacles such as walls but are sometimes susceptible to interference from other radio frequencies. Devices using RF usually offer the consumer a choice of bands to bypass interference on heavily used channels. That is, the consumer can change the frequency band or channel so as not to turn on devices in the neighbor's house. RF transmitters and receivers are often used to open garage doors and unlatch front doors. They are also frequently the controller of

choice to use with an X-10 system that has a RF control box.

Simple EADL

Simple EADLs give simple control over one electrical device. They can contribute to learning cause and effect, increasing personal control, and developing responsibility. Simple EADLs can be set up to work in momentary mode (i.e., work only as long as the switch is activated) or latched mode (i.e., stay on until the switch is pressed again to turn off the device). One simple EADL is the appliance interface, which can be easily incorporated into group participation or fun in the kitchen. Using a single switch, consumers can participate in cooking by turning on small appliances, such as blenders and popcorn poppers. Figure 19-11 shows the Power Link 3 being used with an infrared switch to operate a fan. Therapists can build on this skill and set up other simple switch-controlled EADL interfaces that send ultrasound signals to bedroom lights or fans providing control over personal space. Phones that scan phone numbers or picture phones that combine large buttons and photos with speed dial give modified phone access with simple interfaces. A scanning device like the Relax II is an alternative TV remote control for someone who cannot press small buttons.

Complex EADL

Consumers who have significant impairment or who desire control over more types of appliances within their environment need complex EADL devices with sophisticated functions (see Fig. 19-2). These exist as dedicated EADL devices, as components of a computer-based system, and as a subsystem within AAC devices.

Dedicated devices (e.g., Quartet, Sicare Pilot) perform complex adjustments to multiple systems within a consumer's environment. Some use voice commands; others use scanning input to take commands. They respond and

Figure 19-11 Power Link 3 is a simple EADL tool used to operate appliances. Here it is used with a fan.

transmit control signals to systems in the environment using a combination of transmission technologies based on what is best for the appliance being controlled. These systems can activate intercoms, unlock doors, and dial the phone. Consumers should be aware of their vulnerability in power outages and either install uninterruptible power supplies or have a 911 auto-dial backup system.

Systems with similar capacity can be found in computer-based EADLs. Computer software, such as Words+ or MultiMedia Max, transmits a signal to a control box, which sends IR to a phone, appliance, entertainment center, or X-10 module. Computer-based systems are ideal for work settings where consumers are already interacting with their computers. Improvements in speech recognition enable consumers to use voice commands to control EADL software on a computer, although this same feature may be limiting if the consumer must go to the computer to interact with an appliance.

Many top-end AAC devices include EADL control. A subset of icons like the ones the consumer uses in the choosing of words and phrases can activate and send IR signals either directly to an IR-controlled appliance or to an intermediary device that forwards signals on to X-10 modules or telephone dialers. AAC devices can be customized so functions can be added as the consumer gains skill and confidence.

Sensory Accommodations

Many microprocessor-based aids help people with sensory impairments manage their daily living environments.

Closed-Circuit Television

Consumers with low vision and limited interest in computer-based adaptations may consider closed-circuit television (CCTV) systems. A mounted television camera is focused on the item that the user wants to see. This may be a surface where the consumer places the printed material

to read (e.g., a recipe, invoice, magazine article, or greeting card) or the writing on the blackboard in the front of the room. The camera sends the image to a TV monitor positioned at the consumer's eye level. Screen magnification and contrast can be set to needs. This technology has become lighter and so much more portable that small handheld units are now available. Now CCTV is being used out in the community and not just at home.

Braille Note Takers

For consumers with visual impairment, portable microprocessor-based note takers function like personal digital assistants (PDAs). Consumers can choose between models with a 6-key Braille keyboard or a full QWERTY keyboard. Some models offer speech feedback via earphone; others offer review through a small refreshable Braille display. Consumers record notes from class or meetings and later upload them to a computer or print them directly to a paper or Braille printer. These devices also contain appointments, contacts, clocks, and reminder systems. With the continued development of technology, they now log on to servers, access e-mail and web pages, and/or operate as cell phones.

Closed Captioning

Real-time closed captioning is an excellent accommodation for consumers with hearing impairments. This system combines a court stenographer's skill for capturing spoken language with a computer for processing the text. This technology projects or displays a speaker's words as readable text. It is often used for keynote speakers at large conferences or in office meetings where participants are gathered around a table.

Environmental Access and Universal Design

AT devices enable participation and control only when the human and non-human environments allow access for consumers and their devices. Independent power mobility

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

AT Related to Self-Maintenance Roles

Claire, a 65-year-old widow, is increasingly frustrated in her ADL routines as her macular degeneration worsens. She depends on her daughter, Jean, to stop by her apartment daily to assist her with visual tasks. Claire is upset because Jean's husband has taken a new job in another state and they will be moving soon. Jean has heard that there are low vision aids that might help restore her mother's self-sufficiency and has encouraged her mother to seek assistance. Claire's goals include restoring her independence with food preparation instructions, bill paying, and reading correspondence, the TV guide, and the Senior Activity Newsletter.

1. What kind of AT solution might allow Claire to regain some of her self-sufficiency and ease her daughter's mind about moving away?
2. What pieces of equipment would assist Claire in her environment?
3. What would help ensure a good "fit" between Claire and the equipment?

offers no advantage in places without ramps and rooms where doorways are too narrow to accommodate the wheelchair. Consumers using AAC devices cannot communicate if people will not take the time to interact with them.

Just considering the variability among humans in the design process can eliminate many barriers. Incorporating universal design means that products and environments are designed to be usable by all people, to the greatest extent possible, without the need for adaptation or specialized design (The Center for Universal Design, 1997).

Since people who use AT devices to compensate for impairment are not always given the opportunity to demonstrate their capabilities, the Americans with Disability Act (ADA) supplies the force of federal law to facilitate their opportunities (see Chapters 11 and 36).

Funding

Clearly, AT devices cost money. At times, inexpensive solutions can be found to enhance the consumer's occupational performance, but often the equipment or the training to use it is costly. AT enables consumers to participate in roles that might otherwise be denied to them. Therefore, the consumer's abilities, needs, and specific occupational goals should drive the assessment, not the availability of funding. The compelling need for an AT device or services should drive the search for funding.

AT Should Drive the Funding Process

The consumer's goals may require AT devices that are totally beyond his or her financial resources. When funding drives the assessment, more costly solutions are not reviewed, and the consumer is offered only solutions that are within his or her means. If the best solution facilitates the consumer's occupation but is expensive, the assessment team needs to document that the solution will best meet the consumer's goals and present a strong case to the funding agency.

Legislation and Funding for AT

The Assistive Technology Act of 2004 recently reaffirmed AT devices as valuable tools for individuals with disabilities (United States Congress, 2004). The original law placed AT education and advocacy resources in all states and United States territories (United States Congress, 1988). The new law requires states to increase access to AT devices through lending libraries, recycling programs, and low-interest consumer loan programs.

Congress, recognizing the natural links between people and their societal roles, sought to make paying for AT a responsibility for a range of publicly supported agencies. Therefore, considering an individual's life role leads to good starting points for finding funding for AT.

Workers

Vocational rehabilitation agencies, which are federally funded in each state, are responsible for providing the training, education, services, and AT that working-age consumers need to become employable. Vocational rehabilitation is a major payer for AT evaluations and for the devices and training those evaluations recommend.

The ADA makes it unlawful to exclude persons with disabilities from public services, transportation, telecommunications, and employment. To help pay for reasonable accommodation for an employee or prospective employee with a disability, a business can apply for an Internal Revenue Service (IRS) Business Tax Credit and Deduction or a Department of Labor Work Opportunity Tax Credit to offset their costs. Expenditures to make a workplace accessible include computer adaptations and remodeling bathrooms (Jeserich, 2003; Mendelson, 1996).

Social Security can help a consumer who wants to begin work through a Plan to Achieve Self Support (PASS). Under Social Security rules, any income reduces benefits. With an approved PASS plan, however, that income can be preserved to pay for items such as AT devices or training that are needed to reach a goal or return to work (Social Security Administration, 2004).

The IRS allows workers to take a tax write-off for health care and miscellaneous work expenses. The IRS definition of medical care, "for the diagnosis, care, treatment or prevention of disease or for the purpose of affecting any structure or function of the body," covers the purpose of AT (IRS, 2005). Other tax provisions enable employed consumers with disabilities to deduct work-related expenses, like AT, from their gross income. A tax credit can also be taken when the expenses incurred by a taxpayer for the care of a dependent who has one or more disabilities frees the taxpayer to work (Mendelson, 1996).

Workers with health insurance can use it to fund some types of AT. Since health insurance uses the criterion of medical necessity to decide whether to fund AT devices or services, they are more likely to cover a wheelchair or prosthesis than a computer adaptation. Policies must be reviewed carefully to determine an individual's coverage.

Older Adults and Unemployed Adults

Medicare is the primary insurer for older adults and those on permanent disability. Medicare will pay for durable medical equipment, wheelchairs, and speech-generating devices (i.e., AAC). Medicare only pays for wheelchairs when they are necessary for mobility-related activities of daily living in the home. This need must be well documented in the medical record. Medicare generally pays 80%, and other health insurance pays the remaining 20%, but only if Medicare pays. In early 2001, Medicare expanded coverage to include funding for dedicated AAC devices and services. If a beneficiary can pay for an AT device

with private funds, Medicare outpatient services may cover occupational therapists for AT-related services to increase independence in IADL.

Unemployed adults with disabilities are often eligible for Medicaid. Medicaid is administered at the state level and each state interprets the regulations independently, so coverage varies from state to state.

Injury- and Illness-Related Causes

Health insurance can become a source of reimbursement for AT devices and services when the need for AT devices is the result of an injury or illness. Health insurance, at present, is primarily offered by managed care organizations and health maintenance organizations. Many large health organizations hire case managers to coordinate rehabilitation resources in complex cases. It is clear that consumers who have strokes, head or spinal cord injuries, or progressive neurological disease benefit from AT devices and services. Nevertheless, teaching a case manager about the potential of AT to increase independence and enable a return to occupation remains an important function of occupational therapy practice.

When trauma or negligence causes an injury that necessitates the use of AT, a financial settlement or a trust fund can be the source of reimbursement for AT devices and services. In this case, the occupational therapist may direct a letter of justification to a judge or trustee.

Consumer Loans

Loans are a common way to purchase products. Banks and credit unions are required to offer consumers with disabilities loans that take their special financial circumstances into consideration. The Tech Act Project in each state has information on these low-interest loan programs (United States Congress, 2004).

Charity

When all other sources fail, there are still bake sales, raffles, car washes, and appeals to service clubs and civic organizations as a means of funding AT devices.

Justification Letters

With the knowledge gained from the consumer-centered assessment, trial use of a device, interviews with significant others, and possibly a home visit, the occupational therapist is in a strong position to justify the need for AT devices. This document is called a letter of justification or, in some cases, a letter of medical necessity. A physician's prescription is needed for all requests in medical model services and generally accompanies the therapist's letter of justification. With education- or work-related funding sources, another form of "prescription" may be needed.

The occupational therapist uses knowledge gained in clinical assessment, knowledge of product features, and

the potential outcomes for the consumer to develop a report. Using clear writing, case data, and sometimes photographs or videotape footage of the consumer using the device, the therapist presents how the cost of AT devices will be offset by an increase in function, engagement in education, employability, and/or greater independence. It is important to tailor the letter to the funding source. For example, requests for funds from Medicaid must justify AT devices and services as medically necessary, whereas services through the Individuals with Disabilities Education Act (IDEA) must emphasize educational necessity.

A letter of denial does not necessarily mean no. Many private and public sources of funding use a system of appeals to weed out groundless requests. First, get the denial in writing; then, prepare for an appeal. The mandate for funding AT is clear, but agencies and organizations still attempt to avoid financial responsibility by raising objections. A clear, logical letter of justification has won many appeals for AT devices and services.

ROLES OF OCCUPATIONAL THERAPISTS IN AT INTERVENTION

Even when occupational therapists can advise about AT for common needs, some consumers with complex problems will need referral to an AT center for integration of multiple solutions to allow them to reach their functional goal. A referral to an expert (probably in a metropolitan area or a larger facility) creates an opportunity for OT practitioners to learn more about AT. In addition to the opportunity to provide input, there is an opportunity to learn more about AT and provide follow-up as the consumer learns to integrate a complex solution into everyday tasks and routines. Specific roles for the professionals within the AT assessment team have already been discussed, and now, possible roles for occupational therapists are presented.

AT Specialist

Occupational therapists with AT service delivery experience usually strive for the assistive technology provider (ATP) credential. This certification, offered through the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA), validates an individual's knowledge and experience in AT and sets a standard for entry-level expertise. RESNA is an interdisciplinary association of professionals united in a desire to improve the potential of people with disabilities to achieve their goals through the use of technology. Professionals with ATP credentials are expected to adhere to a code of ethics, to practice in a consumer-centered manner, and to continue to gain competence in their area of AT specialty.

Consultant

Some occupational therapists have developed consulting practices in which they advise organizations on program development, change issues, quality improvement, and planning (Jaffe & Epstein, 1992). Many educational, rehabilitation, governmental, or private sector organizations need assistance to implement AT service delivery. Occupational therapists with consulting skills and knowledge of AT solutions can offer important services to these organizations.

Product Development Team and Product Testing

With their broad clinical knowledge of the limitations caused by impairment and their comfort with functional tasks and environments, occupational therapists contribute important knowledge to engineering and research teams. Their input is helpful when conceptualizing solu-

tions, developing prototypes, and measuring efficacy with consumers.

CONTINUING EDUCATION

AT is always changing. Any occupational therapist practicing in AT must commit to continuing education. RESNA and other organizations continuously offer education (Resources 19-1). University courses, as well as sessions at annual conferences, weekend workshops, and online courses allow practitioners to pick up the knowledge and skills needed to incorporate AT into a range of practice settings. Listserves, like those offered by the American Occupational Therapy Association, RESNA, and university programs, allow novice practitioners to use the expertise and help of experienced AT practitioners to solve practical problems. Therapy departments can hire staff development expertise to increase their comfort with using AT in their practice setting.

CASE

EXAMPLE

Using High-Technology Adaptations

Occupational Therapy Assessment Process

Patient Information

S.S. participated in an AT evaluation. He is a 29-year-old male, left-hand dominant, who is 4 months post TBI with injury to his right motor cortex, sustained in a bicycle collision with a car. He has worked hard in rehab and is eager to return to work as an environmental engineer, resume his active lifestyle, and return to a more balanced relationship with his wife. The following problems were identified: 1) reduced balance and endurance in walking on uneven surfaces; 2) difficulty with handwriting and keyboarding which are essential job skills in his work; 3) mild cognitive impairment in the area of short-term memory and task sequencing; and 4) desire for greater safety and independence in self maintenance activities at home.

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Appreciate the context

"I think that SS has nearly maximized the benefits of in and out patient rehab that were focused on motor return. His desire to return to employment is strong and will help to focus the adaptations and AT services needed to help him return to employment and greater self-reliance. His motivation, encouragement from his wife, support from a vocational rehabilitation counselor, and history of physical fitness and active lifestyle are real facilitators to his recovery and return to occupational functioning."

Develop intervention hypotheses

"I think that the right type of environmental supports and AT devices will enable SS to return to work. His motor limitations seem to be the greatest barrier. His cognitive limitations may be adequately addressed with AT devices. His desire to return to work makes him ideally suited to have AT evaluation and support services paid for by vocational rehabilitation. If he is open to use of adaptive devices and strategies he will be able resume many aspects of his active and independent lifestyle."

Select an intervention approach

"I want to develop a plan that will focus on **compensation** for motor and cognitive deficits through careful use of AT devices and strategies. I expect there will be **remediation** of cognitive deficits through graded return to familiar work task. The predictable and sequential nature of computer software is often helpful. Using computer applications at work should be in long-term memory. I will work to **change the physical and social environment** around him so that he can return to a level of self-reliance. Mobility aids and grab bars may increase his safety, confidence, and endurance in home and work site locations."

Reflect on competence

"S.S. reminds me of other young adults with TBI that I have worked with but his intelligence and desire to return to work are particularly striking. I am not sure he will accept mobility aids, so this may lead to a later decision about whether or not he wants to go out on job sites or work primarily in the office. I suspect that a return to sports and physical activities will be highly motivating so I will look up resources on adaptive sports."

Recommendations

Developing a computer access strategy is a top priority for both return to work and cognitive support. First, an assessment is needed to determine best compensatory strategy for computer tasks. The amount of training needed to teach strategy and integrate it into daily computer use will be determined as part of that assessment. The OT will also visit both home and workplace to determine their physical and social characteristics with the goal of identifying barriers and recommending modifications for safety and independence. She also will set up a consultation with S.S.'s physical therapist and vocational rehabilitation (VR) counselor to discuss adaptations for increasing mobility in community settings.

In collaboration with S.S. and his wife, the OT established the following long-term goals:

- 1) Return to productive computer use with the help of a computer access strategy;
- 2) Learn to use personal information management (PIM) software to help organize daily routines and serve as a memory aid;
- 3) Evaluate the need for modifications to the home and workplace to support safety and independence; and
- 4) Refer to the mobility team to explore use of a 4-wheel scooter at work and in community or jobsite locations.

S.S. and his wife were pleased with this plan as it seemed clearly focused on helping their life return to a more "normal" state.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"It seems like S.S. and his wife are pleased with the plan because it is focused on return to work and greater safety and independence in self-maintenance activities. They are grateful for his recovery to this point. Though they expect more recovery they seem willing to accept and compensate for his physical limitations. They are both eager to return to a more balanced relationship."

"Computer use is important to them both and seems like a welcome new topic apart from all of the medical interventions. Learning to use PIM software is an opportunity for new learning and the software itself will help S.S. more involved in planning his daily routine."

"I think an intensive approach is warranted in order to make return-to-work happen as soon as possible. OT sessions will need to happen about 3 times a week in order to keep parallel processes working, maintain continuity in instruction, and use findings to coordinate intervention among team members."

"I'm not sure that S.S. knows what he is facing but at this point he is relieved to be moving beyond medical rehab and into activities that are focus on return to function."

Summary of Short Term Goals and Progress

S.S. participated in a 2-hour computer access evaluation and the findings led to an agreement on the usefulness of two strategies: using Half QWERTY™ software for routine computer tasks and Dragon NaturallySpeaking™ (DNS) speech recognition for writing reports and long text messages. Also, he will begin to use a track ball to compensate for the reduced motor control in his left hand. Because S.S. reported in the assessment that his desk at work was located in a cube environment, it was necessary to consult with S.S.'s company before confirming the DNS recommendation. His supervisor will accommodate S.S. by moving his desk to an enclosed space and IT manager will integrate his software solutions into the networked computer system at the company.

With this clear, the recommendation is to have OT training in these adaptations 3 times per week for 4 weeks with follow-up activities for practice and continued learning at home. Loaned devices will be used to start training and confirm their suitability before seeking purchase approval from his VR counselor.

- 1) S.S. will successfully integrate the 4-button trackball (with settings adjusted to compensate for his impaired fine motor performance skills) into file management and desktop activities with increased accuracy in pointing and clicking as shown by manipulating cards in computer solitaire.

Assess the patient's comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

"I think the fact that S.S. is an engineer makes him a good problem-solver. He likes the use of technology to solve problems because it is a familiar concept and one that he uses in solving client's problems too."

"Because I need to teach S.S. a series of computer access strategies I am going to teach them sequentially and create as much natural motivation to use them as possible. Mousing is essential for computer use and attaching practice to a game will increase the amount of time S.S. spends in mastery of the task."

"I want him to get a strategy for writing text so we can use text to work on a software-based reminder strategy. I know that once the basic skill is developed, Half QWERTY™ is compensatory strategy that relies on practice to develop automaticity. It will rely on his long-term memory and that should be a boost to his self-esteem too. I like how the software provides a visual aid for learning. This strategy will be most useful when he wants to sit down and type a short e-mail message or add an entry to his to-do list."

"I am much more confident in the approach of teaching practical new skills as a means of restoring cognitive function. I know the research evidence just doesn't support the notion that repetitive cognitive ex-

S.S. realized immediately the value a trackball adds by separating the actions of pointing and clicking. His earlier efforts at mousing has been unsuccessful because the action of clicking the mouse button with his left index finger caused an involuntary arm movement that pushed the mouse off its target. Correcting miss-selections was annoying and time consuming. Next, he determined that placing the trackball 10-12" in from the edge of the desk gave him space to rest his left forearm and increased his motor control due to proximal stabilization. The therapist had him practice mousing skills in computer solitaire because it required him to select, move and release cards in specific places. As S.S. got comfortable with the new motor skill, the OT observed that it required extra effort for S.S. to isolate his little finger for a button click. Relocating the click and drag function to an upper button on the thumb side of the trackball increased his efficiency. This control parameter was modified in the trackball control panel and S.S. was immediately more successful in moving cards. The OT noted this change and will incorporate it into the set up for S.S.'s own trackball when it is installed. The OT sent S.S. home with a loaner trackball to practice. S.S. planned to also practice the new motor skill with a simple graphics application on his home computer.

- 2) S.S. will transfer previous knowledge of touch-typing to the Half-QWERTY™ application and will use his right hand alone to type with a goal of achieving 15/wpm in two weeks.

At the second computer training session, S.S. was introduced to formal instruction in half-QWERTY™ software. The OT had confirmed in a timed typing trial that S.S. was able to type 10/wpm using just his right hand. His left hand was only able to assist with holding down the left shift key or (with significant motor planning effort) in holding control+alt. S.S. reported that he had typed about 50/wpm before his injury. (Half-QWERTY™ allows the right hand to type the letter on the key located in the mirror position when the space bar is held down. Users are able to acquire keyboarding rates that are near 2-handed rates.) The OT first used the tutorial that comes with the application to teach S.S. the concept. S.S. worked to relearn the location of letters that had previously been typed by his left hand. S.S. left the session with a demo version of the software to use in the 2 days before the next visit. The goal was to return with two ~100-word paragraphs typed with his right hand alone. At the next visit, S.S. met the goal but reported that it had gone very slow. The next two sessions were spent with a "drill & practice" typing tutor intended to develop proficiency and speed. The OT reminded S.S. to pursue accuracy over speed, assuring him that new motor patterns would develop and speed would return. Each session ended with assignments and homework. On the 4th session, S.S. was able to type 17 wpm and was pleased to have more than met his goal. He reported he was expending less cognitive effort and had started pressing the correct keys without conscious thought.

ercises lead to functional changes. Working on a reminder strategy and developing new motor patterns will be good cognitive rehab for S.S."

"I know that S.S. is going to appreciate having a reminder system. His wife has been really patient and supportive but I know he want to return to a level of self-sufficiency in remembering things. Besides, in our discussion about return to work S.S. he has mentioned that he has to work very hard to remember his rehab schedule. He appears to have developed the insight that returning to work will mean remembering even more things like meeting schedules, client visits and project deliverable deadlines."

"I'm really seeing progress. S.S. has been very focused on the learning each of these adaptive computer strategies. Each time he comes in with an assignment completed, his self-confidence seems to have grown too. He has been very appreciative of my incremental approach and that makes me feel good too. His team recognizes his potential and that is a strong source of support too."

3) S.S. will learn to use Palm Desktop as a means to set up calendar, reminders, contacts, and a to-do list.

The OT knew that S.S. would rely on a small, pocket size reminder in the future. In the short term it was important to teach the concept with free desktop software. At the 5th session, the OT introduced S.S. to the software. He was taught how to set up a daily reoccurring event on his computer and add a reminder. The OT suggested that he use his new key-boarding skill to enter text and set up reminders. At first the software will be used to create a schedule for computer practice and reminders for therapy visits. S.S.'s wife, who accompanied him on that visit, agreed to install the software on their home computer and set up those 2 calendar activities. If S.S. is successful, the OT will request funding for a handheld from the VR counselor and teach the skill of syncing the device with the desktop software.

4) S.S. will successfully train DNS voice files and use a quick start table of speech commands to write 100 words per day in a daily journal about his recovery.

The OT spent the next 4 sessions introducing S.S. to DNS and developing his confidence with using his voice to write. First they created a voice file and then, using a quick-start menu, started writing text using speech and voice commands. The OT had already determined that S.S. would be most successful with DNS if new learning and the memory load were reduced. Because S.S. is able to use his right hand, he did not need to use voice commands except where convenient. Additionally, the trackball provides access to menus and the half-QWERTY™ keyboard gives convenient access to the alphabet for correcting recognition errors. The OT focused direct intervention on training recognition accuracy and building vocabulary. Focus on these skills reduces corrections and actively builds voice files. The next 2 sessions were focused on developing a speech pattern that emphasizes “preparing to speak” i.e., silently developing an idea before speaking it. During the 3rd session the OT arranged for S.S.'s coworker and friend, Joe, to shadow the 4th DNS training session. The OT wanted to add additional coaching resources into S.S.'s support system. Joe was selected because he already used DNS and only needed to understand more about how S.S. uses the application. By the end of the last DNS training hour, S.S. has written 200 words and had corrected another 4 recognition errors with Joe watching. S.S. has learned to pause and think before speaking and had adopted a speech pattern that was clear and deliberate when using his voice for writing. The plan was made to have a follow up session in 2 weeks. Joe agreed to alert the OT if the progress S.S. had demonstrated was not maintained.

The results of the mobility team consultation with S.S. and his wife led to a decision to rent a 4-wheeled scooter for a 2-week trial. The trial will help to determine if it increases his use of community resources (e.g., going to a community sidewalk festival) or increased S.S.'s potential to visit job sites or meet customers in community locations. This trial will occur approximately 3 weeks before S.S. is scheduled to return to work.

“I am glad that my approach to DNS for S.S. has worked so well. (There are so many ways to teach this application. If I were teaching a client with C-4 quadriplegia my approach would be entirely different.) Since he has the motor skills to use the keyboard and mouse to direct the application, we only need to work on training recognition accuracy. That makes learning for someone with short-term memory deficits just that much easier.”

“Learning about Joe and his skills with DNS was a real bonus. Working on this project appears that it will give these friends a means to reconnect after S.S.'s injury. Having Joe as a back-up will help when I am not available and should help him bridge back into the workplace too. It is good to know that some of S.S.'s coworkers also use DNS. That will create a point of camaraderie as S.S. reintegrates back into the workplace.”

“I am glad my PT colleague on the department AT team is willing to see the scooter as a good strategy for someone as young as S.S. Most PTs would want to work harder and longer on gait strengthening. I guess our past work together on developing compensatory strategies for clients has taught her that returning to functional environments can provide its own form of intense motivation. She agrees with me that using a scooter won't hinder S.S. in developing endurance and balance in continued outpatient PT. Progress in PT may lead to abandoning the scooter in a year. In my opinion, there may always be some occasions when S.S. is safer and more functional when riding a scooter.”

“S.S. and his wife were very open to adding grab bars at home. They recognized that this will ease her mind and allow her to reduce her level of monitoring when he is in the shower or bathroom. She has already asked her dad, who has handyman skills, to install the bars I recommended in the shower and next to the commode.”

“They plan to try using the loaned aluminum, folding ramp during the two-week trial. Depending on how that goes they will decide whether or not to make a permanent modification to their minivan. At least the style of ramp that is suggested can be added or removed without permanently defacing the vehicle.”

At the end of the 2-week trial, the team met again and agreed that a scooter greatly increased S.S.'s range and frequency of community mobility while increasing his independence because of reduced risk of falls. S.S. is not giving up on his desire to walk but is willing to speed his community and employment re-entry through scooter use. He is willing to accept that even if he walks in most settings, there will still be situations in which fatigue or uneven ground will limit his participation. The VR counselor is willing to purchase the scooter.

With the information from this mobility consult, the OT visited S.S.'s home and workplace and made the following recommendations.

- Shower has a built in bench seat. Install grab bars in the shower to increase safety in enter, exiting, and recovering balance.
- Reinforce use of stool in kitchen for food preparation tasks.
- Electricity in the garage will allow S.S. to store his scooter there. The garage door opener will facilitate entry and exit.
- Adding a power assist ramp to their minivan will allow SS or his wife to drive the scooter up and into the van independently if the scooter is needed at work or for leisure activities.
- At work, handicapped parking and accessible bathrooms are available.
- Recommend the addition of automatic door openers to the office building to facilitate entry by S.S. when in his scooter or by other customers with mobility limitation. (Paid for with help of a ADA-based tax benefit for the small business owner.)

Next Steps

The final three computer access sessions will be reserved for follow up. They will be needed for setting up the new software on the workplace computer and for checking on successful integration of S.S.'s new software skills into the workplace environment.

The VR counselor will also be checking on S.S. and has agreed to alert the OT if follow-up is needed. S.S. has agreed to schedule a follow up visit in 3 months to discuss the need for modifications to computer access strategies.

Mobility strategies will also be discussed in 3 months to determine if scooter use is supporting community involvement and access to jobsites for S.S.

“I do think they will decide on the power-assisted ramp because it will give SS independence with the scooter—which is the purpose of using the scooter. If my experience is any indicator, I think they will quickly discover that unfolding one of those ramps is much more work than it looks like it is.”

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if he or she should continue or discontinue therapy and/or return in the future

“As we conclude this intense 5-6 weeks of intervention, I am sure that there will be some unexpected ‘wrinkles’... there always are. With these 3 approved remaining visits, I know I will be able to provide the follow-up that will insure success.”

“This case has been one that really demonstrated the value of an AT team. S.S. must really be a valuable employee because his company really went out of the way to accommodate his needs and reintegrate him into the office.”

“I look forward to seeing S.S. in 3 months. The knowledge of his success with the adaptations that were recommended will reinforce my confidence as a practitioner and give the information I need to build my AT practice repertoire. I will decide at that time whether any short-term intervention is needed or whether I will encourage S.S. to contact the VR counselor if his needs change.”

Clinical Evidence Table 19-1 Best Evidence for Occupational Therapy Practice Regarding Assistive Technology

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Use of automatic speech recognition (ASR) as a means of computer access	Collected performance data via interview and task measures from experienced ASR users on: (1) computer use, (2) type of ASR, (3) reasons for ASR use, and (4) measures of performance on 6 operationalized ASR tasks (e.g., file management, transcription rate, etc.). For 18 users with choice: comparison between ASR and alternative method.	24 users of ASR with > 6 months experience; 5 participants could use ASR only, and 19 used ASR plus keyboard.	Exploration of the ASR experience for variety of experienced users. Results varied widely due to (1) limitations of the technology and (2) limitations in user's ability to maximize effective use of ASR.	One group, descriptive statistics. IIIc1a	Reasons ASR chosen: (1) reduce pain or fatigue, (2) ease of use, and (3) few alternatives. Of participants with choice, 48% used ASR for ≤25% of computer tasks and 37% used ASR for >50% of computer tasks. 63% reported overall satisfaction with ASR. Text entry rate ranged from 3 to 32 wpm, with accuracy of 72–94%. Best users had best repair strategies. Typists with speed >15 wpm got less benefit from ASR.	Those with higher recognition accuracy had higher satisfaction scores, $p = 0.027$. For non-text entry tasks, ASR plus keyboard was 61% slower, $p < 0.05$. For study participants, more agreed with: (1) I can enter text more quickly with ASR than with any other method, (2) ASR is easy to use, and (3) I can enter text more accurately ($p > 0.05$).	Koester, 2004

SUMMARY REVIEW QUESTIONS

1. Describe the main points of the HAAT model.
2. Define high and low technology.
3. List the steps in an AT assessment.
4. What are the various roles the occupational therapist can play on an AT team?
5. List several input and output devices, other than a keyboard and standard mouse, and describe who might use them.
6. Explain the main methods that EADL use to transmit signals from the input device to the control box.
7. Where could consumers look for funding for AT devices?

CHAPTER 20

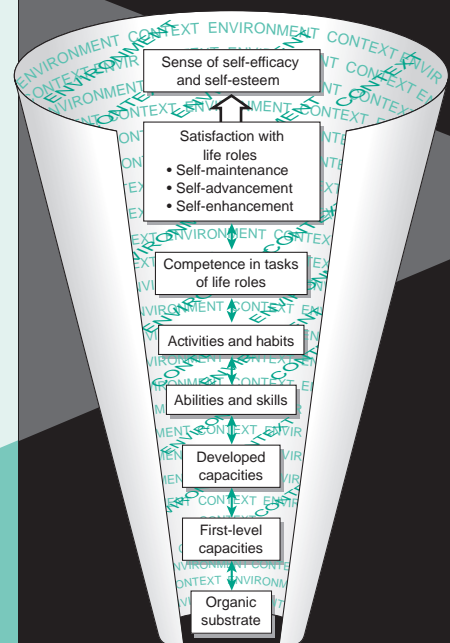

Physical Agent Modalities

Alfred G. Bracciano

LEARNING OBJECTIVES

After studying this chapter, the student will be able to do the following:

1. Describe the phases of wound healing and types of pain.
2. Identify the professional and regulatory issues related to physical agents.
3. Define and discuss superficial and deep thermal agents.
4. List the precautions and contraindications in the use of physical agents.
5. Describe the clinical application of electrotherapeutic modalities.
6. Describe how superficial EMG biofeedback can be used for muscle reeducation.

Glossary

Acute pain—Rapid onset of pain relative to a biological function associated with tissue trauma.

Biofeedback—Procedures or techniques that are used to provide an individual with an auditory or visual cue or “feedback” to learn and gain volitional control over a physiological response.

Chronic pain—Recurring or persistent pain, often poorly localized; may be associated with anguish, apprehension, depression, or hopelessness.

Conduction—Exchange of energy (for example heat or cold) when two surfaces are in direct contact with each other.

Convection—Conveyance of heat by the movement of heated particles, such as air or water molecules, across the body part being treated, creating temperature variations.

Cryotherapy—Application of a superficial cold agent to part of the body. Often used for pain relief, reducing edema, and decreasing inflammation following trauma.

Deep thermal agent—Therapeutic application of any modality to the skin and underlying soft tissue structures to cause a temperature elevation in tissue up to a depth of 5 cm.

Dosage—Amount and intensity of heat delivered to selected tissue causing temperature variations; classified as mild, moderate, or vigorous.

Electrotherapeutic agents—Therapeutic application of an electrical current to selected tissue or monitoring of endogenous electrical activity in tissue. Includes biofeedback, neuromuscular electrical stimulation, functional electrical stimulation, transcutaneous electrical nerve stimulation,

electrical stimulation for tissue repair, high-voltage galvanic stimulation, and iontophoresis.

Impedance—Resistance of tissue to the passage of electrical current or ultrasound waves.

Inflammation—Cellular and vascular response in affected tissue that follows injury or abnormal stimulation; the initial phase of the healing process; the body’s attempt to rid itself of bacteria, foreign matter, and dead tissue and to decrease blood loss.

Pelvic floor—Refers to the pelvic diaphragm, the sphincter mechanism of the lower urinary tract, the upper and lower vaginal supports, and the internal and external anal sphincters.

Physical agent modality—Treatment technique that uses heat, light, sound, cold, electricity, or mechanical devices.

Proliferation—Formation of new collagen tissue and epithelium in the intermediate stage of wound healing.

Referred pain—Pain occurring in an area different from the source of injury or disease.

Remodeling—Third phase of wound healing; dynamic process with maturation of new collagen tissue within the wound.

Superficial thermal agents—Therapeutic application of any modality that raises the temperature of skin and superficial subcutaneous tissue to a depth of 1 cm.

Ultrasound—Deep-heat modality; application of sound waves to soft tissue, causing thermal and non-thermal effects; sound having a frequency greater than 20,000 Hz.

The profession of occupational therapy has a long and colorful history, adapting and changing in response to internal and external issues and challenges. The use of preparatory methods, such as physical agents and **biofeedback**, as a part of clinical practice has become more widely accepted within the profession, with ever-increasing numbers of states adopting regulatory and practice guidelines. This transition has come about in part because of changes in health care delivery, expanded practice specialization, and service delivery in hand therapy and orthopedics. The use of physical agents and biofeedback as a part of clinical practice has been motivated by the need to facilitate outcomes and healing in our patients as quickly and cost effectively as possible. As increasing numbers of occupational therapists use these preparatory methods to facilitate occupational function in their patients, the need for training and education to understand how and why these agents work is crucial.

Physical agent modalities are interventions or technologies that produce a response in soft tissue through the use of light, water, temperature, sound, electricity, or mechanical devices. There are four primary classifications of physical agents: **superficial thermal agents**, **deep thermal agents**, **electrotherapeutic agents**, and mechanical devices. Superficial thermal agents include hydrotherapy/whirlpool, **cryotherapy**, hot packs, paraffin, water, and infrared heating. Deep thermal agents include therapeutic **ultrasound** and phonophoresis. Electrotherapeutic agents include biofeedback, neuromuscular electrical stimulation, functional electrical stimulation, transcutaneous electrical nerve stimulation, electrical stimulation for tissue repair, high-voltage galvanic stimulation, and iontophoresis. Mechanical devices may include vasopneumatic devices and continuous passive motion (CPM) devices (American Occupational Therapy Association [AOTA], 2003).

AOTA (2003) supports the use of physical agents as an adjunctive method of treatment that can be used preparatory to intervention with the intent to enhance engagement in occupation and performance. Physical agents are used to remediate capacities that allow reacquisition of abilities that may enhance participation in activities of daily living and role performance. Use of physical agents without application to functional outcome or occupational performance is not considered occupational therapy treatment. Although other health professions may also use physical agents as part of their treatment protocols, the occupational therapy profession's distinct approach focuses on occupational performance issues at the level of the person and environment.

This chapter provides a broad overview of the physical agents commonly used by occupational therapists. It is important to recognize that physical agents are an additional “tool” that occupational therapists can use as part of their repertoire of interventions preparatory to occupation. Physical agents are most often used as part of the treatment protocol to address pain, edema, muscle weakness or guarding, and loss of function or sensation. This chapter discusses pain theories and wound healing. This information, often overlooked by therapists, is vital to determine which type of agent would be most efficacious and at which point in treatment and healing it should be applied.

This chapter reviews superficial thermal agents, such as hydrotherapy, hot packs, and paraffin; cryotherapy; and deep thermal agents, such as ultrasound, along with their biophysiological effects. A discussion of the principles of electrotherapy and clinical application of neuromuscular electrical stimulation and transcutaneous electrical stimulation are also presented. Surface EMG and biofeedback to decrease pain and improve motor control will also be reviewed. It is beyond the scope of this chapter to present all of the information needed to use physical agents safely and effectively. The intent of this chapter is to provide a basic description of physical agents and their potential for incorporation into clinical practice to facilitate occupational function and performance. The reader is encouraged to continue learning through review of other texts and materials and through further academic preparation and education.

COMPETENCY AND REGULATORY ISSUES

AOTA (2003) revised its position paper on physical agents to ensure that the profession remained current with advances in technology, training, and practice. AOTA (2003) contends that physical agent modalities are considered “preparatory and adjunctive methods” that can only be used or applied by occupational therapists

and occupational therapy assistants who have documented evidence through training and education and possess the theoretical background and technical skills necessary for the safe and competent use of physical agents as part of an occupational therapy intervention plan. Skill and training in these interventions can be accomplished through in-service training or professional education, such as continuing education or accredited higher education programs and courses. It is important to note that the training and education should be verifiable and the therapist must demonstrate competence in **physical agent modality** use. AOTA (2003) states that course work should include foundational education and training in biological and physical sciences as well as modality-specific content in the areas of the biophysiological, neurophysiological, and electrophysiological adaptations that occur because of the application of a selected modality. It is also vital that any education in physical agent modalities include indications, precautions, and contraindications to ensure the safe and efficacious application of the modalities as part of the treatment process. Therapists must be critical consumers of continuing education course work, which may be provided by a manufacturer or sales representative during in-service training. (See Resources 20-1 for a list of manufacturers and vendors.) It is important that education and training in physical agents provide the therapist with more depth and breadth of knowledge than the mere technical skill of application. Without a thorough grounding in the fundamentals of physical agents, occupational therapists become mere technicians, applying physical agents incorrectly, at the wrong time in the treatment process, or without regard to facilitating occupational function.

Occupational therapists who use physical agents as part of their clinical practice also need to know local, state, and institutional rules and guidelines, which may restrict or limit the use of physical agents. Many states have adopted new policies and regulations related to the use of physical agents by occupational therapists. California, Montana, Tennessee, New Hampshire, Nebraska, and other states identify specific training and competency standards that are regulated by licensing boards. It is illegal in these states and others to apply physical agent modalities without meeting the licensing criteria and guidelines outlined in their respective laws. Some state guidelines may also regulate or limit specific applications by occupational therapy assistants. It is the responsibility of the occupational therapist to stay up to date concerning any local or state regulatory issues related to practice in their state. All occupational therapists who anticipate using these agents should contact their respective state regulatory board to obtain the most current information and should be able to document and defend their training and expertise to their colleagues and patients in meeting any competency requirements.

pain, and physiological effects of these agents so as to apply them in a timely, appropriate, and safe manner.

Normal Wound Healing

An understanding of wound healing and an appreciation for the sequence of events that follows an injury are necessary to determine the appropriate intervention to facilitate healing. Tissue and wound healing is a complex process affected by both physical and psychological components. In the healthy individual, the body's attempt to heal itself in response to an injury is well ordered and sequenced (Fig. 20-1, A–D). The stages of healing and repair may overlap, but they consist of three primary phases: inflammatory, proliferative, and remodeling.

Phase I: Inflammatory

The inflammatory phase is the initial response to an injury; it is both vascular and cellular. The inflammatory response is the body's attempt to rid itself of bacteria, foreign matter, and dead tissue and to decrease blood loss. The inflammatory response may be associated with changes in skin color (red, blue, or purple), temperature (heat), turgor (swelling), sensation (pain), and loss of function. Acute **inflammation** usually lasts for 24–48 hours and is completed within 7 days, although a subacute phase may last for 2 weeks.

Phase II: Proliferative

The proliferative phase of recovery is also known as the fibroplastic, granulation, or epithelialization phase. At this point, the injured area is filled with new connective tissue, and the wound is covered with new epithelium (**proliferation**). The primary components of this stage of healing are granulation, epithelialization, and wound contraction. Wound contraction, which is caused by the forming of red granulation tissue, shrinks the affected area. It begins approximately 5 days after the injury. It is complete approximately 2–3 weeks after injury. Fibroblasts are responsible for fibroplasia and collagen synthesis. Cross-linkages of the collagen tissue provide the wound with its tensile strength and durability, with the fibers becoming more organized (Davidson, 1998). This phase overlaps with the inflammatory phase, continuing until the wound is healed. The proliferative phase is complete when epithelialization has covered the wound, a collagen layer has formed, and initial remodeling is achieved.

Phase III: Remodeling

Remodeling is also known as the maturation phase. This stage begins about 2 weeks after injury and may continue for a year or more. Remodeling is characterized by a

WOUND HEALING AND PAIN

Physical agents have been defined as treatment techniques that use heat, light, sound, cold, electricity, or mechanical devices. They include electrical therapeutic modalities that induce heat or electrical current beneath the skin to obtain a specific biophysiological effect. In addition to course work related to the properties of light, water, temperature, sound, and electricity, occupational therapists using physical agents should have a thorough understanding of the wound healing process, classification of

Figure 20-1 **A.** Initial injury. Trauma to right upper extremity hand secondary to motor vehicle accident. Patient’s arm went out the window and scraped along the pavement after his vehicle rolled over. Note extensive tissue loss and extensor tendon lacerations. Patient also suffered multiple fractures and radial nerve laceration. **B.** Patient’s hand ready for skin grafting. Note tissue colors indicating various stages of healing. “Black” area indicates necrotic tissue, which must be debrided for skin grafting. **C.** Status/post percutaneous pinning and skin graft on dorsal surface of the hand. Note pins in place and staples securing skin graft. **D.** Patient’s hand 6 weeks after grafting and occupational therapy intervention. Note pink viable tissue. Some edema remains in the hand. Percutaneous pins have been removed, and fractures are solid.

balance of collagen synthesis and collagen lysis, formation, and breakdown. During this time, the scar becomes more elastic, smoother, and stronger. If collagen synthesis exceeds collagen lysis, hypertrophic scarring or keloids may occur. As remodeling continues, the collagen fibers assume the characteristics of the tissue they are replacing. Internal and external factors, such as presence of foreign objects, infection, nutrition, and medications may slow or affect the healing process; they are most significant in elderly people (Mulder, Brazinsky, & Seeley, 1995). Physical agents applied at the appropriate sequence and phase

during wound healing can accelerate healing and resolution of the injury. Appropriate selection of the type and depth of penetration of the thermal agent may significantly affect the healing process at a cellular level.

Wound Assessment

When treating open wounds, therapists should obtain baseline information on the wound’s appearance prior to treatment. Documentation should include the anatomical

location and area of wound, the size and shape of the wound, the color of any dead or necrotic tissue, a description of the exudate (purulent, with pus or a milky look; serous [clean, yellowish]; or serosanguinous [pinkish]), any granulation tissue or epithelialization, and a description of the surrounding intact skin (erythema, heat, pain, or edema).

Pain Perception

Pain, which may limit participation in occupational tasks, is reported by many of the patients seen by occupational therapists. By using physical agent technologies to treat pain, we may be able to help patients more fully assume their primary roles and activities, improving outcomes and quality of life. Understanding the pain experience informs clinical reasoning and influences our selection of physical agents.

Pain occurs when there is a noxious event, such as injury or inflammation, to an area of the body causing an excitation of the nociceptors in somatic or visceral tissue (Hakim, 1995). Nociceptors (sensory receptors specific to pain), which have variable thresholds, identify potential or actual tissue damage and respond to mechanical distortion, variations in the chemical components, and thermal changes in the tissue fluid. There are several ascending tracts that transmit pain signals to the brain.

Pain is characterized as being acute or chronic and can be referred, that is, felt in an area of the body other than the site of injury.
