<i>Western Neuro Sensory Stimulation Profile</i> (Ansell & Keenan, 1989)	Assesses cognitive function in severely impaired adults (Rancho levels II–IV) and monitors change in non-comatose patients who are slow to recover. Battery consists of 32 items related to arousal, attention, response to stimuli, and expressive communication and results in a profile of 6 subscales that summarize individual patterns of responses.
<i>Coma Recovery Scale</i> (Giacino et al., 1991)	Detects subtle changes in neurobehavioral status; predicts outcome in acute rehabilitation patients with severe alterations in consciousness (Rancho levels I–IV); consists of 35 items in 6 areas: auditory, visual, motor, oromotor-verbal, communication, and arousal. Responses are criterion referenced: specific stimuli are administered to elicit specific responses.
<i>Disability Rating Scale</i> ^a (Rappaport et al., 1982)	Single instrument to provide quantitative information on recovery from severe TBI from coma to community; consists of 8 items in 4 categories: arousal and awareness; cognitive ability to handle self-care functions; physical dependence upon others; and psychosocial adaptability for work, housework, or school. Scoring takes 30 seconds (if clinician is very familiar with both tool and patient) to 15 minutes (Center for Outcome Measurement in Brain Injury [COMBI], 2006). Scale is thought to be relatively insensitive in detecting problems and progress for persons with mild TBI (COMBI, 2006).
<i>Agitated Behavior Scale</i> ^a (Corrigan, 1989)	Allows objective measurement of agitation, particularly as a serial assessment to evaluate effectiveness of interventions to reduce agitation (COMBI, 2006); consists of 14 items; total score reflects overall agitation, with subscales specific to disinhibition, aggression, and lability.

^a Available online at <http://www.tbims.org/combi>.

Cunningham, 1984; Jennett & Teasdale, 1981). Many researchers have attempted to assess the predictive power of age, clinical observations (such as the GCS, pupillary reactions, and eye movements), data from CT, surgical lesion, length of post-traumatic amnesia (i.e., the length of time after the accident before the return of continuous memory), brainstem dysfunction, evoked potentials, increased ICP, or a combination of these factors (Braakman et al., 1980; Bricolo, Turazzi, & Feriotti, 1980; Karnaze, Weiner, & Marshall, 1985; Salcman, Schepp, & Ducker, 1981). Even with sophisticated clinical and radiological techniques, however, during the first days after injury, it is not possible to predict outcome with sufficient accuracy to guide early treatment or justify withholding treatment (Marion, 1996). Repeated observations of neurological recovery over weeks or months remain the best means to predict complete or nearly complete recovery (Marion, 1996).

As mentioned previously, the GCS is often used to predict outcome. An initial score of 8 or below that is maintained for 6 hours post injury predicts a mortality rate of 50% or survival with moderate to severe disabilities. Choi et al. (1988) found that a low motor score on the GCS, a fixed and dilated pupil, and age greater than 60 years strongly predicted death or severe disability and that the combination of factors had more predictive accuracy than any one of them used independently. The length of post-traumatic amnesia is another frequently used predictor of

outcome. Post-traumatic amnesia is a loss of memory of day-to-day events after an injury. Post-traumatic amnesia lasting less than 1 hour indicates mild injury; 1–24 hours indicates moderate injury; 1–7 days indicates severe injury; and more than 7 days indicates very severe injury (Bond, 1990).

Outcome scales have been developed to allow physicians to correlate “final” recovery levels to early treatment and prognostic indicators. The *Glasgow Outcome Scale* (GOS) is widely used. Its categories are death, vegetative state, severe disability (conscious but dependent), moderate disability (independent but disabled), and good recovery (able to participate in normal social life and return to work), with 90% accurate assessment of prognosis possible 6 months post injury (Jennett & Teasdale, 1981; Satz et al., 1998). The GOS does assess some aspects of mental and physical function in assigning outcome categories (Jennett et al., 1981). Some researchers consider that more detailed neuropsychological and/or social factors should be considered in determining outcome (Hall, Cope, & Rappaport, 1985). When these factors are added, more residual disability is identified than by the GOS, and improvements in levels of disability are identified more accurately (Hall, Cope, & Rappaport, 1985). Addition of these factors also allows assessment of continued subtle recovery to be made beyond 6 or 12 months post injury (Hall, Cope, & Rappaport, 1985; Najenson et al., 1974).

The therapist is not required to predict but should consider the predictive factors listed herein when deciding on treatment goals or length of rehabilitation efforts. Cognition, personality, and motivation, all of which may substantially affect quality of survival (Jennett et al., 1981), are also to be considered in determining treatment goals. Outcome predictions are based on groups of patients, not on individuals, who may have family and character strengths that allow them to recover more completely than anticipated.

Intervention for Patients with Severe Alterations in Consciousness

Rehabilitation for patients with severe alterations in consciousness aims to foster alertness and behavioral responsiveness (Giacino et al., 1997) and to prevent complications associated with prolonged immobilization (Mysiw, Fugate, & Clinchot, 1996). Early intervention is believed to result in shorter rehabilitation stays and higher Rancho levels at discharge (Lippert-Grüner, Wedekind, & Klug, 2003). With contradictory evidence regarding its effectiveness, however, sensory stimulation remains particularly controversial (Giacino et al., 1997). Giacino et al. (1997) recommended that, at a minimum, patients with alterations in consciousness receive intervention that includes range-of-motion exercise, positioning protocols, and tone alteration methods. They suggested that the additional provision of sensory stimulation trials be considered on a case-by-case basis, appreciating that it is often difficult to distinguish between brain recovery and an intervention effect (Davis & Gimenez, 2003). Finally, reducing possible agitation (Eames, Haffey, & Cope, 1990) and supporting and educating overwhelmed family members are critical aspects of rehabilitation at this phase (Phipps et al., 1997).

For patients with alterations in consciousness, members of the rehabilitation team often have similar roles and responsibilities. For example, both occupational and physical therapists often perform range-of-motion exercises and collaborate to optimize positioning. All team members, including family, follow a consistent sensory stimulation protocol to enhance the reliability and interpretability of observations. For patients at this phase of recovery, intervention typically addresses first-level and developed capacities to lay the foundation for later focus on activities, tasks, and roles (Procedures for Practice 39-1). Because of the medical acuity of many of these patients, occupational therapists attend to the safety precautions summarized in Safety Note 39-1.

POSITIONING

Occupational therapists collaborate with other members of the rehabilitation team to optimize positioning to normalize muscle tone and ultimately affect motor performance (Rinehart, 1990). Some typical abnormal positions seen in patients with severe traumatic brain injuries include abnormally forward head, protracted and forward-

PROCEDURES FOR PRACTICE 39-1

Goal Setting for and with Persons with TBI

Occupational therapy treatment goals address changing aspects of occupational functioning as patients with severe TBI progress through recovery and adaptation. Here are some examples based on Chestnut et al.'s (1999) phases of recovery and adaptation.

Medical Treatment Phase (treatment focuses on first-level and developed capacities)

- In 3 weeks, the patient will make localized responses in less than 15 seconds after the presentation of tactile, olfactory, auditory, or visual stimuli at least 75% of the time to lay the foundation for using a communication board.
- In 3 weeks, the patient will demonstrate improvement in upper extremity range of motion, gaining at least 10% in shoulders and elbows, to facilitate ease and thoroughness with caregiver-provided hygiene activities.

Rehabilitation Phase (treatment primarily focuses on abilities and skills, activities and habits, and task competency)

- In 2 weeks, the patient will be able to follow a checklist to carry out personal hygiene tasks with no more than occasional specific cues.
- In 2 weeks, the patient will independently locate and follow a daily schedule in his planner.
- In 2 weeks, the patient will independently follow written and pictorial instructions to carry out his upper extremity range of motion exercises.

Survivor Phase (treatment primarily focuses on habits, competency in tasks, and satisfaction with life roles)

- In 4 weeks, the client will use compensatory cognitive strategies to structure his children's afternoon activities.
- In 4 weeks, the client will use an alarm cueing device to improve his completion of time-specific tasks at work.

tipped scapulae with or without elevation, posterior pelvic tilt with unilateral retraction and/or elevation, severe trunk tightness with lack of trunk dissociation from neck and head, hip flexor and adductor tightness, and foot plantar flexion and inversion.

The patient's position must be reevaluated frequently. Assistive positioning supports are used intermittently and removed as the patient's neuromuscular status improves. The nursing staff and the patient's family must be made aware of the desired bed and wheelchair positioning and

SAFETY NOTE 39-1

Safety Precautions for Treating Patients in Altered States of Consciousness

The patient with a severe TBI may be referred for occupational therapy before he or she is completely medically stable. Precautions may be numerous because of systemic injuries, secondary effects of the brain injury itself, disturbance of basic body regulatory systems, and the life support equipment used to treat the patient; such precautions must be heeded by the therapist. Typical precautions are described here; other precautions may also be necessary and should be ascertained from the nurse, physician, or patient's chart before the evaluation begins.

- A major concern with acute brain trauma is control of intracranial pressure (ICP). Sustained increased ICP can be fatal (Jennett & Teasdale, 1981). The patient with an ICP monitor can be readily checked during treatment sessions. The therapist must closely observe patients not on a monitor for pupil changes; decreased neurological responses; abnormal brainstem reflexes; flaccidity; behavioral changes; vomiting; and changes in pulse rate, blood pressure, and respiration rate. Fluids may be restricted, or the patient's head may be positioned in neutral at 30° of elevation in an attempt to regulate ICP (Turner, 1985). Turning the patient's head to one side may obstruct the internal jugular vein and result in a sudden increase of ICP (Boortz-Marx, 1985). The neck should be neither flexed nor extended but kept in neutral for maximum venous drainage and decreased ICP. The presence of a family member, gentle touching, quiet talking, and stroking the face have been found to decrease ICP in adults (Mitchell, 1986). Side-lying with the head of the bed elevated is the most desirable position. Side-lying avoids the increased extensor tone promoted in supine. Prone lying is contraindicated with increased ICP, and supported sitting at 90° is used as soon as tolerated to help breathing, to provide symmetrical body alignment, and to increase awareness of surroundings (Palmer & Wyness, 1988).
- Early post-traumatic epilepsy occurs in 5% of patients with brain injuries, and late-onset epilepsy affects 20% of those with prolonged unconsciousness, depressed skull fracture, or intracranial hematoma (Jennett & Teasdale, 1981; Schaffer, Kranzler, & Siqueira, 1985). To reduce the chance of a seizure during treatment, begin tactile stimulation and range of motion slowly to assess the patient's physiological response. Monitor the heart rate, blood pressure, and facial color and any autonomic changes, such as sudden perspiration or increased restlessness. As the therapist becomes more familiar with the patient's responses, he or she gradually increases intensity of stimulation. Use seizure precautions: avoid rapid, repetitive stimuli, such as vibration, flickering lights, and an oscillating fan. If a seizure does occur, ensure that the airway is open, position the patient on his or her side to prevent aspiration of stomach contents, and summon medical assistance (Greenberg, Aminoff, & Simon, 1993). The patient's limbs should not be restrained during a seizure.
- If the patient has had a craniotomy for evacuation of a hematoma, the bone flap may be left off, and the brain may be covered only by scalp to allow the brain to expand. Direct pressure to this site must be avoided.
- The patient may have a tear in the dura and cerebrospinal fluid leak. In this case, the patient initially is treated with head elevation, antibiotics, and precautions against nose blowing (Jennett & Teasdale, 1981; Schaffer, Kranzler, & Siqueira, 1985).
- If the patient has other systemic trauma, such as fractures or chest cavity trauma, appropriate precautions must be taken when he or she is stimulated or moved. Care must also be taken to avoid disturbing intravenous lines, tracheostomy, nasogastric tube, endotracheal or respirator tubes, and traction for extremity fractures. If the patient has a nasogastric tube, caution must be taken that the patient's head remains above the level of his or her stomach to avoid regurgitation and aspiration (Miller, Pentland, & Berrol, 1990).

of the wearing schedule for any splints. To reduce abnormal tone and to reduce or prevent contractures, the positioning must continue throughout the day and night.

Bed

Side-lying or semiprone, if permitted, with good body alignment is preferable to supine if the patient has abnormal posture (Carr & Shepherd, 1980; Farber, 1982). Lying supine triggers an extensor response. In side-lying, the head, resting on a small pillow, should be in neutral alignment with the trunk; the bottom upper extremity should be in scapular protraction and humeral external rotation; the top upper extremity should be in scapular protraction,

slight shoulder flexion, and resting on a pillow to avoid horizontal adduction; the bottom elbow should be flexed; the top elbow should be extended; wrists should be in extension; and cones should be placed in the hands to decrease spasticity and maintain thumb web spaces. A pillow between the knees decreases hip internal rotation and adduction. The lower leg also may need pillow support to align it with the thigh. The hip and knee are flexed only slightly. Elongation of the lower side of the trunk between the shoulder and pelvis is desirable. A side-lying trunk position may have to be maintained by a pillow or sandbag behind the back and shoulder. Footboards should be avoided because they elicit extensor thrust. Splints or special shoes (Farber, 1982) that are cut to avoid pressure to

the ball of the foot but still maintain ankle flexion to 90° and reduce foot drop are used to avoid stimulating an extensor thrust.

If the patient must be supine, a small pillow under the head is used, with small rolled pillows under that pillow to keep the head in midline if the patient cannot do so. Furthermore, small pillows are placed under the scapulae to protract them, shoulders are positioned in slight abduction and external rotation, elbows are extended, and cones or finger spreaders position the fingers (Charness, 1986). If the pelvis is retracted on one side, a small folded towel is placed behind it, and that leg is positioned in neutral rotation. Some knee flexion should be encouraged by a small towel roll placed under the distal thigh just above the knee. Keep in mind that experts recommend a semirecumbent bed positioning (with head-of-bed angle maintained at 45°) to minimize risk of aspiration and pneumonia for patients on mechanical ventilators (Helman et al., 2003).

Wheelchair

Early and correct upright positioning in a wheelchair helps to facilitate arousal by stimulating the visual and vestibular systems, inhibiting abnormal tone, providing normal proprioceptive input, and reducing the likelihood and/or extent of contractures and complications from prolonged bed rest. The pelvis must be positioned correctly before other areas can be addressed. The pelvis should be in a neutral position or have a slight anterior tilt and should be symmetrical, without one side retracted or elevated. Weight bearing equally through both buttocks is essential to improvement of tone. Solid seat and back inserts are necessary, as the typical wheelchair seat and back sag and facilitate posterior pelvic tilt, unequal weight bearing through the hips, and hip internal rotation and adduction. If necessary, a small, flat lumbar roll is placed above the pelvis and below the scapula to facilitate anterior pelvic tilt. If the pelvis is retracted on one side, wedged back pieces may be helpful for positioning. If unequal weight bearing with habitual elongation of one side of the trunk is occurring, an insert under the habitual weight-bearing buttock may be helpful. The back of the chair may be reclined 10–15° to position the trunk and head more appropriately. Hip flexion of 90° can be achieved by a wedge cushion with the high end at the distal thigh. The seat belt should come from the corners of the seat at a 45° angle and fasten over the lower pelvis and hip area to help maintain the anterior pelvic tilt and equal weight bearing through the buttocks. The patient may need firm pads on the outer aspect of the thighs to reduce excessive abduction or a knee abductor to decrease excessive adduction. If the seat belt cannot keep the patient from scooting forward in the chair, a removable padded bar may have to be placed close to the pelvis and femurs.

The trunk, positioned next, should be symmetrical and in midline, with shoulders over pelvis in sagittal, frontal,

and horizontal planes. Lateral trunk supports can be used to decrease lateral trunk flexion. Experimentation with the positioning is essential because trunk control varies among patients. The therapist must not provide too much trunk support, only enough to facilitate the patient's normal movement and control. With a solid seat and back, the patient may not require additional trunk support.

A harness, shoulder straps, or a chest strap may be necessary to prevent forward trunk flexion. These should not fasten directly on top of the shoulders but should extend a little higher before going through the seat back to fasten. An additional seat belt can also be placed horizontally across the anterior superior iliac crests to provide backward pressure (Charness, 1986).

Knees and ankles are flexed to 90°, heels are slightly behind the knees in sitting, feet are in neutral pronation-supination and inversion-eversion. The footplate should be large enough to support the whole foot. Ankle straps are avoided because they encourage plantar flexion in some patients; a foot wedge, heel loops, an insert behind the foot, special shoes, toe guards, or a combination of these may be helpful in decreasing abnormal tone and in achieving weight bearing on the heel.

The ideal upper extremity position is neutral scapular elevation or depression with the scapulae in slight protraction, slight shoulder external rotation, and slight flexion and abduction. Elbows are in comfortable flexion, and the forearm is in pronation. The wrists are in neutral flexion-extension and neutral ulnar-radial deviation; the fingers are relaxed; and the thumb is radially abducted. Excessive scapular retraction may require contouring of the seat back or reclining the seat unit by about 10°. Positioning of shoulder straps, chest straps, and/or lateral trunk supports may help to obtain adequate shoulder position.

A lapboard positioned at the proper height to allow good upper extremity weight bearing is helpful. The lapboard should not be pushed against the patient's abdomen but placed far enough away so the patient can flex forward slightly at the hips. There should be a cutout so that the lapboard fits around the patient, and the lapboard should be large enough to accommodate the whole arm. A V-shaped piece of dense foam can be positioned behind the patient's elbow to decrease elbow flexion and retraction of the arm off the back of the lapboard. The lapboard may also have a contoured surface for the hands. Hand fixation is avoided because it usually causes the patient to pull back against the fixation.

Ideally the head should be in midline, with cervical elongation and the chin tucked in slightly. It is important that positioning eliminate chin jutting and neck hyperextension. The position of the patient's shoulders and upper trunk influences head position. A customized head support may be required (Farber, 1982). Pressure directly to the occipital area elicits increased extensor tone of the head and trunk. Therefore, the pressure to right the head is applied up from the occipital process to each side of midline

and around the forehead with a backward and downward pressure. Such a head support has to be fastened to a headrest, which is recessed so that the patient's head cannot push or rest against it. Lateral head supports may be necessary to position the patient's head adequately. See Chapter 18 for further discussion of wheelchair selection and positioning.

PASSIVE RANGE OF MOTION

Passive range of motion (PROM) can be difficult when muscle tone is increased. Inhibitory movements opposite the abnormal tone are performed slowly, holding the stretch until muscles relax. Sudden stretch and inappropriate stimulation and handling should be avoided. Scapular mobility should be addressed before upper extremity PROM to free the scapula and facilitate normal scapular and humeral movement during the rest of PROM (Palmer & Wyness, 1988). PROM within the limits of pain and positioning helps to minimize contractures from heterotopic ossification (Citta-Pietrolungo, Alexander, & Steg, 1992). See Chapter 21 for a complete discussion of exercise to improve range of motion.

SPLINTING AND CASTING

The goals of splinting and casting are to decrease abnormal tone and increase the patient's functional movement. The patient's quality of movement is constantly reassessed to determine continued necessity of the splints or the need for modifications. Splints should be very carefully monitored when used with severely spastic or posturing patients, as they can aggravate abnormal tone and rapidly create pressure areas.

With severe spasticity in elbow, wrist, knee, ankle, or foot, plaster or fiberglass serial casting may be indicated (Mortenson & Eng, 2003; Pohl et al., 2002). Serial cylinder casting provides neutral warmth and more even skin pressure and allows for less movement than splints (Fig. 39-2). Casts are usually left on for 1–7 days before being replaced by a new one. Pohl et al. (2002) found that shorter cast-change intervals (1–4 days) provided improvements in range of motion that were comparable to longer intervals (5–7 days) but with fewer complications. Dropout casts, which leave a portion of the limb free to relax out of a tightly contracted position; bivalve casts, which are split in two, with moleskin protecting the edges so they can be removed during therapy and nursing procedures; and weight-bearing inhibitory casts, which are fabricated to approximate the ideal weight-bearing posture of the foot or hand, can also be used (Carr & Shepherd, 1980). Hill (1994) found casting more effective than traditional treatment of PROM, stretching, and splinting in reducing contractures in a group of 15 head-injured patients. The effect of casting on spasticity was variable, and Hill recommended further study. Decisions to use serial casting are informed by the patient's cognitive level. If the patient has

Figure 39-2 Occupational therapists fabricate a series of casts to help patients with brain injury improve range of motion and decrease spasticity. Casts are relatively inexpensive (as compared to splints), and can be replaced with new ones as the patient gains range of motion.

severe agitation, casts may pose safety problems (O'Dell, Bell, & Sandel, 1998). Casting is contraindicated with uncontrolled hypertension, major open wounds, unhealed fracture, impaired circulation, acute inflammation, and recent episode of autonomic dysreflexia, or if professionals need access to the extremity for lines or vitals (Stoeckmann, 2001). Rinehart (1990) recommended against casting more than one joint if the patient is confused or easily agitated or has short-term memory problems.

SENSORY STIMULATION

The goals of a sensory stimulation program are to promote arousal, appropriate patterns of movement, and interaction with the environment (Rinehart, 1990) by enhancing recovery processes such as neuroplasticity (Davis & Gimenez, 2003). Sensory stimulation programs are individualized to the patient's physical and cognitive functioning, but they always include multiple periods of observation and careful data collection (Mysiw, Fugate, & Clinchot, 1996). Clinicians use consistent protocols to standardize the administration of stimuli and data sheets to record observations regarding rate of response and changes in respiration, pulse, blood pressure, head movements, eye opening, eye movements, eye fixations, mimic responses, aimed and non-aimed motor reactions, and articulations (Lippert-Grüner & Terhaag, 2000). Responses are measured at the beginning and end of every session and as each sense is stimulated. Clinicians monitor observation records in the hopes of seeing patterns of increasingly specific responses to stimuli, signifying improved responsiveness.

Each stimulus is provided with a desired motor response in mind. The response is verbally requested and/or

implied through the therapist's handling. Patients at Rancho level II often demonstrate non-specific responses, such as motor restlessness in response to auditory stimuli. As the patient moves to level III, the responses become more stimulus specific. For example, with oral motor stimulation, one expects a motor response such as lip closure.

Tactile, vestibular, olfactory, kinesthetic, proprioceptive, auditory, and visual stimuli are used. Gustatory stimulation may be used if the patient's oral motor status permits. Pleasant and unpleasant and familiar and unfamiliar stimuli are used; stimuli with emotional significance to the patient may be most likely to elicit a response. Trials of organized stimulation periods of 15–30 minutes each are scheduled throughout the day (for up to 90

minutes total). These sessions must be spaced to allow for rest and nursing care. The patient's response to stimulation may be quite slow because central nervous system processing is slowed or prevented by the damage. The therapist should wait for a response to the stimulation and, if necessary, repeat the stimulus. Procedures for Practice 39-2 describes how to administer various types of stimuli.

MANAGEMENT OF AGITATION

Once patients begin localizing stimuli, they may become quite agitated and restless (Scott & Dow, 1995). Post-traumatic agitation is reported to occur in the acute setting in 33–50% of patients with TBI (Sandel, Bell, & Michaud, 1998) and may last for days or weeks (Malkmus,

PROCEDURES FOR PRACTICE 39-2

Multisensory Stimulation

Stimuli are presented in a consistent and meaningful manner, typically one sensory modality at a time. The patient is told what the therapist is doing and often given an instruction specific to a desired response. Minimize competing visual and auditory stimuli by turning off the television, closing the door, or pulling the drape. Give simple, clear verbal feedback on every response elicited such as, "Good. You are turning your head toward my voice." Here are examples of how various types of stimuli are presented.

- Tactile stimulation focuses on the qualities of touch, pressure, and temperature (Lippert-Grüner & Terhaag, 2000). For example, rub patient's skin with items of various texture or temperature and use a firm or moving touch on the patient's limbs with verbal cues to orient the patient to his or her body. Performing passive range of motion provides both tactile and kinesthetic stimulation. Bathing and dressing are excellent sources of varied input, especially if verbal orientation to body parts being washed or moved is included.
- Provide gentle kinesthetic, proprioceptive, vestibular stimuli by changing body position (from supine to sitting, sitting to side-lying), by head and neck movements, rolling, tilting the bed to sitting, side-to-side or antero-posterior movement of the patient in bed or on a mat, or rocking. Gelling et al. (2003) recommend standing coma and minimally conscious patients (using electric standing frames or tilt tables) as the optimal means of enhancing arousal and awareness of the environment.

Kinesthetic, proprioceptive, vestibular stimulation may be contraindicated, however, in patients with a tracheostomy, elevated ICP, or seizures and therapists must seek physician approval and orders before providing intervention of this nature. The patient's reaction must be closely monitored during and after all stimulation, with careful attention to desired ranges of heart rate, ICP, and blood pressure.

- Stimulate the olfactory sense with noxious or pleasant odors, such as spices, almond, vanilla, banana, lemon, perfume, coffee, or other smells familiar to the patient. This stimulation may be most effective when it is done before the patient is fed. The therapist must offer an effective concentration of the odor. Saturated cotton balls or a sniff bottle are held close to but not touching the patient's nose for 2–5 seconds (Farber, 1982). This cranial nerve is sometimes injured in TBI, so olfactory stimulation may not elicit a response (Jennett & Teasdale, 1981). **Avoid odors with fumes, such as ammonia and artificial vanilla, because they irritate cranial nerve V.** A tracheostomy or nasogastric tube eliminates or reduces the air passing through the nostrils and hence reduces the effectiveness of olfactory stimuli.
- Auditory stimulation consists of tapes of favorite music or familiar voices, bells, loud alerting noises such as clapping hands, direct conversation to the patient, verbal commands, explanations, and feedback. The therapist uses clear, firm speech, often presenting information to the patient regarding his or her circumstances and whereabouts. During therapy sessions, radios, televisions, and other noises should be eliminated as much as possible so that voice commands for motor responses or the selected auditory stimuli are the most prevalent auditory input.
- Provide visual stimulation to elicit attention, focus, and visual tracking with brightly colored objects, a mobile over the bed, mirrors, colored lights, a flashlight in a darkened room, or pictures of family and friends of the patient. Move brightly colored objects in front of the eyes, if they are open. Have the family label the pictures to assist in orienting the patient to them. Environmental changes from the bed to the therapy room or from indoors to outdoors are important sources of visual stimulation.

Booth, & Kodimer, 1980). Agitation is a subtype of delirium in the coma-emerging patient that is associated with frontotemporal injury, disorientation, comorbid medical complications, and/or use of anticonvulsant medication (Kim, 2002). Agitation causes excesses of behavior that include some combination of aggression, akathisia (motor restlessness or a sense of inner restlessness [Ivanhoe & Bontke, 1996]), disinhibition, and emotional lability (Center for Outcome Measurement in Brain Injury, 2006; Sandel, Bell, & Michaud, 1998).

Behavioral disorders associated with TBI have distinct causes and characteristics at various points of recovery (Eames, Haffey, & Cope, 1990). Eames, Haffey, and Cope suggested that efforts to manage behavior be preceded by a contextual assessment in which clinicians attempt to determine what factors are contributing to the problem. Clinicians examine the following variables:

- Personal context—extent and location of brain damage, state of bodily dysfunction, including pain, and pre-morbid factors such as intellect, personality traits, and coping style
- Social context—persons present during maladaptive behavior; reinforcers
- Physical context—properties of the environment in which problematic behavior occurs

During the period of medical instability, patients may exhibit agitation that stems from post-traumatic confusion and inability to process information (Eames, Haffey, & Cope, 1990). Patients may demonstrate apparently non-goal-directed body movements, such as thrashing; goal-directed behaviors, such as trying to remove life-sustaining tubes or get out of bed; screaming, moaning, or bizarre verbalizations; and disinhibited behavior, such as uncontrolled laughter or inappropriate sexual behavior (Eames, Haffey, & Cope, 1990). The primary aim of behavior management at this phase is to ensure the continuation of medically necessary treatment and to do as little as possible to impede the natural course of recovery (Eames, Haffey, & Cope, 1990). Procedures for Practice 39-3 has specific suggestions regarding management of agitation during occupational therapy sessions.

PROCEDURES FOR PRACTICE 39-3

Managing Agitation: Rancho Level IV

During this stage of recovery, occupational therapists primarily seek to decrease the patient's agitation by attempting to normalize the environment and employing appropriate physical management methods that allow the patient to move and release energy without jeopardizing safety (Eames, Haffey, & Cope, 1990; Kim, 2002). Remember that the patient is not accountable for the agitation, hostility, or aggressiveness. He or she is responding to internal confusion, not specifically to you as a person or professional. At the same time, you must structure your interactions to protect the patient and yourself.

Strategies to Normalize the Environment

- Minimize the influence of confusion by asking family members to bring in familiar objects (photographs or belongings) and position them so they are visible to the patient (Eames, Haffey, & Cope, 1990).
- Work in a quiet environment with minimal distracters that may further alarm or confuse the patient.
- Attempt to provide orientation information and maintain a predictable daily structure and routine to reduce confusion.
- Normalize interactions by introducing yourself at each session, telling the patient where he or she is and what you are going to do (Eames, Haffey, & Cope, 1990). Extend the same courtesies, even to comatose patients,

that you would to patients without cognitive impairments (Eames, Haffey, & Cope, 1990).

Strategies for Physical Management

- Use equipment and devices that maximize freedom of movement along with safety. Mittens without separations for the thumb may keep patients from resisting care or from pulling out tubes. A floor bed (a mattress on the floor that is surrounded by portable walls lined with therapy mats) allows the patient to move freely in bed without risk of falling. Extensions to the wheelchair so that it can neither tip over backward nor fit through doorways also allow for safe mobility (Eames, Haffey, & Cope, 1990).
- Engage the patient in gross motor activities such as face washing, catching a ball, hitting a balloon, and putting on simple clothing, if he or she is able. Physical activity, walking, or even being wheeled in the wheelchair may help decrease agitation (Baggerly, 1986).
- Be prepared to change activity at the first sign that the patient is becoming restless or agitated. Consider moving to another environment or offering a drink or snack if the patient has normal oral motor activity. Avoid responding to obscenities or bizarre verbalizations; simply view them as cues to distract the patient with another activity.
- Exude calm, confidence, and acceptance; the patient needs you to provide consistency and predictability that counters his or her confusion.

FAMILY SUPPORT AND EDUCATION

TBI has almost as many implications for family members as it does for the patient. After a loved one undergoes a severe TBI, family members are typically relieved that the patient has survived but have little experience to help them understand the situation or what lies ahead (Phipps et al., 1997). Television portrayals of people who abruptly “wake” from coma with no apparent deficits may lead families to expect full recovery, and they may have difficulty processing information that is inconsistent with that hope (Phipps et al., 1997).

To truly collaborate with family members and provide right-timed education, clinicians try to learn about patient and family background. Clinicians are advised to employ interpersonal communication skills such as the use of reframing statements or clarifying questions to inquire about such matters as family structure, family routines and activities, and experiences with service providers (Sohlberg et al., 2001).

Many families relish the opportunity to contribute to their loved one’s recovery. They support the therapist’s efforts to position the patient and learn to perform PROM exercises. Family members also make important contributions to the sensory stimulation program by providing information about the patient’s preferences, typical manner of responding, and background. They may also receive instruction so they can perform the sensory stimulation protocol and collect data on responses. Families often see a level of responsiveness that is not verifiable by staff, and early in recovery, they tend to interpret unresponsiveness in

ways other than as a reflection of cognitive status, such as deafness, lack of interest, or laziness (Phipps et al., 1997). Since the patient’s level of responsiveness often drives decisions about what services are appropriate, how long they will be provided, and whether the patient is making progress, tension between the overwhelmed family and rehabilitation team is fairly common (Phipps et al., 1997). By providing the family with clear and concise information that matches their most immediate concerns, therapists can help families begin to understand what has happened in ways that neither inflame expectations nor squelch hope.

Holland and Shigaki (1998) proposed a three-phase model for educating families and caretakers of persons with TBI. They suggested that families benefit from information that is relevant to the patient’s stage of recovery and their own stage of adjustment. They recommended that, during the first phase (ICU through acute hospitalization), family education should focus on providing basic orientation to help the family decipher what is unfolding and to clarify terms and procedures associated with trauma care and TBI. Family members also need help to understand the disordered and occasionally bizarre behavior associated with agitation and to appreciate it as a natural part of recovery (Eames, Haffey, & Cope, 1990). Finally, conversations and instructions have to be repeated frequently, as the family is under considerable stress and flux (Livingston, 1990). (See Holland and Shigaki’s excellent bibliography of phase-specific materials available for families, some of which are in Spanish, as well as Resources 39-1 for materials that could be used in family education.)

Rehabilitation

“My occupational therapist (OT) has promised to take me to the hospital chapel to play the organ. My mom brought my organ books to the hospital. . . . Now I can show the therapists that I don’t need their exercises . . . [and] don’t belong here in the hospital.” (Rain, 2000, p. 6)

Rehabilitation occurs in inpatient, outpatient, and residential settings for weeks, months, or years, although not continuously, until goals are achieved and/or the patient no longer appears to benefit from intervention. In general, the primary goals of inpatient rehabilitation are medical stability, reduction of physical impairments, and acquisition of basic self-care skills. Post-acute rehabilitation emphasizes reducing the obstacles of community integration posed by cognitive and behavioral impairments (Malec et al., 2000). Decreases in lengths of stay, however, often due to expiration of funding, results in many patients being discharged from inpatient rehabilitation settings without realizing their potential to recover capacities and basic skills (Yody & Strauss, 1999). Therefore, post-acute rehabilitation increasingly addresses medical needs, fundamental capacities, and basic skill acquisition before or instead of community reentry (Yody & Strauss, 1999).

Inpatient Rehabilitation

Patients can fully participate in intensive inpatient rehabilitation when they demonstrate stimulus-specific responses and when post-traumatic confusion and agitation either resolve or do not present a barrier to participation in intensive therapies, such as Rancho levels V and VI. At level V, patients are still disoriented and confused but increasingly goal directed (Heinemann et al., 1990) and capable of teaching-learning interactions (Abreu & Toglia, 1987). They cannot process information at a normal rate or produce an appropriate response to all environmental situations. A patient at this level may require maximum assistance for independent living skills, exhibit significant neuromuscular impairments, need maximum cueing for orientation, display severe memory impairment, possibly show confused verbal and mental processes, and have little carryover of new learning. As patients progress to Rancho level VI, they remain inconsistently oriented but begin to be aware of appropriate responses to staff and family and demonstrate carryover for relearned, familiar tasks (Hagen, 1998).

The value and effectiveness of inpatient rehabilitation are generally recognized by providers, consumers, and payers. Najenson et al. (1974) studied the outcome of 169 patients with severe brain injury who underwent a program using postural reflexes, self-care tasks, locomotor tasks, and communication training. The statistics showed that 84% of the patients were independent in daily living skills

at discharge. The authors found recovery continuing up to 3 years after injury and stressed the need for continued follow-up of these patients after discharge from a rehabilitation hospital. Gerstenbrand (1972) described a rehabilitation program beginning in the acute stage after trauma that included use of reflexes to influence muscle tone and more active mobilization and socialization techniques later. He briefly stated the results for 170 patients in terms of being back at work and concluded that rehabilitation at full intensity was essential. Cope and Hall (1982) studied two groups of patients with severe brain injuries and compared the time required for rehabilitation and the outcome. The first group was admitted for rehabilitation less than 35 days post injury, and the second group was admitted more than 35 days post injury. The researchers concluded that those admitted later required twice as much rehabilitation as those admitted early, despite similar severity of initial injury. Outcome 2 years post injury, however, was not significantly different between groups. Finally, Heinemann et al. (1990) demonstrated that persons with moderate to severe TBI who received inpatient rehabilitation improved in self-care and mobility skills and maintained those gains at follow-up.

Assessment: Inpatient Rehabilitation

Patients with TBI who are in rehabilitation can participate in formal assessment. Occupational therapists often begin by screening vision, visual perception, and cognition. Chapters 8 and 9 detail numerous assessment tools and methods appropriate for persons at this phase of recovery from TBI, such as the *Galveston Orientation and Amnesia Test* (Levin, O’Donnell, & Grossman, 1979), *Loewenstein Occupational Therapy Cognitive Assessment* (Katz et al., 1989), and the *Patient Competency Rating Scale* (Prigatano et al., 1986). Clinicians must determine the extent to which patients can scan, attend, follow, and retain instructions to interpret performance on other traditional assessments, including upper extremity strength and function and activities of daily living. A number of tools developed specifically to assess patients with TBI are used in a variety of rehabilitation disciplines, including occupational therapy (Table 39-4). Others are detailed at www.tbims.org/combi.

Treatment: Inpatient Rehabilitation

Occupational therapy during inpatient rehabilitation is aimed at optimizing motor, visual-perceptual, and cognitive capacities and abilities; restoring competence in fundamental self-maintenance tasks; contributing to the patient’s continuing behavioral and emotional adaptation; and supporting the patient’s family as they prepare for discharge.

OPTIMIZING MOTOR CAPACITIES AND ABILITIES

Therapists initially help patients optimize their motor capacities and abilities by engaging them in gross motor

Table 39-4. Assessment and Outcomes Tools for TBI Patients in Rehabilitation

Instrument	Brief Description
<i>Supervision Rating Scale (SRS)</i> ^a (Boake, 1996)	Measures level of supervision patient receives from caregivers. Based on interviews with patient and caregiver (such as nurse or family member), clinician rates on 13-point ordinal scale reflecting intensity and duration of supervision needed for safety. Ratings automatically sort patient into one of five levels of supervision: independent, overnight supervision, part-time supervision, full-time indirect supervision, or full-time direct supervision.
<i>Functional Assessment Measure</i> ^a (Hall, 1997)	12-item addition to <i>FIM</i> ; relates to community functioning (i.e., car transfers, employability, adjustment to limitations, swallowing). Makes <i>FIM</i> more sensitive to the problems of persons with TBI.
<i>Neurobehavioral Rating Scale</i> (Levin et al., 1987)	27-item clinical rating scale measures common cognitive, behavioral, and emotional disturbances associated with TBI; used to track neurobehavioral recovery, measure behavioral change in response to intervention.
<i>Mayo-Portland Adaptability Inventory</i> ^a (Malec & Thompson, 1994)	Designed for interdisciplinary post-acute rehabilitation; covers broad range of observable attributes, such as physical function (including pain and mobility), cognitive capacity, emotional status, social behavior, self-care, work, and driving status. Based on team consensus, patient's status on 30 items is rated on a 4-category scale: no impairment; impairment on clinical examination but does not interfere with everyday function; impairment does interfere with everyday function; or complete or nearly complete loss of function.
<i>Community Integration Questionnaire</i> ^a (Willer, Ottenbacher, & Coud, 1994)	15-item instrument to assess home integration, social integration, productivity (employment, volunteer work, school); can be completed by self-report with assistance from family member.

^a Available online at <http://www.tbims.org/combi>. *FIM*, *Functional Independence Measure*.

activities that they can perform almost automatically, such as playing catch or hitting a punching bag (Fig. 39-3). Such activities minimize the demands on weakened cognitive capacities, such as attention, concentration, and memory for instructions. Intervention increasingly focuses on refining motor capacities and abilities as the patient's motor and cognitive recovery progress. Patients perform traditional exercise regimens as well as exercise and activity delivered by virtual reality to improve strength and balance (Holden, 2005; Thorton et al., 2005) (Fig. 39-4). Occupational therapists use approaches that best match therapy goals and the patient's abilities, many of which are detailed in Chapters 21 to 27.

OPTIMIZING VISUAL-PERCEPTUAL CAPACITIES AND ABILITIES
TBI frequently results in visual-perceptual disturbances that impair occupational function (Bouska & Gallaway, 1991). With TBI, the visual field loss is often in the superior fields; loss of acuity relates to loss of contrast sensitivity; and the oculomotor system is frequently impaired, with poor fixation, deviation of the eyes resulting in diplopia, and difficulty in visual scanning (Scott & Dow, 1995). Limitations in complex visual processing become evident during perceptual evaluation (Warren, 1993). Chapter 8 details specific assessments applicable to patients with TBI. As Quintana recommends in Chapter 28, intervention for primary visual deficits emphasizes environmental adaptation, compensatory techniques, assistive devices, and pa-

tient and family education. It is important to identify possible visual impairments as early as possible so that appropriate patients are referred for ophthalmology assessments and therapists can make an effort to circumvent the influence of visual impairments on performance. The efficacy of perceptual remediation is controversial. Based on her review of research on remedial perceptual retraining, Neistadt (1994a) was pessimistic about its appropriateness for TBI patients: "Far and very far transfer from remedial to functional tasks will not occur for clients with diffuse brain injuries and severe cognitive deficits, in either early or late stages of recovery, even with a variety of training tasks and up to 6 weeks of training" (p. 232).

OPTIMIZING COGNITIVE CAPACITIES AND ABILITIES
Chapter 29 presents four general strategies for optimizing cognitive capacities and abilities: remediating the deficit, changing the physical or social context, acquiring behavioral routines, and learning compensatory cognitive strategies; all are appropriate for persons with TBI. Inpatients with TBI are typically in a period of relatively rapid improvement, so therapists provide cognitive remediation activities and exercises to challenge and stimulate primary cognitive domains (orientation, attention, memory) in the hope that natural recovery will be enhanced and accelerated. Card or board games, puzzles, and paper and pencil tasks, such as word recognition or letter or number cancellation drills, may be used. Computer programs can

Figure 39-3 Early efforts to optimize motor function focus on eliciting automatic movement. Occupational and physical therapy co-treatment sessions are common.

help retrain the patient's ability to focus attention, increase visual scanning, improve reaction time, improve visual-motor coordination, improve simple problem-solving skills, and increase frustration tolerance. Patients may participate in group treatment, such as an orientation

Figure 39-4 Virtual reality allows patients with brain injury to practice skills while participating in interesting and motivating activities that might otherwise be unsafe or unavailable to them.

group in which they rehearse and reinforce awareness of date, place, and circumstances.

The effectiveness of cognitive remediation has been questioned (Carney et al., 1999; Salazar et al., 2000), and other methods of optimizing cognitive capacities and abilities should also be employed. For example, Cicerone et al. (2000, 2005) suggest that evidence supports strategy training for attention deficits but not sole reliance on repeated exposure to and practice of computer-based tasks devoid of clinician involvement. Occupational therapists often use a dynamic investigative approach (Toglia, 1989) in which cognitive retraining activities become opportunities for assessing performance under a variety of circumstances. Careful activity analysis and logging of observations and environmental variables informs discharge recommendations to families regarding the circumstances in which their loved one is best able to function. Such information is invaluable to families as they assume day-to-day responsibility for structuring the patient's time and activities.

Occupational therapists also use the physical context to optimize patients' cognitive capacities and abilities during this phase of recovery. Specialized brain injury units typically incorporate signage and physical landmarks that enhance orientation and technology, such as monitoring systems, that allow the patient to move even though he or she may be confused and disoriented. Occupational therapists also strategically place familiar pictures and objects, calendars, and clocks in the patient's room to optimize orientation.

Patients in this phase of recovery rarely appreciate the significance and implications of cognitive impairments and therefore are usually not ready to learn to use compensatory cognitive strategies that require initiation and insight. Occupational therapists, however, often assemble a simple memory log and help patients use it to follow a schedule, reconstruct previous activities and instructions, and remember names of staff.

RESTORING COMPETENCE IN BASIC SELF-MAINTENANCE TASKS

As previously mentioned, inpatient rehabilitation usually focuses on helping patients reacquire basic self-care skills, such as bathing, dressing, hygiene, and eating. In general, a given self-care task is simplified until the patient is consistently successful in performing it, and then the complexity is gradually increased while the externally provided structure is gradually decreased. Environmental distractions are kept to a minimum. The therapist structures the task, gathers the items to be used, and sequences the task by providing the patient with the appropriate item and instructions, one step at a time. For example, in dressing, the therapist first hands the patient his undershorts and then gives simple verbal instructions and physical assistance as necessary to have the patient put the shorts over his legs and pull them up. The therapist does not present the patient's tee shirt until the shorts are on. Initially, the therapist selects solid colors with

minimal fastenings to decrease perceptual confusion. The therapist may also choose to limit the task by having the patient do only one or two steps of the entire task (e.g., put on tee shirt only) if the patient has very low endurance, low frustration tolerance, or limited motor skills. Selection of the position of the patient (i.e., dressing in bed, sitting in the wheelchair, or sitting on the edge of the bed) and the method of dressing is based on the patient's neuromuscular function. Gradually, as the patient becomes more successful in dressing, the therapist decreases verbal and physical cueing, using checklists and/or graded cues (see Chapter 29). Bathing, hygiene training, feeding, and wheelchair transfer training are structured in the same fashion. Occupational therapists can help set the stage for establishing consistent and automatic self-care routines at home by outlining the sequence of steps in which the patient is most successful.

During inpatient rehabilitation, occupational therapists assess the patient's ability to handle other self-maintenance tasks, such as preparing a sandwich, counting and handling money, and using the telephone (Fig. 39-5). Again, a dynamic investigative approach is employed to determine under what circumstances the patient can safely and competently carry out these activities.

CONTRIBUTING TO BEHAVIORAL AND EMOTIONAL ADAPTATION

Behavioral sequelae may intermittently influence the patient's ability to participate in therapy at this stage. Brain damage itself may cause psychosocial changes, such as irritability, aggressiveness, or apathy (Prigatano, 1992). As the patient becomes more alert, his or her awareness of the situation may increase irritability, uncooperativeness, or mood fluctuations. Patients who lack awareness of deficits may also become frustrated with staff and family who limit their activities. Furthermore, patients who repeatedly fail on a variety of tasks may become depressed or anxious (Prigatano, 1992). It is important for occupational therapists

Figure 39-5 Occupational therapists often simulate real-life activities, such as using the telephone book and gathering information over the telephone.

to appreciate the state of internal chaos and vulnerability of many patients with TBI at this phase of recovery (Groswasser & Stern, 1998). Without the anchor of intact memory to make connections between experiences, “life is downgraded to a collection of unrelated, disjointed, and sporadic episodes” (Groswasser & Stern, 1998, p. 73). Rather than force confrontation of deficits, therapists avoid placing patients in situations that are fraught with frustration and failure and instead structure experiences that reinforce patients' confidence that they still have the potential to accomplish things (Groswasser & Stern, 1998). Doing so establishes therapeutic trust, the foundation for later phases of recovery, when patients are better able to compare pre-morbid and current capabilities. See Chapter 15 for guidelines to establish a therapeutic relationship.

When behavioral sequelae associated with brain injury interfere with progress and the potential for community reintegration, the rehabilitation team establishes an interdisciplinary plan to minimize or eliminate socially unacceptable behavior and promote prosocial, adaptive behavior. Eames, Haffey, and Cope (1990) pointed out, “Since the primary aim of rehabilitation is a return to the community, simple containment or toleration of disordered behavior within the rehabilitation setting is inadequate because the community at large will not adopt a lenient attitude toward such behavior” (p. 420). Ylvisaker, Jacobs, and Feeney (2003) recommend focusing on antecedents associated with positive behavior and less on consequences related to problems. The following are examples of strategies that contribute to patients' ability to learn effective behaviors during inpatient rehabilitation and beyond:

- Redesign or normalize the environment (Ylvisaker, Jacobs, & Feeney, 2003). For example, if noise and distractions seem to contribute to a patient's irritability and aggressiveness, provide treatment and care in areas that are calm and quiet.
- Capitalize on the superiority of procedural over declarative memory by helping patients learn context-sensitive routines rather than broader transfer-dependent strategies (Ylvisaker, Jacobs, & Feeney, 2003).
- Identify positive competing behavior, and as a team, consistently and frequently reward all instances of adaptive behavior (Eames, Haffey, & Cope, 1990).
- Withhold all rewards that maintain maladaptive behavior. Use time-outs in a calm, mechanical manner that does not reward the patient with increased social contact (Eames, Haffey, & Cope, 1990).
- Address cognitive impairments that may be contributing to maladaptive behavior.
- Help the patient to learn new skills and to experience success to reduce frustration-induced maladaptive behavior.

Supporting the Patient's Family

Patients' families continue to require information and support to understand the recovery and rehabilitation process and to inform their decision making and discharge planning. Holland and Shigaki (1998) recommended that the rehabilitation team provide the family with information about the following topics: (1) the full spectrum of possible TBI outcomes to enhance realistic expectations; (2) the effects of TBI on family systems and possible alterations in family dynamics post discharge; (3) the benefits, challenges, and responsibilities of caretaking and supervision post discharge; and (4) resources available for post-acute rehabilitation. Furthermore, by attending occupational therapy treatment sessions, family members encourage their loved one while learning about the patient's strengths and weakness and techniques for helping him or her optimize performance. Participation in inpatient rehabilitation also helps families to frame gains and improvements as continuations of a new start and to minimize expectations of an abrupt recovery to the "same person" the patient was before the injury (Phipps et al., 1997).

Post-Acute Rehabilitation

Malec and Basford (1996) described the array of post-acute rehabilitation programs in the literature and possibly available to clients with TBI. (The transition to references to the "client" rather than "patient" signifies the increasingly collaborative therapeutic relationship between therapist and TBI survivor during post-acute rehabilitation and survivor phases.) Occupational therapists are typically involved in all of these options, including the following:

- Home-based therapy provides a single discipline or interdisciplinary intervention for clients who are either unable to get to clinic-based services or who require context-specific training within the home environment.
- Residential neurobehavioral programs provide intensive treatment for clients with severe behavioral disturbances.
- Residential community reintegration programs provide integrated cognitive, emotional, behavioral, physical, and vocational rehabilitation to clients who cannot participate in outpatient programs because of severe cognitive and behavioral impairments or lack of availability of outpatient options.
- Comprehensive (holistic) day treatment programs provide integrated, multidisciplinary rehabilitation that emphasizes self-awareness, social skills, and cognitive compensation as precursors to return to work.
- Outpatient community reentry programs provide specific rehabilitation therapies as well as vocational services.

In their review article comparing outcomes of post-acute brain injury rehabilitation with natural recovery after TBI, Malec and Basford (1996) concluded, "Although generally uncontrolled, the studies reviewed document benefits for many individuals with brain injury, including increased independence and a rate of return to independent work or training that exceeds 50% and may reach 60% to 80% for intensive comprehensive (holistic) day treatment programs" (p. 198). Post-acute rehabilitation typically is not a continuous sequence of rehabilitation services but, more often, a time-limited, goal-specific series of rehabilitation episodes.

In general, the aim of post-acute rehabilitation is to prepare the client to reenter the community, although some programs also offer specialized tracks or pathways that focus on prerequisite physical, behavioral, cognitive, or self-care skills (Abreu et al., 1996). Compensation is emphasized; rarely do these programs focus on deficit remediation. While the occupational therapist's roles and responsibilities vary with the type and even location of the program, this section of the chapter reviews areas that are typically addressed. This section also discusses mild brain injury, as these survivors rarely receive inpatient rehabilitation services.

Occupational Therapy Assessment: Post-Acute Rehabilitation

Occupational therapists continue to use many of the instruments and methods described earlier in this chapter (see Table 39-4) and text. As clients have more real-world experiences and their self-awareness continues to improve, tools like the *Canadian Occupational Performance Measure (COPM)* (Law et al., 1994) become important for identifying treatment goals that are important to the client. Trombly, Radomski, and Davis (1998) used the *COPM* to select treatment goals with 16 adults with TBI who were in outpatient occupational therapy and to measure treatment outcome. This instrument, however, is not useful for clients with significant problems with insight and self-awareness because these individuals are unlikely to view themselves as having problems that can be addressed in therapy (E. S. Davis, personal communication, September 7, 1998). In the aforementioned study, for some clients, progress was marked by self-rated decreases in performance scores at discharge, reflecting improved accuracy of self-appraisal (E. S. Davis, personal communication, September 7, 1998).

Treatment: Post-Acute Rehabilitation

After discharge from acute rehabilitation, many clients require occupational therapy treatment aimed at teaching them to compensate for residual cognitive and visual-perceptual impairments so that they may resume self-maintenance, self-advancement, and self-enhancement roles.

OPTIMIZING COGNITIVE CAPACITIES AND ABILITIES

In post-acute rehabilitation, clients (usually in Rancho level VII or VIII) may continue to demonstrate specific impairments in short- and long-term memory, reasoning, conceptualization, comprehension, abstract thinking, information-processing speed, organization of information, simplification of problems, judgment, and problem solving (Dikmen, Reitan, & Temkin, 1983; Gianutsos, 1980). They may display decreased attention during attempts to store information, inability to determine the salient or relevant details of what they hear or read, decreased ability to structure or associate incoming information appropriately, and decreased cognitive flexibility (Scherzer, 1986). Especially if the client also has decreased self-awareness, these impairments will affect his or her ability to make coherent decisions and plan for the future.

Occupational therapists continue to help clients and their families to change the physical and social context to optimize occupational functioning. This may include decreasing stimulus arousal properties and increasing important visual cues at the home and work site to optimize cognitive function. Home and work site visits allow therapists to identify opportunities for these modifications. Also, because clients in post-acute rehabilitation have a more stable living situation than they did as inpatients, their occupational therapists can capitalize on consistency of clients' environments and daily activities to help them create routines and habits that minimize the demands of information processing with frequently performed tasks. Occupational therapists also use a variety of activities and exercises, such as computer games, worksheets, crafts and projects, and simulated work tasks, to help clients improve their awareness of strengths and weaknesses. As clients appreciate the significance of residual cognitive impairments and implications for resumption of roles, occupational therapists teach them to use compensatory cognitive strategies, such as day planners, alarm cueing devices, and problem-solving schemata, in the context of personally relevant real-world tasks (see Chapter 29).

OPTIMIZING VISUAL-PERCEPTUAL CAPACITIES AND ABILITIES

Similarly, occupational therapists continue to help clients make changes in environment and strategy to circumvent the influence of visual-perceptual impairments. For example, Williams (1995) described occupational therapy intervention for problems with reading and writing of a woman who was more than 12 months post TBI. A comprehensive low-vision evaluation performed by an ophthalmologist and occupational therapist revealed adequate central visual acuity, slightly reduced contrast sensitivity, an inferior visual field cut in both eyes, and a dense scotoma bordering the fovea in both eyes. Intervention, which consisted of changes in lighting for reading and writing, oculomotor exercises, and strategy training, ultimately allowed her to resume these valued activities.

RESTORING COMPETENCE IN SELF-MAINTENANCE ROLES

Clients who have not achieved independence in basic self-care and homemaking tasks continue to work toward those goals in post-acute rehabilitation. Giles et al. (1997) used behavioral training to help TBI clients in a transitional living center develop independence in dressing and washing skills in a relatively short period (11–37 days) of treatment. Even clients with proficient self-care skills benefit from treatment that links individual skills to automatic routines (see Chapter 29). Based on performance on the *Rabideau Kitchen Evaluation-Revised* (Neistadt, 1992), Neistadt (1994b) used a meal preparation protocol to help outpatients with TBI learn to prepare a hot beverage and snack. After three 30-minute sessions per week for 6 weeks, participants made gains reflecting improvements in independence and decreased their performance times. Intervention specific to self-care and homemaking always involves input from family and/or caregivers and measures to ensure transfer of newly acquired skills to the client's living environment.

When client and family are satisfied with the client's ability to perform physical daily living skills and homemaking tasks, such as cleaning, meal preparation, and laundry, occupational therapy addresses community and necessary survival skills. Many clients rely on occupational therapy to help them relearn to manage money, write checks, go shopping, use the bank and post office, move in crowds, handle architectural barriers, and use public transportation, the telephone, the newspaper, and the phone book. To do so, clinicians again adapt the environment, help clients acquire behavioral routines, and teach clients to use compensatory strategies.

The therapist must carefully assess the amount of supervision and structuring necessary because of impaired judgment and problem-solving ability. The client's ability to bend over and get something from a lower cupboard, climb on an escalator, cross the street safely, organize time adequately, manage finances, and interact with others in a functional manner factor into occupational therapy recommendations regarding the need for continuing assistance or supervision.

Almost as soon as they are discharged from the hospital, many survivors of TBI inquire about their readiness to drive. The client's residual physical, cognitive, perceptual, and visual dysfunction must be thoroughly assessed to determine his or her ability to drive safely. The client's psychosocial status, including self-control, impulse control, and frustration tolerance, must be also carefully considered. A complete history of the medical status, current medications, and driving record is also taken. Simulated driving on a computer is helpful if available. A car can be adapted to compensate for some physical problems (see Chapter 31), and the client can be trained to compensate for visual field neglect (Scott & Dow, 1995). No compensation, however, can be made for slowed reaction to emergencies, lack of

judgment or problem-solving ability, spatial or directional confusion on the road, impairment in depth perception, or decreased endurance (Jones, Giddens, & Croft, 1983). Following evaluation, if the client appears suitable for driving, an on-the-road test covering all driving situations is performed in a dual-control car or the patient's own car, with the assistance of an adaptive driving instructor (Jones, Giddens, & Croft, 1983). The therapist performing a driving evaluation should be familiar with the department of motor vehicle regulations applicable in that state.

RESTORING COMPETENCE IN SELF-ENHANCEMENT AND SELF-ADVANCEMENT ROLES

Occupational therapy plays an important role on the post-acute rehabilitation team by helping the client resume previous leisure activities or determine new leisure outlets that are more in line with current abilities. Since lack of initiative and cognitive inflexibility may hinder independence in play and leisure skills, occupational therapists teach clients to use planning and structuring strategies to ensure an optimal balance in their activities.

Many survivors of TBI have to change not only what they do for fun but also with whom they do it. Few friendships withstand the cognitive, behavioral, and emotional upheaval that comes with TBI. Occupational therapy intervention may focus on helping the client initiate new social contacts, participate in support groups, and reestablish the social skills necessary for maintaining and building a social network. Social skills retraining following severe head injury develops skill in social behaviors and facilitates successful social interactions. In general, behavioral learning methods are the most effective for training severely brain-injured individuals to overcome social skill impairments (Giles & Clark-Wilson, 1993). Treatment typically entails instruction and modeling of the social skill, practicing the skill with feedback, and shaping the skill until it is used correctly (Boake, 1991). For example, Yuen (1997) reported how positive talk training (learning to give compliments) in occupational therapy helped a man who was 20 years post TBI to engage in social interactions that were not riddled with what had become his usual style of negative, sarcastic comments. Gutman (1999) described use of a set of guidelines for occupational therapy to help adult men with TBI to achieve greater satisfaction with male social roles.

Once clients reestablish their competence in self-maintenance roles, they are ready to explore return to work. Post-acute occupational therapy facilitates that process with pre-vocational programs that focus on work behaviors and habits, such as punctuality, thoroughness, response to feedback, and ability to take and use notes. Occupational therapists may also link clients with appropriate volunteer jobs where they can employ newly learned compensatory cognitive strategies and build their endurance and work tolerance.

CONTRIBUTING TO BEHAVIORAL AND EMOTIONAL ADAPTATION

As clients attempt to resume familiar activities, they cannot escape the awareness that they have changed in some manner (Groswasser & Stern, 1998). Emotional and behavioral difficulties can be attributed to pre-morbid personality and coping style, cognitive consequences of TBI, and/or grief associated with injury-related losses (Hanks et al., 1999). These emotional and behavioral changes may include social or sexual disinhibition, low tolerance for frustration or stress, reduced insight or judgment, labile affect, irritability, impulsivity, and depression (Jorge et al., 1993). In the extreme, the patient may experience psychiatric disorders such as paranoia, phobias, confusion, or delusional ideation (Ashman et al., 2004; Benton, 1979). Regardless of the specific goals of therapy, occupational therapists support and guide clients with TBI as the clients confront and address impairments and inefficiencies that interfere with performance. Clinicians maintain dual roles as reassuring companion and objective observer by providing sensitive and timely feedback regarding behaviors that could otherwise result in rejection and social isolation in the community. As depression negatively influences psychosocial functioning after TBI (Hibbard et al., 2004; Ownsworth & Fleming, 2005), occupational therapists also respond to indicators that clients may be in need of psychological or psychiatric intervention and make referrals as needed (see Chapters 10 and 35).

Supporting the Client's Family

In most cases, the client's family ultimately provides long-term assistance and support for the survivor, and the family's stresses apparently do not decrease over time as do the stresses related to other traumatic injuries (Muir, Rosenthal, & Diehl, 1990). As time passes and the client moves through the rehabilitation continuum, the implications of the injury become clearer, and many families feel losses as "partial death" (Muir, Rosenthal, & Diehl, 1990, p. 436). The person they knew, loved, and depended on to fulfill their expectations is "dead," and long-established roles within the family have changed. Since the course of recovery is unknown (filled with hope, euphoria, and despair), family members undergo mourning that is intense, disorganized, and prolonged (Muir, Rosenthal, & Diehl, 1990).

Many roles within a marriage change when a spouse has a TBI, including roles as provider and parent. Less discussed are changes in sexual roles because of primary and/or secondary sexual dysfunctions (Griffith, Cole, & Cole, 1990). Primary sexual dysfunctions result directly from the brain injury and resultant neural or endocrine disorders influencing sexual interest, activity, responses, and fertility (Griffith, Cole, & Cole, 1990). For example, sexual activities may be altered or inhibited by any of a number of motor or sensory disorders, such as hypertonicity or apraxia (Griffith, Cole, & Cole, 1990). Secondary sexual dysfunctions and

disturbances of psychosocial abilities or sexual responses because of cognitive impairments and psychological reactions range from hypersexuality syndromes to total apathy and inactivity (Griffith, Cole, & Cole, 1990). Partners with TBI may exhibit disinhibited behaviors that are inappropriately provocative or seductive or break unwritten rules regarding personal space and touching (Gronwall, Wrightson, & Waddell, 1998). Forgetfulness regarding aspects of personal hygiene further add to the distance and even engender repulsion between previously affectionate partners. Occupational therapists can help clients and their partners resume satisfying sexual roles, first by being willing to discuss matters of intimacy and sexuality. Couples may be referred for medical assessment of primary sexual dysfunctions and counseling for some aspects of secondary sexual dysfunctions. Inappropriate social and sexual behaviors should be addressed in a deliberate and consistent manner by the rehabilitation team.

Finally, occupational therapists continue to support families by providing education (Research Note 39-1). Holland and Shigaki (1998) recommended emphasis on the following topics in family education at this phase of recovery and adaptation: (1) the protracted nature of TBI recovery, (2) the experience of recovery from the patient's perspective, (3) adjustment to and possible management of behavioral and personality changes, (4) sexuality issues, (5) community resources, and (6) home adaptation.

Mild Brain Injury

It is estimated that, each year, more than 1.1 million people in the United States experience a mild brain injury (National Center for Injury Prevention and Control, 2003). Mild brain injury has been defined as a traumatically induced physiological disruption of brain function as manifested by at least one of the following: any period of loss of consciousness, any loss of memory of events immediately before or after the accident, any alteration in mental state at the time of the accident, and focal neurological deficits that may or may not be transient (American Congress of Rehabilitation Medicine [ACRM], 1995a). Symptoms of mild brain injury may include nausea, dizziness, headache, blurred vision, cognitive deficits, and behavioral changes (ACRM, 1995a). Most people with a mild brain injury return to normal functioning within 1–3 months (Ruff, Camenzuli, & Mueller, 1996), although approximately 10% of patients continue to have problems a year after injury (Ruff, Camenzuli, & Mueller, 1996).

Experts disagree about the persistence and cause of cognitive problems after mild TBI (Dikmen, Machamer, & Temkin, 2001). Some link cognitive inefficiencies to acute stress disorder (Bryant et al., 2003), while others attribute disability to brain damage (deKruijk, Twijnstra, & Leffers, 2001). Montgomery (1995) described a multifactor explanation for disability after mild TBI. He suggested that personal factors (perfectionism or tendency toward negative

RESEARCH NOTE 39-1

Abstract: Wells, R., Dywan, J., & Dumas, J. (2005). Life satisfaction and distress in family caregivers as related to specific behavioural changes after traumatic brain injury. *Brain Injury, 19*, 1105–1115.

The purpose of this study was to determine the extent to which TBI-related behavioral sequelae, coping strategies, and life circumstances predicted caregiver satisfaction. TBI-related neurobehavioral changes, caregiver coping strategies, satisfaction with caregiver role, and overall life satisfaction were examined using multivariate regression analyses. Seventy-two pairs (survivor with TBI and family caregiver) completed questionnaire packets. Family members had an average of 10 years in the caregiving role. Survivors with TBI completed a self-report version of the *Brock Adaptive Functioning Questionnaire (BAFQ)* (ratings of neurobehavioral functioning). Caregivers completed the *Caregiving Questionnaire*, *Symptoms Checklist*, *Satisfaction with Life Questionnaire*, and *Methods of Coping Inventory* and also a version of the BAFQ to capture their appraisal of their loved one's neurobehavioral functioning.

Overall, caregivers in this study expressed more positive than negative feelings about their caregiving role. The nature of their loved ones' neurobehavioral deficits and coping strategies employed appeared to affect caregiver outcomes. Engaging the support of family appeared to be the most effective way to avoid depression and anxiety. While poor impulse control on behalf of the survivor was associated with caregiver anger and irritability, lack of empathy on behalf of the survivor was identified as most detrimental to the caregiver's life satisfaction.

Implications for Practice

- Because family caregivers assume long-term responsibility for survivors of severe traumatic brain injury, their coping and satisfaction are of importance to occupational therapists.
- As social support appears to be linked to caregiver coping and satisfaction, occupational therapists encourage family caregivers to avail themselves of friends' and family assistance as well as to participate in local brain injury support groups.
- It is critical that family caregivers understand the neurobehavioral consequences of traumatic brain injury, especially the possibility that cognitive dysfunction may contribute to problems with empathy. As family members understand that the survivor with TBI may be cognitively unable to appreciate or even recognize their sacrifices and efforts, they may adjust expectations and seek affirmation and support from other sources.
- Occupational therapists assure family members that, despite the challenges involved, many long-term caregivers report positive feelings about their caregiving roles.

thinking) interact with transient sequelae of mild brain injury, such as headache and mental inefficiency, that lead to short-term decrements in performance. Premature resumption of normal activities places an undue load on information-processing capacities that leads to errors and slowness of performance. Over time, the individual begins to make misattributions of causation and starts questioning his or her fundamental competence and even sanity (Montgomery, 1995). These individuals profit from outpatient rehabilitation services that address residual physical symptoms, provide information and support, and teach them to use cognitive compensatory strategies that decrease the demands on working memory. By normalizing and explaining cognitive inefficiencies, helping reestablish routines, and teaching use of memory backups such as day planners, occupational therapists can play a pivotal role in helping these clients resume pre-morbid tasks and roles.

Clinicians need to appreciate that persons with mild brain injury who find their way to rehabilitation professionals represent a fraction of the cases with mild TBI and that cognitive problems may be observed for a variety of reasons that have nothing to do with brain injury (artifacts from testing, pre-existing conditions, litigation, emotional problems) (Dikmen, Machamer, & Temkin, 2001). Given the disagreement regarding the mechanism underlying cognitive problems after mild TBI, it is not surprising that there is little consensus about the best intervention. At present, there is little in the literature to guide occupational therapists looking for an evidence-based approach to intervention. Existing studies do not specifically mention occupational therapy intervention, which is why there is no evidence table to accompany the mild brain injury case example in this chapter.

Survivorship

“I have been living with multiple effects of a severe TBI for 23 years. . . . Many of these years were spent in lonely isolation, wondering when the nightmare would end. . . . Now, I am focusing my energy on reaching out as well as within to live this life.” (Rain, 2000, p. 6)

The medical treatment and rehabilitation phases of life for the survivor are relatively brief compared to the years, even decades, during which he or she will continue to live with the consequences of TBI. Most survivors ultimately achieve independence in self-care skills and recover motor function (Olver, Ponsford, & Curran, 1996), but cognitive, behavioral, and emotional problems are long-term barriers to good quality of life (Klonoff, Snow, & Costa, 1986; Koskinen, 1998). Olver, Ponsford, and Curran (1996) compared outcome after TBI 2 years and 5 years post injury for Australian survivors of moderate to severe injury.

Survivors improved in terms of independence in self-maintenance tasks but had more complaints about cognitive, behavioral, and emotional issues at 5 years post injury than at 2 years post injury. More than 60% of their subjects 5 years post injury complained of memory problems, fatigue, and irritability; more than 50% reported that they had lost friends and had become more socially isolated. Koskinen (1998) described a similar pattern in her follow-up study of Finnish survivors of severe TBI 10 years post injury. Subjects indicated that the most unsatisfying aspects of their lives were contacts with friends, sexuality, and leisure activities. Neurobehavioral and emotional consequences of TBI had significant effects on both the quality of life of survivors and level of strain felt by family caregivers.

Olver, Ponsford, and Curran (1996) reported that fewer survivors were working 5 years post injury than 2 years post injury (50% of the sample was employed at 2 years; 40% was employed at 5 years), which is of particular concern, since employment appears to be linked to quality of life after TBI (O’Neill et al., 1998). O’Neill et al. found that being employed part or full time contributed to survivors’ sense of well-being, social integration, and pursuit of meaningful home activities. In fact, individuals who worked part time had fewer unmet needs, were better integrated socially, and more often engaged in home activities than full-time workers, presumably because of more discretionary time and energy.

These long-term and often unmet needs underscore the importance of intermittent long-term rehabilitation services and community resources for persons with TBI. Unfortunately, most rehabilitation services remain medically oriented, focusing heavily, often exclusively, on intervention for physical impairments. Koskinen (1998) reported that survivors with physical deficits received rehabilitation services over a 10-year period, but physically functioning individuals with cognitive, behavioral, or emotional problems had no possibilities for rehabilitation of any kind. Unfortunately, depression represents a barrier to psychosocial functioning for years after TBI (Hibbard et al., 2004).

The contrast between need and service availability is particularly disturbing to occupational therapists who have the education and skills to make a difference in the lives of survivors of TBI. For example, Nelson and Lenhart (1996) described a case in which weekly outpatient occupational therapy sessions over 5 months helped a woman who was 5 years post TBI to improve her ability to handle school, household, and social responsibilities. Trombly, Radomski, and Davis (1998) and Trombly et al. (2002) found that adults with TBI met self-identified goals in outpatient occupational therapy, many of whom were more than 2 years post injury.

The survivorship phase of life for persons with TBI presents opportunities for clinicians to employ all that is truly unique to occupational therapy, synthesizing the to-

tality of our education, philosophy, and values to enhance occupational functioning in society. Readers are challenged to consider the following ways to poise themselves for action:

- Recommend that a life care plan be prepared for survivors of moderate to severe TBI (Sherer, Madison, & Hannay, 2000). Based on expert diagnosis and prognosis, a life care plan delineates the services and items required for the current and long-term care of the survivor as well as the costs of these services (Sherer, Madison, & Hannay, 2000). The life care plan can be used clinically to plan appropriate long-term care, including intermittent follow-up, and for forensic purposes, such as determination of an appropriate settlement that will provide for the lifetime needs of the injured person (Sherer, Madison, & Hannay, 2000). In fact, occupational therapists have the background to be credentialed to prepare life care plans for the disabled.
- Promote to possible referral sources what you as an occupational therapist are able to do to enhance community integration and quality of life for persons with TBI. Join your local brain injury association; connect with

your state’s vocational rehabilitation division; familiarize yourself with key personnel supporting disabled students at local colleges and universities. Showcase your contribution to clients’ occupational function in your documentation. Access resources that will allow you to maintain your expertise (Resources 39-1).

- Establish the kind of therapeutic relationship with clients that will make them want to return to you for help. Respecting the client’s readiness for treatment means sometimes not intervening but making sure that he or she knows that your door is open in the future.
- Make sure that the discharge from outpatient occupational therapy incorporates plans for follow-up and clear information regarding possible circumstances in the future when further occupational therapy services may be helpful. Provide information to the survivor and his or her family regarding mechanisms to reinstate services. Remember that the nature of TBI interferes with survivors’ ability to advocate for themselves (e.g., lack of initiation, impaired memory), and so you must build in opportunities to discern and respond to their needs.

CASE

EXAMPLE # 1

K.R.: Occupational Therapy During Acute and Rehabilitation Phases of Recovery from Severe TBI

Occupational Therapy Intervention Process

Patient Information

K.R. is a 20-year-old college student who sustained a TBI in a motor vehicle accident. Prior to the accident, K.R. was a physics major described by family as dependable and hard-working, with a 3.8 grade point average during his first 2 years of college.

Examination in the emergency department revealed a laceration over his forehead and right pneumothorax. His blood alcohol level was 0.226 (more than twice the legal limit). He had an initial *Glasgow Coma Scale* score of 3. Intracranial pressure was elevated. He sustained facial fractures and an undisplaced right suprapubic ramus fracture. Serial computed tomography demonstrated diffuse axonal injury, edema, and right posterior temporoparietal intraparenchymal hemorrhage. Within the first week of the TBI, a tracheostomy and feeding tube were inserted, and shortly

Clinical Reasoning Process

Objectives

Understand the patient’s diagnosis or condition

Know the person

Examples of Therapist’s Internal Dialogue

“K.R.’s recent medical history suggests that he had a severe brain injury and will likely require occupational therapy services and other rehabilitation services throughout the continuum of care (acute medical, inpatient, outpatient, follow-up).”

“From what his parents tell me, K.R. sounds like a really hard-working guy. Apparently, in addition to his course work, K.R. worked 16 hours a week as a dishwasher in his dormitory. It sounds like K.R. tends to be quiet and soft-spoken but enjoys the company of a small circle of friends. I found out that his leisure interests include golf, cross-country skiing, and playing piano. It was really worth the time it took to talk with K.R.’s parents. I can tell that I will like working with them, and the information they provided me with will

thereafter, K.R. underwent open reduction and internal fixation of the right zygomatic maxillary complex fracture.

Occupational and physical therapy were initiated 10 days post injury, with orders for range of motion, positioning, and assessment of response to sensory stimuli. At the time he was first seen in occupational therapy just before his transfer from ICU to the medical unit, his passive range of motion (PROM) was within normal limits for all extremities; muscle tone was unremarkable. K.R. did not speak or follow commands consistently. He was frequently observed to thrash around, primarily moving his left side, and at times, his movement appeared purposeful (pulling at tubes, seeming to scratch his right leg with his left foot). He appeared to track objects with his left eye inconsistently. His initial total score on the *Western Neuro Sensory Stimulation Profile* was 23, and he was believed to be functioning at a Rancho level II to III (increasingly responsive to specific stimuli).

help me as I try to make therapy interesting and engaging for K.R.”

Reason for Referral to Occupational Therapy

After less than a week on the medical step-down unit, K.R. was transferred to the inpatient brain injury rehabilitation unit and was again referred to occupational therapy and to physical therapy, speech-language pathology, and neuropsychology (he was 3 weeks post injury). He was referred to occupational therapy to assess responsiveness to stimuli, positioning, neuromuscular reeducation, and ADL training as appropriate. Consistent with his acute hospitalization, a family member (typically his mother) was present at most therapy sessions.

Appreciate the context

Develop provisional hypotheses

“The transfer from the medical unit to the rehabilitation unit represents a significant change in K.R.’s care. There is much more stimulation on the rehabilitation unit, and the overall emphasis of care changes from one of medical survival to recovery and adaptation.”

“I anticipate that, by putting in place formal interventions and observational protocols, we will be able to maximize K.R.’s responsiveness to stimuli and ultimately his ability to benefit from rehabilitation. It will be important to involve his family for their sake as much as for his.”

Assessment Process and Results

- *Western Neuro Sensory Stimulation Profile* was readministered, and K.R. obtained scores ranging from 54–80, with notable improvements in auditory comprehension, visual tracking, object manipulation, and arousal and attention.
- During assessment, K.R. sustained eye contact less than 25% of the time and was awake for approximately 15 minutes of each session. He horizontally tracked across midline with both eyes approximately 50% of the time and tracked vertically in one direction somewhat less. He generally followed gross motor commands approximately 25% of the time.
- Minimal formal assessment of K.R.’s right upper extremity function was performed, but he was observed to not use or move it. His range of motion appeared to within normal limits for both upper extremities.
- During assessment, it was evident that K.R. could not contribute to any aspect of ADL.

Consider evaluation approach and methods

Interpret observations

“I need to primarily rely on observational methods during assessment and carefully document what I am seeing so that I will be able to detect changes in responsiveness and function.”

“I am finding that my assessment sessions really blur with treatment; it seems I am doing both at all times. I am encouraged that K.R. is demonstrating more specificity in his overall responses. While his speech is not intelligible, he seems to be making more frequent verbalizations. Since he came to the rehab unit, I am noticing that he can participate for longer periods of time, and that is encouraging as well.”

Occupational Therapy Problem List

- Decreased arousal and attention
- Decreased and inconsistent visual tracking
- Inability to follow commands consistently
- Decreased right upper extremity function
- Dependence in activities of daily living (ADL)

Synthesize results

“K.R.’s overall responsiveness appears to be steadily improving based on records of his status on the acute medical unit. I am going to try to use my interventions related to ADL and upper extremity function as vehicles to improve arousal and attention.”

Initial Occupational Therapy Goal List

Because it was difficult to predict the patient's rate of recovery or response to therapy, the team set goals for 2-week intervals, with the understanding that the patient's length of stay on the rehabilitation unit would be dictated by his apparent ability to profit from intervention. Meanwhile, the patient's family was exploring possible discharge options to home for continued home-based services or to a subacute rehabilitation facility.

K.R. will stay awake for two 20-minute sessions per day, demonstrating sensory-specific responses to visual and auditory stimuli at least 50% of the time.

K.R. will respond to one-step commands at least 50% of the time, such as during light hygiene activities.

K.R. will safely sit upright during occupational therapy sessions with proper wheelchair positioning.

K.R.'s parents will be able to perform systematic sensory stimulation and track responses on a data collection form.

Develop intervention hypotheses

Select an intervention approach

Consider what will occur in therapy, how often, and for how long

"My underlying assumption is that, as we provide that 'just-right' amount of stimulation and structure, K.R. will become increasingly aroused and attentive, which is necessary for him to be truly engaged in the rehabilitation process."

"At this point, my primary approach to intervention is remedial."

"K.R. is at the beginning of what will likely be a long course of rehabilitation, and it is impossible to come up with firm projections as to how long that process might be. Based on my experience, I expect that it may be a matter of a couple of weeks before K.R. can consistently follow instructions and truly participate in therapy. I will be seeing him at least three times per day throughout his inpatient rehabilitation stay, which could be 3 to 4 weeks. I am always reluctant to talk about specifics at this point, especially to family members, because it really is hard to project the outcome with any certainty."

Intervention

K.R. was seen three times daily, twice in the therapy clinic, with sessions lasting 10–30 minutes as tolerated. He participated in daily light hygiene activities in which, for example, he was instructed to turn on the faucet and was handed a wet washcloth and asked to wash his face. Nursing, occupational therapy, and family collaborated to ensure that K.R. was fully dressed each morning. As recommended by the therapist, K.R.'s parents brought in pictures of friends and family and posted them in his room. PROM for the right upper extremity was incorporated into his sensory stimulation program, and efforts were made to elicit automatic upper extremity movement by, for example, challenging K.R. to catch or hit a balloon. He made steady gains in all areas, so that within 3 weeks of his admission to rehabilitation, he followed one-step commands approximately 70% of the time and participated in morning hygiene activities for 20-minute intervals with ongoing verbal and tactile cues. He was able to feed himself with the utensil in his right hand once the therapist scooped food. K.R. started speaking in short phrases approximately 6 weeks after onset and progressed rapidly to whole sentences, indicating, for example, when he had to go to the bathroom. As K.R.'s cognitive recovery progressed, the occupational therapist helped him to become more independent in dressing, grooming, and his upper extremity exercise program and to increase his orientation and attention span. He was able to use a memory log (with entries recorded by others) to answer questions about his daily activities.

Assess the patient's comprehension

Understand what he is doing
Compare actual to expected performance

Know the person

Appreciate the context

"At the time of his transfer to the rehabilitation unit and referral to occupational therapy, K.R.'s cognitive status posed the primary barrier to his functioning, specifically his low levels of arousal and attention. Motor and ADL activities are means by which I can try to promote arousal, tracking, responsiveness, and K.R.'s ability to follow commands. I can begin to provide more of a learning-based intervention when K.R. begins to show within-session carryover."

"I am beginning to see glimpses of K.R.'s personality and so are his family members. Even though he is disoriented and quite unaware of his circumstances, he can be easily engaged in therapy tasks, especially if he views them as competitive."

At the time of discharge, K.R. needed supervision with grooming and upper extremity dressing and moderate assistance with lower extremity dressing and bathing. K.R.'s mother was taught methods to assist him at home. He was able to walk with a quad cane and moderate assistance; he needed contact guard assistance with standing balance. At discharge, he was oriented to person, place, and time, scoring in the normal range on the *Galveston Orientation and Amnesia Test*, and demonstrated at least some degree of session-to-session carryover. The therapist recommended 24-hour supervision because of continued impairments in memory, problem solving, and judgment. He was discharged to his parents' home 2 months post TBI with plans to return for daily therapy in the day hospital program (supervised all-day multidisciplinary therapies with return home each evening).

“K.R. was discharged home before he was fully competent in self-maintenance because his parents were able to provide assistance and supervision and because intensive outpatient services were available.”

Next Steps

The occupational therapy intervention plan during K.R.'s 3 weeks in the day hospital focused on use of a memory aid and reestablishing competence in instrumental ADL, including light meal preparation, laundry, checkbook management, and bill paying. His living situation contributed to motivation and improved insight more than the insulated experience of the rehabilitation unit. When he no longer required all-day supervision, he was discharged from the day hospital but continued outpatient occupational therapy three times a week.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“I feel good about the fact that we can offer K.R. and his family comprehensive and long-term rehabilitation services. They will need us off and on as they face new milestones over the next year such as driving, return to independent living, and return to school and work. His parents have joined a support group and are working closely with our staff to carry over what he is working on in therapy.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Occupational Therapy Intervention in the Survivor Phase of Recovery

K.R. had a neuropsychological evaluation a year after he sustained the TBI. Results suggested that, despite his considerable neurological and behavioral recovery, K.R. demonstrated general cerebral dysfunction that affected his information-processing speed, expressive abilities, abstraction, higher level reasoning, planning, organization, and memory. K.R.'s pre-morbid attributes, such as above-average intelligence and diligence, appeared to contribute to his recovery, and K.R. had plans to reenter college within 2 months of testing. The neuropsychologist advised against this plan, suggesting that K.R. allow himself more time to recover and that he further develop compensatory cognitive strategies to optimize the likelihood for successful return to school. The neuropsychologist further recommended that K.R. establish connections with a counseling psychologist, anticipating a point when K.R.'s expectations to fully resume his career track might clash with his post-injury capabilities. K.R. felt that the neuropsychologist was unduly pessimistic, but with the encouragement of his parents, he agreed to participate in occupational therapy and at least meet with the counseling psychologist.

Assuming that K.R. has not been actively involved in occupational therapy for the past 6 months, what assessment tools and methods would you use to guide your treatment plan? What aspects of occupational functioning do you anticipate having to address in treatment?

CASE

EXAMPLE # 2

Dr. N.: Occupational Therapy after Mild Brain Injury

Occupational Therapy Intervention Process

Clinical Reasoning Process

Objectives

Examples of Therapist’s Internal Dialogue

Patient Information

Dr. N. is a 29-year-old single woman who sustained a mild TBI when she fell off her bicycle; she was not wearing a helmet. She reports that she did not lose consciousness, and her *Glasgow Coma Scale (GCS)* score in the emergency department was 13. She was hospitalized for 2 days with a small epidural hematoma over the right occipital region and significant headaches. Dr. N. returned to work 2 days after her hospital discharge despite continued headaches and balance and memory problems.

Dr. N. has a degree in biochemistry and works as a post-doctoral fellow at a university. Her parents and four siblings reside in another state, and she lives with her significant other of 4 years.

Dr. N. participated in neuropsychological assessment approximately 6 months post injury because cognitive inefficiencies continued to interfere with her function, especially at work. Findings suggested mild impairment for recent verbal and non-verbal memory and subtle impairment for executive abilities. These cognitive changes contributed to decreased efficiency at work (slowness in problem solving, needing to reread professional literature, frequent note taking). Furthermore, Dr. N. was anxious and depressed. She reported difficulty falling asleep despite overwhelming fatigue. She worried about whether or not she had completed intended tasks, checking and double-checking herself throughout the day. She described herself as easily frustrated, lacking confidence, and overdependent on her significant other. She continued to have headaches approximately 4 days a week. The neuropsychologist expected Dr. N. to maintain her job successfully and pursue pre-morbid career goals with assistance in adjusting self-expectations and information-processing habits.

Understand the patient’s diagnosis or condition

“Given her GCS score and the fact that she did not lose consciousness, I can assume that her TBI was not severe and that she has a good prognosis for a full recovery.”

Know the person

“My guess is that Dr. N. is used to pushing herself, as evidenced by a rather speedy return to work after her hospitalization. Clearly, Dr. N. is a bright woman and has high expectations of herself. The cognitive inefficiencies since her injury must be frightening and confusing for her. I am glad that she appears to have social support.”

Reason for Referral to Occupational Therapy

Dr. N. was referred to occupational therapy for assistance in developing compensatory cognitive strategies and behavioral routines that would improve her efficiency at home and work. She was also referred to a psychologist for support and biofeedback to help her manage her headaches.

Appreciate the context

“Dr. N. was referred to an outpatient brain injury clinic that specializes in serving people with mild brain injury. The staff knows to avoid overemphasizing concerns about permanent cognitive impairment and encourage clients to reinterpret symptoms as short term and manageable.”

Develop provisional hypotheses

Assessment Process and Results

- Interview and self-report questionnaire related to client's problems, inefficiencies, and concerns and learn about how Dr. N. manages information at present
- Interview regarding "typical day"
- Observations of response to orally-presented homework and follow-through

Consider evaluation approach and methods

"Because I have reviewed the results of Dr. N.'s neuropsychological evaluation, it is not necessary or appropriate to assess cognition in occupational therapy. In fact, repeated assessment of similar domains might be detrimental, potentially overemphasizing cognitive inefficiencies that will likely be short term. Instead, I will try to find out about performance patterns and daily functioning."

Interpret observations

"When I asked her to bring photographs to her next session, Dr. N. wrote a note to herself on 1 of approximately 8 'sticky notes' that were affixed to her wallet. She seems comfortable with note taking, but I'm guessing that her notes do little to supplant her memory as she likely doesn't find them when she needs them."

Occupational Therapy Problem List

- Misattributions and misperceptions regarding personal competence
- Inadequate use of external information-processing strategies
- Disruption of personal routines, especially surrounding bedtime

Synthesize results

"Dr. N. did not link distracters, such as headache and fatigue, to episodes of memory failure and absent-mindedness or understand the implications of a limited working memory. I noticed that Dr. N. started writing lots of notes to herself but did not store or refer to them in a systematic manner; she worked off a mental plan each day but could not set priorities among multiple tasks. I am concerned about so much sleep in the early evening followed by more active household tasks. It's no wonder she is having difficulty with sleep."

Initial Occupational Therapy Goal List

The anticipated length of treatment was four to six sessions.

Dr. N. will independently employ compensatory cognitive strategies to increase her effectiveness and efficiency with work and personal tasks.

Dr. N. will make changes in her daily routine that contribute to improved balance among work, leisure, and rest.

Develop intervention hypotheses

"There seem to be many contributions to Dr. N.'s problems right now, including the after-effects of mild brain injury, anxiety associated with misattributions related to the problems she's experiencing, and a rather limited repertoire of external information-processing strategies. Interventions in occupational therapy will focus on helping her make correct attributions related to performance problems and broadening her repertoire of information-processing strategies."

Select an intervention approach

"I will use an education-consultative approach, teaching her about information processing and helping her refine her information management strategies."

Consider what will occur in therapy, how often, and for how long

"I think that she will need a relatively short duration of occupational therapy. I recommend that she come to therapy once per week for a few weeks, which will allow her to try out the strategies that we discuss, and we can work together to refine them accordingly."

Intervention

Dr. N. participated in five treatment sessions over 3 months, attending weekly sessions for 3 weeks and two follow-up sessions over 6 weeks. As cognitive inefficiencies were reframed as partly consequences of a working memory overload related to stress and the distraction of physical symptoms, Dr. N. eagerly explored methods to decrease the demands on internal information processing. She purchased a day planner and, with input from the therapist, established daily and weekly planning routines. Daily and weekly plans helped her set priorities among tasks and allocate time for leisure. She experimented with establishing routines for certain aspects of her “typical” day, scheduling breaks and allocating tasks with low cognitive demands to periods when her energy tended to be low. Her after-work routine changed as well: she set the timer to take a 20- to 30-minute nap followed by a 30-minute walk. She also established a bedtime wind-down routine that ultimately decreased the amount of time she needed to fall asleep.

Assess the patient’s comprehension

Understand what she is doing

Compare actual to expected performance

Know the person

Appreciate the context

“Dr. N. had relatively mild or subtle impairments that changed her cognitive capacity. Similar to many bright individuals, Dr. N. had never thought about her own thinking strategies and did not have a broad repertoire of techniques or habits of mind that she could default to. Furthermore, in her attempts to understand changes resulting from her injury and their implications, Dr. N. failed to appreciate the cumulative effect that subtle impairments, stress, reliance on pre-morbid cognitive strategies, and distractions associated with pain exerted on her information processing. She was relieved to learn that she was not ‘losing it’ and quickly engaged in problem solving with me regarding possible changes in strategies and routines that would buoy her everyday performance. Her relatively brief involvement in treatment shows the benefit of holistic occupational therapy services in dramatically improving an individual’s occupational functioning and quality of life.”

Next Steps

Discharge from occupational therapy.

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“I do not expect that Dr. N. will need further therapy and anticipate that, as her headaches and fatigue abate, her overall functioning will improve. She seems to now make correct attributions related to cognitive inefficiencies and has a good sense of when to employ compensatory strategies to lighten her load.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Implications of Severity of TBI on Treatment Planning

Because Dr. N.’s cognitive impairments were relatively mild, she was aware of cognitive changes and able to learn information-processing principles and independently apply them in novel situations. Explain how the treatment plan would likely change if Dr. N. had sustained a moderate or severe TBI. How might Dr. N.’s cognitive profile be different? What would be the implications in terms of therapist’s role, treatment methods, length of treatment, and outcome expectations?

Evidence Table 39-1 Best Evidence for Interventions Used in Occupational Therapy after Severe Brain Injury

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Multisensory stimulation ^a	Experimental group received multisensory stimulation protocol (auditory, tactile, olfactory, gustatory, visual, kinesthetic, proprioceptive, vestibular) that was administered by family members; controls did not receive this intervention.	Total of 24 patients (ages 17–42 years) who were 2–12 days post severe brain injury and who had a <i>Glasgow Coma Scale</i> (GCS) score less than 8 (n = 12 in experimental group; n = 12 matched controls).	Multisensory stimulation provided to experimental group for approximately 1 hour, 1–2 times per day for duration of coma. (Coma was said to have ended when patient was observed to obey commands and make purposeful movements.)	Quasi-experiment, cohort study; 12 patients in each of the 2 conditions. II C 3 c	Total duration of coma was significantly less for experimental group than control group. Experimental group showed signs of greater responsiveness (based on weekly averages of GCS), but researchers did not test the significance of these differences.	$p < 0.05$; $r = 0.5830$	Mitchell et al, 1990

(continued)

Evidence Table 39-1 Best Evidence for Interventions Used in Occupational Therapy after Severe Brain Injury (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Multisensory Stimulation ^a	Same as above.	31 patients (ages 6–75 years) who were in coma or persistent vegetative state 2 weeks after severe brain injury received multisensory stimulation; outcomes compared with historical reference group from the literature with similar characteristics (n = 135).	Multisensory stimulation provided to experimental group up to 8 hours per day, 7 days per week, until the participant was accepted for conventional rehabilitation therapy.	Case-control study with 31 patients in experimental group. II B 3 c	No significant differences in either time taken to follow a simple command or in <i>Glasgow Outcome Scale</i> 10–12 months post injury.	N/A	Pierce et al., 1990
Self-care skills training	Subjects received a washing and dressing protocol that involved behavioral methods (behavioral observation, task analysis, consistent practice, faded cueing).	4 patients living in a residential setting (3 sustained a TBI; 1 had brain injury after cerebral bleed) who were at least 7 months post injury and who had severe physical and cognitive impairments.	Daily ADL retraining with fading physical assistance and cueing.	4 single-subject studies. IV C 2 b	3 of 4 subjects achieved independence in washing and dressing (in 20, 37, and 11 days, respectively); 1 of 4 did not.	No formal statistical tests reported.	Giles et al., 1997

^aNote how two studies with similar levels of evidence come to different conclusions regarding effectiveness.

SUMMARY REVIEW QUESTIONS

1. What are some treatment planning implications related to age of onset of TBI? Describe the relevance of the cause of injury, developmental stage, and possible comorbidities.
2. In what ways do occupational therapists use information regarding mechanisms of injury of each patient in the clinical reasoning process? For example, how is the clinical presentation of a diffuse brain injury different from that of a focal brain injury? How can the therapist obtain information about the mechanisms of injury for a given patient?
3. Describe specific ways a patient's pre-injury characteristics and background may affect rehabilitation and outcome.
4. Summarize terms used to describe patients in altered states of consciousness and why distinctions between these states are important to the occupational therapist.
5. Analyze the similarities and differences between providing sensory stimulation and managing agitation for a minimally responsive patient.
6. What are some of the frequently cited predictors of prognosis and rehabilitation outcome after TBI? What are the occupational therapy implications of these predictors in planning treatment for patients in terms of goals, length of treatment, and role or needs of the family?
7. Describe the adjustment and adaptation process of the patient with TBI as compared to that of the family. Detail what support and education patients and family members need from occupational therapy during each phase of recovery and adaptation.
8. How might the treatment approach used to optimize cognitive capacities and abilities for an inpatient be different from the treatment approach used in post-acute rehabilitation or if the patient returns for services years later?
9. Compare Montgomery's multifactor explanation for disability after mild TBI with your own explanation of disability after severe TBI.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe four neurodegenerative diseases, including their courses and their symptoms.
2. By completing the occupational therapy evaluation, select appropriate assessment and evaluation tools for clients with neurodegenerative diseases based on individual clients' characteristics and requirements.
3. Determine appropriate interventions for clients with neurodegenerative disease based on their individual characteristics and requirements.
4. Select appropriate equipment for home, work, and community to help a client with neurodegenerative disease maintain independent function at the highest possible level.

CHAPTER 40

Neurodegenerative Diseases

Susan J. Forwell, Lois F. Copperman, and Lucinda Hugos

Glossary

Glossary

Akinesia—Impaired ability to initiate voluntary and spontaneous motor responses, such as the interruption of performance in movement when attention is distracted (e.g., freezing in Parkinson’s disease).

Axonal transection—Separation of an axon from its postsynaptic neuron, permanently interrupting action potential propagation.

Bradykinesia—Slowness or poverty of body movement.

Cogwheel rigidity—Series of catches in the resistance during passive motion.

Fasciculations—Rapid, flickering twitching movements of a part of a muscle occurring irregularly in time and location.

Festinating gait—Marked by very small rapid steps and occurs in persons with Parkinson’s disease when the posture of the head and trunk involuntarily lean forward ahead of the feet, moving the center of gravity (COG) forward. Rather than taking a large step to correct the imbalance, several hurried small steps increasing gait velocity occurs, resulting in running or “chasing” one’s COG, which remains in front of the feet.

Myelin—Lipid-rich insulating material covering nerve fibers that speeds conduction of impulses.

Rigidity—Hypertonicity of agonist and antagonist muscles that offers a consistent, uniform resistance to passive movement.

Neurodegenerative diseases are generally chronic and potentially progressive and frequently require coping with existing disability and the threat of future losses. The underlying pathologies of these diseases are described in this chapter and are shown to have mechanisms that attack the peripheral nervous system (PNS) and central nervous system (CNS), resulting in impairments and limitations that affect all aspects of life. Although the underlying diseases are not curable, research and medical advances have led to treatments that alter the progressive course of many neurodegenerative diseases and allow people to live longer, more productive lives.

This chapter begins with an overview of occupational therapy for persons with neurodegenerative diseases. Broad considerations related to evaluation, goal setting, and intervention are reviewed, followed by detailed discussions of multiple sclerosis (MS) and Parkinson’s disease (PD), amyotrophic lateral sclerosis (ALS), and Guillain-Barré syndrome (GBS).

OCCUPATIONAL THERAPY FOR NEURODEGENERATIVE DISEASES

Occupational therapy frequently begins at diagnosis and continues throughout the continuum of comprehensive care; it may take place in inpatient acute care, inpatient rehabilitation, outpatient, in-home, or long-term care settings. Inpatient acute treatment usually follows a relapse or deterioration in the disease and/or a crisis and is generally short and limited to stabilizing symptoms with medical interventions. Inpatient rehabilitation may last 1 to several weeks, with daily therapy sessions geared to develop new strategies to deal with changed symptoms and to identify and obtain equipment. Outpatient therapy is

usually weekly, with 1-hour individual sessions to demonstrate strategies to maximize independence, instruct in home programs, minimize the effects of symptoms on daily activities, and identify and obtain needed equipment. Occupational therapy in long-term care facilities may be similar to inpatient rehabilitation for people adjusting to changing symptoms or developing palliative care plans for patients whose neurodegenerative disease has progressed to the point they cannot be cared for at home.

Neurodegenerative diseases affect most aspects of life and commonly individuals in their young and middle adult years. It is imperative occupational therapy focus on activities and occupations that are most relevant, valued, and important to the individual and significant other(s). Evaluative screens help the therapist to determine the client’s most relevant activities and to target these specific areas during assessment. For example, an individual may set a high priority on continuing employment and be willing to delegate home and self-care tasks. Assessment and intervention for this person would focus on maximizing independence in activities necessary for work and setting up the support systems needed for home functions. Occupational therapists must also keep an eye on their own coping and objectivity, especially when treating clients whose disease course portends increasing disability or death.

Occupational Therapy Evaluation

Occupational Profile

The occupational therapy evaluation begins with an interview that gathers information about the client’s relevant history of disease, valued roles and occupations, and screens for specific concerns or problems. This interview must be sensitive to the client’s changing function and

fear of the unknown as well as illuminate problem areas that may not be spontaneously discussed such as fatigue, depression, sexual function, and cognitive concerns that impact their occupations and social network. With this information, an occupational profile assists to direct further assessment.

Occupational Analysis

Based on the occupational profile, the occupational therapist will select assessments and measurement tools that will provide in-depth information on occupational areas of concern. For persons with neurodegenerative disease, the content of these measures may be limited to a few or cover a broad spectrum of occupational performance areas (such as ADLs, IADLs, and work) or symptoms (such as sensation, spasticity, weakness, memory, and fatigue).

Occupational Therapy Intervention Process

Goal Setting

The primary goals of intervention are to reduce the effects of disability resulting from disease impairments and to maintain or promote independence and quality of life; that is, safe, functional, and comfortable participation in chosen tasks and roles. Goal setting is a collaborative process that includes the client, occupational therapist, and as appropriate, family and other significant persons. The unplanned and profound impact of neurodegenerative disease frequently makes realistic goal setting complex, and requires sensitivity, flexibility, and negotiation skills of the occupational therapist. The therapist frequently helps the client modify behaviors and assumptions of a lifetime while assisting the person and significant others to move toward realistic new goals. Treatment goals should be in sync with the client's priorities and grounded in evidence-based research. Given the progressive nature of many neurodegenerative diseases, regular reassessment and reordering of goals and priorities may be necessary.

Intervention Implementation

Due to the complexity of disability, intervening in one area may affect several other factors, such as fatigue, pain, and weakness. Interventions are varied and frequently involve significant others, especially as the disease progresses. The following is an overview of ways occupational therapy optimizes performance in key occupational roles for persons with neurodegenerative diseases.

Self-Maintenance Roles

In basic and instrumental ADL, the occupational therapist assists the client to attain safety, maintain independ-

ence in priority activities, use specialized equipment, and participate using energy-conserving methods. Treatment strategies include the following:

- Priority setting
- Education in areas such as the disease process affecting motor or cognitive changes
- Environmental modifications at home and work to promote safety and independence
- Exercise to prevent loss of range of motion and strength needed to dress
- Behavior modification such as use of energy conservation and time management techniques
- Identifying and obtaining equipment to compensate for weakness or other symptoms
- Balancing independence with assistance from others

Self-Advancement Roles

The onset of neurodegenerative diseases affects employment in or outside of the home. Contrary to popular expectations, however, many individuals can and should continue to work rather than claim disability. Medical treatments affecting disease progression and legislation mean that modification of employment is frequently more appropriate than an immediate disability claim. Continued employment has implications for financial independence, health care choices, socialization, identity, and self-esteem. Occupational therapists critically review job expectations and, as required, make modifications to the environment, recommend behavioral changes, prescribe equipment, identify resources, and make recommendations to the individual or the employer. Nonprofit groups such as the National Multiple Sclerosis Society (NMSS) provide resources and are excellent sources of information for both patients and therapists (Resources 40-1).

Self-Enhancement Roles

Maintaining leisure pursuits may be a high priority for individuals with neurodegenerative diseases but are often the first roles to be abandoned. Modifying activities and proper equipment often enable the individual to continue to carry out these important meaningful occupations.

Members and Roles of Rehabilitation Team

Depending on the type and severity of functional limitations, involvement of the rehabilitation team may vary, although it is essential in maintaining the highest level of function and quality of life (Martin & Weiler, 2003). When cognitive problems interfere with everyday occupations, psychologists, speech therapists, and occupational thera-

pists are often consulted (Brown & Kraft, 2005). Neuropsychologists may be called upon to conduct in-depth cognitive assessments, make recommendations, and engage in intervention. In addition to cognitive issues, the speech therapist may be involved when dysarthria is present or expressive communication is labored. In the presence of dysphagia, an occupational therapist, speech therapist, and/or dietician commonly form the intervention team. Social work services assist when there is a shift in financial or care needs to advise on and make application to appropriate programs and counsel individuals and significant others to better cope with role change and demands. Physical changes as a result of weakness, spasticity, sensory problems, pain, and decreased endurance and range of motion necessitate the services of physical and occupational therapy to enhance mobility, upper extremity function, and overall conditioning to reduce falling and to provide guidance for appropriate exercise programs. Occupational therapy services are used when individuals

are having difficulty caring for themselves or their immediate environment or engaging in work and/or familiar leisure occupations.

SPECIFIC NEURODEGENERATIVE DISEASES

The following sections present four specific neurodegenerative diseases: multiple sclerosis (MS), Parkinson’s disease (PD), amyotrophic lateral sclerosis (ALS), and Guillain-Barré syndrome (GBS). The first section discusses MS and provides detailed insights into the clinical reasoning that is involved in occupational therapy treatment and evaluation that may be applicable across conditions. For example, a client with ALS who has fatigue may benefit from the energy conservation techniques mentioned in the section on MS. As such, issues that occur

across neurodegenerative diseases are not elaborated upon in subsequent sections. Each neurological disorder, however, has its own underlying pathology, peculiarities, and prognosis. Understanding these issues helps the therapist develop appropriate intervention plans.

Multiple Sclerosis

MS is the most commonly diagnosed neurological disease that can cause disability in young adults (Stolp-Smith et al., 1997). An estimated 400,000 people in the United States have MS (NMSS, 2006). MS causes severe disability in some people, but many continue to lead active, productive lives and are not severely disabled (Rodriguez et al., 1994; Stolp-Smith et al., 1997). Therapists may have a skewed perspective because it is the relatively severely disabled people who are typically referred for therapy. Unfortunately, by the time a person requires wheeled mobility, a tremendous window of opportunity has passed for interventions such as upgrading ambulation skills, fatigue management, and employment modifications. Therefore, therapists should work to alert physicians and other referral sources to the need for early intervention with persons with MS.

The cause of MS remains unknown. The present theory is an environmental trigger initiates the autoimmune response in people with genetic susceptibility (Trapp et al., 1998). The *multiple* in multiple sclerosis refers to both time and location. The *sclerosis* refers to the hardened or sclerotic plaques that are the scar tissue resulting from autoimmune attacks on the CNS (axons and **myelin** covering).

Axonal transection is considered as significant as demyelination in MS damage (McGavern et al., 2000; Trapp et al., 1998). At least temporarily, demyelinated axons may remyelinate and provide conduction of nerve impulses. Transected axons are permanently destroyed and lose all potential for conduction. At autopsy, Trapp et al. (1998) found as many as $11,236 \pm 2,775$ transected axons in a cubic millimeter of active lesions in subjects with definite MS compared to 0.7 ± 0.7 in white matter of subjects without brain disease. Evidence has also been seen of continued disease activity even during periods that are clinically quiet (Trapp et al., 1998). The demyelination and axonal damage occur in the presence of inflammation, which may explain the rapid improvement often seen in treatment of relapses with corticosteroid anti-inflammatory agents.

Diagnosing MS

Individuals who are diagnosed with MS are typically between the ages of 15 and 50 years, although children are increasingly being diagnosed (Krupp & Macallister, 2005). Peak age of onset is 20 to 30 years. Women are two to three

times as likely to get MS as men. Caucasians of northern European descent have the greatest risk of developing MS (Bourdette, 1997). The incidence of MS increases with distance from the equator, both north and south, similar to the pattern of European settlement (Frankel, 1990; Kurland, 1952). The individual risk is related to where a person spends the first 15 years of life (Alter, 1978; Frankel, 1990) and is about 1:1,000 in the United States (NMSS, 2006).

The diagnosis of MS is based on findings of the history, neurological examination, and overall clinical picture. Additional tests, such as analysis of cerebrospinal fluid and magnetic resonance imaging, are used only to prove the clinical signs and not solely as the basis of the diagnosis. Objective demonstration of two or more white matter lesions in discrete parts of the CNS is necessary to make the diagnosis (Poser et al., 1983). Episodes of CNS dysfunction must be reported or demonstrated over time, or there must be ongoing progression over 6 months with no other explanation of these problems.

Signs of MS include weakness, hyperreflexia, positive Babinski sign, dysmetria, nystagmus, and impaired vibratory or position sensation. The *Expanded Disability Status Scale (EDSS)* (Kurtzke, 1983) and the *MS Functional Composite (MSFC)* (Fischer et al., 2001) are the most commonly used impairment rating instruments in both clinical and research settings. The presence of several signs and symptoms may result in profound limitations such as unemployment and loss of independence.

The Course of MS

The course of MS is typically categorized into four types: relapsing-remitting, secondary progressive, primary progressive, and progressive-relapsing. The relapsing-remitting course of MS produces clearly defined relapses of acute worsening of neurological function followed by partial or complete improvement and then stable periods of remission between attacks. The most common course of MS at the time of diagnosis, relapsing-remitting MS often becomes secondary progressive MS with time (NMSS, 2006; Trapp et al., 1998). People with secondary progressive MS start with a relapsing-remitting course of up to 10–15 years following diagnosis. The secondary progressive diagnosis is typically made when there is continued neurological deterioration. People with primary progressive MS have continuously declining neurological function from onset (Lublin & Reingold, 1996; NMSS, 2006). The fourth course of MS is progressive-relapsing, which differs from relapsing-remitting MS because disease progression continues through the periods between relapses.

Two other terms occasionally used to refer to MS disease course are benign and malignant (Lublin & Reingold, 1996). People with benign MS are fully functional 15 years after the disease onset. People with malignant MS have

rapid progression leading to significant disability or death in a short period.

Disease-Modifying Medications for MS

Four immune-modulating medications approved for use in the United States (NMSS, 2006) have been shown to have positive effects on slowing the disease progression: interferon-beta-1a (Avonex); interferon-beta-1b (Betaseron); glatiramer acetate (Copaxone), and interferon-beta-1a (Rebif). A fifth medication, utilized primarily when the other four drugs no longer seem effective, is mitoxantrone (Novantrone). Medications are also used for the treatment of MS signs and symptoms, such as Amantadine and Provigil for fatigue, baclofen for spasticity, numerous antidepressants for depression, gabapentin for pain, and ditripan for selected urinary problems.

Clients commonly discuss with therapists and ask their opinion on the value of medications. This is true particularly of MS disease-modifying medications because they are not designed to improve the patient's condition or reverse disability but rather slow disease progression. Clients often wonder whether it is worth taking the medications when they are not seeing improvement. The therapist's responsibility is to understand and reinforce the importance of continuing to take appropriate medications.

With the increased stability of the disease course that results from these medications, patients may realize greater benefits from rehabilitation intervention, such that they live fuller lives, remain employed, and participate in high-priority occupations longer. The costs of these medications may make maintaining employment-related prescription coverage a very desirable outcome of therapy.

Potential Emotional, Social, and Economic Consequences

A disease that primarily strikes young adults has substantial economic and employment consequences. Between the ages of 20 and 40, people typically are entering the labor market, establishing themselves in their careers, and forming families. MS, with its common symptoms of fatigue, weakness, difficulties with prolonged standing or walking, and cognitive problems, can impede productivity both at work and at home. Studies conducted prior to the development of disease-modifying medications revealed that more than 70% of individuals with MS were out of the labor force 10–15 years after initial diagnosis (Kalb, 1996). The influence of disease-modifying drugs (data is being collected to look at the effect), however, together with employment disability legislation such as the Americans with Disabilities Act, has resulted in opportunities for people to maintain productive paid employment for longer periods. Persons with MS who leave the labor market are likely to have greater social isolation

and psychological distress, lower incomes, and more limited access to health insurance than if they remain employed (Kalb, 1996).

Symptoms Typically Addressed in Occupational Therapy

A number of symptoms associated with MS may include weakness, sensory changes, balance disturbance, visual changes, bowel and bladder disturbance, cognitive changes, dysarthria and dysphagia, dizziness or vertigo, pain, ataxic gait, tremor, sexual dysfunction, depression, spasticity, and fatigue. The most common and pervasive symptom is fatigue (Freal, Kraft, & Coryell, 1984; Paralyzed Veterans of America [PVA], 1998). A few of these symptoms are described here as they present in MS to provide examples for the implications for occupational therapy services.

Fatigue

Fatigue, one of the most common MS symptoms, affects approximately 60–80% of people with MS (PVA, 1998). Fatigue is a significant contributor to disability and a primary reason people with MS are referred to occupational therapy. People with MS often report that their symptoms tend to worsen when they tire. Fatigue can vary from slight to severe, worsening in the afternoon, and may be related to increased core body temperature (Fig. 40-1). Therapists must be alerted to the types and potential sources of fatigue associated with MS (Definition 40-1) (PVA, 1998). With the types of fatigue identified, the therapist can then target treatments appropriately (Forwell, 2007).

Figure 40-1 Woman in cooling vest cooking at the stove.

DEFINITION 40-1

Types of Fatigue in MS

- Primary MS fatigue— Fatigue directly due to MS disease process. Causation is poorly understood.
- Fatigue due to poor sleep— Sleep problems are often related to muscle spasms, depression, or urinary problems.
- Fatigue due to depression.
- Nerve fiber or motor fatigue—Fatigue probably related to inefficient nerve conduction.
- Fatigue due to impairments, such as weakness and spasticity.
- Fatigue secondary to medication side effects or infections.

Weakness

Weakness is another common symptom resulting in referral to therapy. Weakness may occur in all parts of the body. One of the most common initial complaints is weakness in the foot dorsiflexors resulting in stumbling or falling, especially on uneven surfaces.

Cognition

Approximately 40–60% of people with MS have cognitive problems that vary considerably in severity (Beatty et al., 1995; Rao et al., 1991). In an electronic survey conducted by the Rocky Mountain MS Center in 2003, 73% of respondents reported some cognitive difficulty; of these, 44% had not discussed the subject with a health provider. Cognitive problems are seen at all stages of the disease and are not directly correlated with motor impairments (Maurelli et al., 1992). Studies have found correlations between cognitive impairments and the extent of brain damage on weighted magnetic resonance brain scans (Foong, Rozewicz, & Quaghebeur, 1997; Rovari et al., 1998).

Common cognitive problems of people with MS include word retrieval difficulties; slowed speed of information processing and difficulties learning new material; and problems with attention, concentration, memory, and executive functions, such as diminished judgment, difficulty with abstract reasoning, and reduced verbal fluency organization (NMSS, 1998). People with MS may have other perceptual-cognitive problems, such as visual-spatial impairments that might be evidenced by a tendency to get lost or a history of motor vehicle accidents.

Cognitive problems are likely to vary during the day, increasing in the afternoon or when the client has performed tasks requiring sustained mental concentration (Krupp & Lekins, 2000). The cognitive problems of MS are frequently subtle. Both individuals and their families may

be unaware that cognitive problems are related to the disease and are not personality or psychological issues. There is no “MS personality,” but executive function problems, such as reduced insight and inflexible thinking, may be mistaken for personality changes.

Many areas of cognition may remain intact, and screens such as the *Mini-Mental State Exam* are unlikely to detect such problems (Beatty & Goodkin, 1990). Consequently, it has been necessary to complete a lengthy neuropsychological evaluation. More recently, however, a group of experts came to consensus on a 90-minute, 6-measure neuropsychological battery designed specifically for MS called the *Minimal Assessment of Cognitive Function in MS (MACFIMS)* (Benedict et al., 2002). Baseline individual cognitive performance using appropriate cognitive tests is encouraged for documentation of future change and possible future employment disability claim. Identification of cognitive impairments, information about their effects on function, and the development of individualized compensation strategies may reduce the impact of the problems.

No medications have been proven effective in treating cognitive problems. Intervention, however, that includes group therapy, stress management, computer-assisted retraining, and cognitive-behavioral therapy, has been shown to have positive effects on cognitive function (Brown & Kraft, 2005).

Pain

Pain is estimated to be a problem for 40–60% of people with MS (Moulin, Foley, & Ebers, 1988). Pain directly due to the neurological lesions is considered primary to MS and is usually treated with medications. Pain that is secondary to MS and is often a result of poor posture, positioning, or spasticity is often relieved by therapy.

Spasticity

Spasticity in MS is usually greater in the lower extremities than in the upper extremities. Therapists should be familiar with the standard medications for spasticity, such as baclofen and tizanidine, and their side effect of drowsiness, which may increase fatigue (PVA, 2003). The intrathecal baclofen pump may help to improve function for people with moderate to severe spasticity.

Tremor and Ataxia

Intention tremor occurs during motor performance and is the most common tremor seen in MS. It is one of the most difficult problems to manage (NMSS, 2006). As an activity progresses, the tremor increases such that the tremor is at its worst at the end of range or when the activity is at its target or goal, a point when the greatest control and precision is required. Intention tremor occurs in the upper extremity and is evidenced primarily in the fingers, hand,

and wrist. Intention tremor may also occur in the lower extremities, torso, and neck (NMSS, 2006).

Ataxia presents in the trunk and lower extremities where postural responses tend to occur before upper extremity movements. As such, the proximal segments are too early to counteract the destabilizing effects of the upper extremity. The functional challenges of ataxia are further magnified because of the multiple joints involved in the ataxic movement.

Dysphagia

Swallowing problems in MS are receiving increased attention because research that did not use videofluoroscopy (VF) suggested that 34–43% of individuals studied experienced dysphagia, although only half of these patients reported swallowing difficulties (Calcagno et al., 2002; Thomas & Wiles, 1999). When VF was used, most asymptomatic persons with MS were shown to have abnormalities (Weiser et al., 2002). These studies indicated that risk factors for dysphagia were severity of disease and cerebellar or brainstem involvement. This suggests that occupational therapists should routinely screen for choking, aspiration, and swallowing difficulties.

Adjusting to MS

Although only a small percentage of people with MS are severely disabled, the diagnosis is often devastating. The continual need to adjust to changing symptoms and varying impairments and the fear of and uncertainty about the disease process affect self-esteem, relationships, sexuality, physical activities, vocational goals, and recreational interests. From questions about pregnancy to cognitive changes influencing competence or safety, MS subtly or not so subtly affects every role and relationship. The variability of the disease and the hidden nature of many of the symptoms, such as cognitive changes and fatigue, often make it difficult and uncomfortable to explain to friends, coworkers, and family members.

Each person's reaction to MS events varies and has implications for adjustment. Research has shown that emotion-focused coping techniques were used more often by those experiencing an MS relapse, whereas problem solving and using one's social network were used by persons with MS in remission (Pakenham, 1999). This is supported by evidence that emotional involvement was a marginal indicator of new MS lesions as shown on MRI (Mohr et al., 2002). It has also been demonstrated in a 1-year follow-up study that a greater use of problem-solving strategies to cope was an indicator of better psychological adjustment (Warren, Warren, & Cockerill, 1991).

Initially, people are typically quite preoccupied with their diagnosis because it represents a major new and unknown threat that suddenly challenges former assumptions about the future. As time passes, particularly if the

individuals with MS return to full function, they frequently ignore the diagnosis and pay little attention to MS issues. As long as the inattention does not result in adverse decisions, this may be a healthy attitude. The occupational therapist helps clients process the implications of changes and identifies modifications to minimize their effects. Information about new symptoms may be all a person needs to make a successful adjustment.

Occupational Therapy Evaluation

During the evaluation process of a person with MS, there are unique features that must be understood and incorporated from the individual's history with MS and from his or her life experience. The occupational therapist can then select evaluation tools and methods appropriate for the person with MS.

Occupational Profile

The occupational therapy assessment begins with an interview about the person's goals for therapy and a brief history of symptoms and treatment since diagnosis. This gives the therapist an idea of the course of the disease and the person's past coping style. Throughout the interview, the therapist actively listens for hints of cognitive difficulties. The therapist should always remember that many people with MS who appear symptom free may have significant hidden impairments. Brief questions regarding dizziness, thinking problems, dropping things, numbness and tingling, manual dexterity, prolonged walking and standing, employment, home physical and social environment, leisure interests, bladder problems, ADL, IADL, fatigue, sleeping pattern, equipment, muscle cramping, pain, fine motor activities, falling and balance problems, and stiffness can provide clues to the specific assessments that are likely to be relevant to the person's problems. If possible, particularly if cognitive problems are present, a family member or significant other should be encouraged to attend the evaluation if the client consents. The therapist can best probe for symptoms if the client completes selected survey instruments, such as the *Pain Severity Scale* (PVA, 1998), and lists his or her medications prior to the interview.

Analysis of Occupational Performance: Tools and Methods

The initial interview and history give the therapist a quick indication of what evaluation tools and methods to use. Upper extremity range-of-motion and manual muscle tests, manual dexterity, and dynamometer evaluations are routine unless clearly inappropriate. An evaluation tool being used in MS drug studies that measures short-distance walking, hand function, and cognition is the *MS Functional Composite (MSFC)* measure, which includes a timed 25-ft walk, the *Nine-Hole Peg Test*, and the *Paced Auditory Serial Addition Test (PASAT)* (Fischer et al., 2001).

Therapists select a variety of other standardized evaluation tools and methods based on the client's history and priorities, including:

- Fatigue assessment, such as *Modified Fatigue Impact Scale* and a qualitative assessment (PVA, 1998)
- The *6-Minute Walk Test* to assess endurance and fatigue (Pankoff et al., 2000)
- Sleep history, questionnaire, or diary (PVA, 1998)
- Cognitive screening such as the *MACFIMS* (Benedict et al., 2002)
- Vision evaluation
- Depression instruments such as the *Beck Depression Inventory-18* (BDI-18) (Mohr et al., 1997)
- Gait, bed mobility, and/or transfer assessment such as the mobility section of the *Functional Independence Measure (FIM)*
- ADL, IADL, and dysphagia assessments
- Manual dexterity and coordination tests, such as the *Nine-Hole Peg Test* or *Purdue Pegboard*
- Sensory testing, including *Semmes-Weinstein Monofilaments* and proprioception
- Spasticity assessment using the *Modified Ashworth Scale*
- Tremor and ataxia assessments
- Trigger point evaluation for head, neck, and shoulder muscles
- Vestibular evaluation

Administering such measures, however, requires the therapist to accurately interpret findings in the context of the client's situation. For example, therapists must attempt to differentiate among various types of fatigue by considering results of several assessments. A high score on a depression index, for example, may indicate that depression is contributing to the patient's report of fatigue, while slow times on the *6-Minute Walk Test* may also suggest a nerve fiber or motor fatigue component. Alternatively, information from a sleep questionnaire may provide evidence that disturbed sleep due to urinary frequency is a source of daytime fatigue. It is common for persons with MS to have several different sources of fatigue (Forwell et al., 2007), and multiple health care professionals may be involved in treating them. Finally, if the person reports repeated falling or safety issues, a home visit may also be appropriate.

Occupational Therapy Intervention Process

Goal Setting

Clients' priorities and interests are the cornerstone of goal setting and treatment planning. Frequently, however, both they and the referring provider mistakenly believe they have to live with problems as a result of MS that, in fact, are treatable through therapy. The collaborative

process of goal setting assists to achieve realistic and satisfying outcomes.

Intervention Plan

Following the evaluation and a full discussion of the findings, the occupational therapist discusses the various types of interventions that may help the person manage the identified problems. Due to the progressive nature of the disease, occupational therapy is generally compensatory, teaching the client techniques to manage the symptoms and compensate for disability resulting from impairments rather than alleviating them.

The intervention plan must also take into account the unique issues of individuals with MS. For example, Finlayson (2004) suggests that, for older adults with MS, the occupational therapist must ensure they feel a sense of control over their future, work with families affected by the MS, and advocate for enhanced community support options.

Intervention Implementation

Increasingly, evidence is demonstrating the benefits of occupational therapy intervention for clients with MS. In a meta-analysis of occupational therapy intervention for MS, a positive effect on MS symptoms emerged (Baker & Tickle-Degnen, 2001). Although the level of evidence was not strong and research design flaws were noted, the body of literature is growing to support evidence-based practice.

Due to the interaction of multiple symptoms, intervention usually addresses the relevant occupations where problems present. Isolated treatment of symptoms is unlikely to be very effective, and concurrent occupational and physical therapy is often indicated. For example, physical therapists may treat fatigue by obtaining gait equipment, promoting aerobic exercises, and educating on the difference between energy expenditure during functional activities and exercise routines to increase endurance, while the occupational therapist instructs the client in energy conservation, identifies adaptive equipment, and helps the client modify home and work tasks. Taken together, these changes may significantly reduce fatigue. Occupational therapy intervention typically involves one or more of the following: instruction in activity strategies and energy conservation; establishing an appropriate exercise program; addressing pain and spasticity; implementing cognitive compensations; and identifying equipment, environmental, and employment modifications.

ACTIVITY STRATEGIES AND ENERGY CONSERVATION

If a client complains of fatigue, the occupational therapist should suspect multiple types of fatigue and direct interventions appropriately. Fatigue treatment begins as the therapist provides written and oral explanations of each relevant underlying type of fatigue in an easily understood

fashion. Guidelines for the treatment of fatigue are available (PVA, 1998). At the beginning of intervention, the client typically fills out a detailed activity diary and makes a list of individual goals and priorities (PVA, 1998). The occupational therapist and client use the diary as a starting point to identify and develop activity modifications to reduce fatigue through a systematic analysis of daily work, home, and leisure activities in all environments relevant to the individual.

Most energy conservation strategies are designed to enable persons with MS to use their limited energy on useful, meaningful activities that are important to them. This approach allows the client to exercise choice and control in everyday occupations. Research has demonstrated the effectiveness of occupational therapist-led group intervention for people with MS in energy conservation strategies (Mathiowetz, Matuska, & Murphy, 2001; Mathiowetz et al., 2005; Vanage, Gilbertson, & Mathiowetz, 2003). In addition, throughout the United States, chapters of the NMSS offer a 6-week video course called *Fatigue: Take Control!* developed by Copperman and Hugos (NMSS, 2003). Preliminary studies of course effectiveness have demonstrated positive outcomes (Campbell, 2006). The course provides both information and treatment on MS fatigue and is useful for therapists and people with MS.

Essentially, the therapist helps the client analyze activities, understand rest-activity ratios, incorporate energy conservation strategies and exercise routine, and identify modifications and equipment to help the individual perform valued tasks and activities. Recommended changes may include the following:

- Decrease prolonged standing and walking by modifying tasks and using powered mobility devices for distances.
- Alternate periods of activity with intervals of rest, such as walking, sitting, and then walking again.
- Teach the client about the relationship between increased body temperature and increased fatigue, a phenomenon probably due to a decrease in the efficiency of nerve conduction in a demyelinated CNS.
- Identify modifications to help maintain cooler body temperature, such as layering clothing, purchasing an air conditioner, eliminating hot showers, sitting when showering, using a cooling vest (Figs. 40-1 and 40-2) when walking or active, and not using down comforters when sleeping.
- Shift important activities to the morning.
- Use appropriate equipment, such as a hinged ankle-foot orthosis, to compensate for weakness and reduce the energy required to walk.
- Obtain seating systems for trunk support in wheelchairs and properly fit ergonomic chairs with armrests and possibly headrests for computer and work activities.

Figure 40-2 Woman in cooling vest vacuuming.

Written recommendations and summaries should always be provided at the end of the 2- to 4-hour sessions usually necessary to treat fatigue. Clients should also be encouraged to return to occupational therapy if changes in their symptoms result in problems in their function. Follow-up is recommended in 2–3 months.

Equipment, Behavioral, and Environmental Modifications

Generally, equipment, environmental, and behavioral modifications help patients compensate for weakness, spasticity, tremor, fatigue, ataxia, and cognitive problems. Environmental modifications may help in areas as diverse as providing access to mobility equipment, maintaining independence in ADL, and decreasing the distance to the bathroom. Many standard pieces of adaptive equipment are helpful. Computers and voice-activated software and memory aids may help decrease limitations due to weakness or tremor. Powered wheeled mobility devices, such as scooters or electric wheelchairs, are frequently effective in limiting fatigue and aiding functional limitations related to weakness and spasticity. Powered mobility devices that

are capable of adaptation later, such as adding a tilt feature to an electric wheelchair, accommodate to changing status. Because of fatigue, self-propelling manual wheelchairs are often not indicated. When appropriate, the therapist identifies needed equipment and helps the client arrange equipment trials. Home and/or work visits may be necessary to identify environmental modifications.

Behavioral changes, such as switching an exercise program from lunch to after work and incorporating a lunchtime nap, frequently improve an individual's ability to perform productively. Changing behavior to use the elevator, for instance, might be combined with obtaining a scooter for distance walking and widening the doorways. The combination of the right equipment, behavior changes, and environmental modifications depend upon the individual's needs, resources, and personal preferences. Scheduled follow-ups are recommended to determine the need for new or further modifications as changes occur.

Exercise Programs

Occupational therapists teach clients to monitor the effects of any MS exercise program on both fatigue and their ability to perform high-priority activities to achieve the right activity balance. Two common MS symptoms, fatigue and spasticity, often decrease with regular exercise. Fatigue may be reduced by a structured aerobic program (Petajan et al., 1996; PVA, 1998), and spasticity may be managed with a stretching program done independently or by a caregiver. People with MS who have limited energy must carefully consider the optimal time of day to exercise and the most effective exercises because exercise often reduces the ability to perform activities immediately following the exercise for minutes to hours. Occupational therapists may help the client integrate exercise into his or her routine and to identify the best timing for the exercise regimen.

An aerobic home program will vary based on several considerations. For example, for an employed individual with limited time and leg weakness, a home stationary biking program for 25 minutes three or four times a week may be best. Alternatively, a water exercise program at the recreation center may be beneficial because the buoyancy helps reduce the effects of weakness. Of note, aquatic programs for people with MS should occur in cool pools due to heat sensitivity. Stretching programs for persons with MS generally emphasize relatively few repetitions and holds of 30–60 seconds. Finally, a strengthening program is indicated after a motivated client has successfully maintained a stretching and aerobic exercise program. The neurological weakness in MS cannot be reversed by strengthening, but deconditioning weakness may be reduced.

In general, MS exercise regimens are most likely to be successful if they start slowly and gradually increase in time, repetitions, and/or intensity. A realistic exercise program performed regularly is more desirable than an

ideal program that is never followed. Good illustrations and written instructions should accompany every home program.

Spasticity Interventions

The appropriate intervention for spasticity depends on the severity and the extent to which it interferes with function. In addition to stretching exercises, adapted dressing techniques may prove helpful, such as using a stool to maintain hip flexion to decrease extensor spasm and/or using dressing sticks to compensate for inability to reach the feet. A standing home program may also be employed, using a standing frame for 30–60 minutes per day. Other interventions include resting splints and posture and positioning techniques, such as bringing the hips into 90° or more of flexion to decrease extensor tone in the lower extremities (PVA, 2003). Should a baclofen pump be indicated, the therapist may be involved in assessment prior to pump implantation and should reevaluate following implantation.

Cognitive Compensation

Occupational therapy for cognitive problems helps clients compensate for deficits and inefficiencies. Careful attention to timing of cognitive problems, fatigue levels, nature of the problem, and the environment in which problems occur helps the therapist develop individualized compensations. For example, treating fatigue with energy conservation techniques and mobility equipment often improves self-reported cognitive performance. Performance is also optimized as clients schedule cognitively demanding tasks for periods during the day when they typically feel their best, in minimally distracting environments. For example, tasks requiring higher levels of cognitive function should generally be performed in the morning if possible. Employment responsibilities and requirements should be scheduled to reduce the influence of the problems on job performance.

Education of both the client and his or her significant others regarding the problems is often beneficial. As families and others become aware that these problems are due to disease and not personality, the pressures on the individual can be eased, and modifications can be undertaken. Caution should be exercised in the disclosure of specific cognitive problems to employers, with careful consideration given to individual employment circumstances. Examples of modifications to facilitate cognitive functions include:

- Changing the environment to reduce distractions and interruptions and promote organization
- Teaching problem-solving techniques and reinforcing use of social network to assist with decision making, while showing the disadvantages of emotion-focused strategies

- Using a memory aid, such as a day planner or personal data appliance (PDA)
- Providing simple step-by-step written home and/or work directions
- Changing the difficult cognitive tasks to the morning
- Doing one activity at a time
- Incorporating assistive technology to improve function in high-order IADL, such as money management and bill payment
- Increasing the time allotted for an activity
- Delegating difficult tasks to others
- Using repetition in the learning process
- Assessing driving safety and recommending appropriate interventions

Pain Intervention

For pain related to weakness or spasticity, interventions such as posture training, ergonomic seating, stretching, and focal heat modalities on muscle trigger points may be effective. An ergonomic workstation should be used to minimize pain and fatigue in the employment environment.

Tremor and Ataxia Intervention

The hallmark of occupational therapy intervention for tremor and ataxia is proximal stabilization or support, modified approach to occupations, and adapted equipment and orthoses. Proximal stabilization includes supporting the trunk and larger joints of the upper and lower extremities. For example, for meals, lean one's torso against the table and have arms resting on the table (Gillen, 2000); because the position is sitting, the lower extremity is supported, the trunk is stabilized by leaning against the table, and the shoulder and elbows are supported. A modified approach may be the use of hand-over-hand for writing or dialing a cell phone. If one hand is unaffected by tremor, consider retraining the unaffected hand as tolerated. Orthoses might include a cervical collar to reduce the travel of the head and neck or wrist splints to minimize travel and number of joints in motion in the presence of tremor (NMSS, 2006).

Employment Modifications

The problems described in the preceding sections may affect the performance of individuals with MS at work. Many people with MS apply for disability benefits prematurely because they fear problems that may occur later or do not know about possible modifications. With the advent of medications that slow disease progression, interventions can frequently help individuals continue productive employment for many years. Job modifications may include:

- Changing the times at which tasks are performed
- Limiting prolonged walking and standing by using conference calls, increasing e-mail consultation, using powered mobility devices, and changing to an office near the bathroom
- Alterations in workstations, such as ergonomic chair with armrests, headsets, and mouse and keyboard trays
- Modifying work hours
- Working completely or partly at home
- Using voice-activated software and other technology
- Setting up a place where one can rest periodically

Parkinson's Disease

Parkinson's disease (PD) is a progressive, variable condition. It is most common in later adult years, with the mean age of onset 55–60 years. The incidence of PD is 1%, or 1,000 per 100,000 persons (Stern, 1993). Generally, PD is gradual at onset, and symptoms may take years to develop (Baker & Graham, 2004). PD is typically defined by the three cardinal signs of tremor, **rigidity**, and **bradykinesia**. Postural instability is often added to this list (Conley & Kirchner, 1999). Tremor, commonly the first complaint, is a resting tremor that increases with stress and may present as pill-rolling (Gelb, Olliver, & Gilman, 1999; Uitti, 1998). Rigidity is not a diagnostic feature of PD because it tends to occur at a more advanced stage (Conley & Kirchner, 1999; Gelb, Olliver, & Gilman, 1999). Bradykinesia causes a lack of facial expression, or “mask face,” and affects walking, involvement in activities, and eye blink (Conley & Kirchner, 1999). Postural instability begins with reduced arm swing, head and trunk leaning forward, and shorter strides that progress to a shuffling gait. Lack of postural reflexes often results in increasing falls and **akinesia**, or episodes of “freezing” that reduce or eliminate spontaneous initiation of gait and impede turning and crossing thresholds (Conley & Kirchner, 1999; Gelb et al., 1999; Hass et al., 2005; Ward & Robertson, 2004).

Other symptoms of PD, particularly in the middle to later stages, include swallowing changes, **festinating gait**, autonomic deficits, psychiatric complications (particularly depression), and dementia (Conley & Kirchner, 1999; Gelb et al., 1999; Giladi et al., 2001; Phillip, 1999). When festinating gait is coupled with “freezing” of gait, 37% of those with PD report an increased occurrence of falls (Giladi et al., 2001). For swallowing problems, research has shown that overall disease severity is not related because a high percentage of those in early stages have difficulties with delayed swallow reflex, residues of food materials, and abnormal tongue control that may result in nutritional problems (Colcher & Stern, 1999; Fuh et al., 1997).

Dementia related to PD occurs in 15–20% of individuals and tends to occur in those who are older at the time of

diagnosis and who have a long history of the disease and depression (Aarsland et al., 1996). The areas of cognitive function that seem to be most affected are motor planning, abstract reasoning, concentration, organizing, and sequencing (Monza et al., 1998; Ward & Robertson, 2004). It has also been shown that persons with PD rely on external cues, feedback, and repetition when learning new tasks (Ward & Robertson, 2004).

The cause of PD is thought to stem from both hereditary and environmental factors. Hereditary factors have been linked to a chromosome 4 mutation in 5–10% of cases, although the contribution of this mutation to PD is uncertain (Conley & Kirchner, 1999; Muentner, Forno, & Hornykiewicz, 1998). Environmental factors implicated in PD include exposure to well water and pesticides and living on a farm (Conley & Kirchner, 1999; Marder et al., 1998).

The pathogenesis of PD is related to the loss of dopaminergic neurons of the substantia nigra that provide input to the corpus striatum and, in part, modulate the thalamus and its connections to the motor cortex (Conley & Kirchner, 1999; Ward & Robertson, 2004). There is also suggestion that further biochemical anomalies in the basal ganglia are present (Conley & Kirchner, 1999).

Diagnosing PD

In autopsy studies, PD has been shown to be misdiagnosed in 25% of cases (Calne, 1995). In part, the difficulty is a result of the lack of definitive biological markers. Clinical imaging techniques (positron emission tomography) remain experimental (Conley & Kirchner, 1999). At present, diagnosis is based on clinical evidence using clinical diagnostic criteria.

The Course of PD

PD has been described as having either five stages (Hoehn & Yahr, 1967) or three stages (Bradley, 1996) (Definition 40-2). These stages are broadly described by presence of symptoms, functional implications, and response to medications.

Potential Emotional, Social, and Economic Consequences

In the initial stages of PD, the degree of physical disability is minimal. The emotional burden and social consequences, however, can be marked. Resting tremor, rarely resulting in motor disability, is a frequent source of psychological distress, with many individuals reporting feeling embarrassed or self-conscious (Uitti, 1998). In later stages, Peto, Jenkinson, and Fitzpatrick (1995) found that tremor and rigidity were highly correlated with distress and reduced quality of life. Another study found that the highest predictors of poor quality of life for persons with PD were depression, sleep disorders, and increasing dependence (Karlson et al., 1999). Major depression or

DEFINITION 40-2 *definition*

Stages of Parkinson's Disease

Hoehn & Yahr (1967)

Stage 1: Unilateral symptoms, no or minimal functional implications, usually a resting tremor.

Stage 2: Midline or bilateral symptom involvement, no balance difficulty, mild problems with trunk mobility and postural reflexes.

Stage 3: Postural instability, mild to moderate functional disability.

Stage 4: Postural instability increasing, though able to walk; functional disability increases, interfering with ADL; decreased manipulation and dexterity.

Stage 5: Confined to wheelchair or bed.

Bradley (1996)

Early: Not disabling; monosymptomatic; responds well to medication; may remain at this level for years.

Non-fluctuating: Some disability; levodopa added to medication regimen; 80% of function is restored.

Fluctuating: Function limited; side effects to levodopa; difficult-to-control symptoms, postural instability, and gait disturbance become debilitating.

depressive symptoms have been found in 45% of those with PD, suggesting that early identification and intervention are crucial (Karlson et al., 1999). Self-esteem is challenged when the person with PD is unable to perform previous roles or mundane tasks, such as feeding or dressing oneself (Gillen, 2000). Persons with PD report that fatigue, pain, and social isolation contribute to distress and compromised quality of life (Friedman & Friedman, 1993; Karlson et al., 1999).

The economic implications of PD are frequently related to the cost of medications, wheeled mobility, accessibility modifications, self-care and safety equipment, and in-home support. If the individual is employed, increasing limitations may require employment modifications and early application for disability benefits accompanied by loss of income. PD-related dementia may decrease the ability of the person to manage finances. An elderly caregiver is also likely to require caregiver assistance and/or respite care, which is a further financial consideration. Finally, if required, placement in a long-term care facility is costly.

The social consequences of PD are striking. In the early stages, for example, handwriting may be somewhat shaky and micrographic, which reduces legibility (Conley & Kirchner, 1999; Gillen, 2000; Uitti, 1998). In the intermediate and later stages, the voice softens and becomes monotone. Reduced facial expression and minimal hand gesturing also contribute to decreased communication with others (Tickle-Degnen, 2006; Uitti, 1998). The person with PD may have waning interest in social and/or previously enjoyed leisure activities. PD challenges ability to

cope and alters relationships and roles in families with increasing dependence. Both the individual and family members may have feelings of guilt, despair, and anger as care giving increases and falls to a spouse or adult child (Baker & Graham, 2004).

Occupational Therapy Evaluation

In the early stages of PD, occupational therapy is rarely indicated unless there are functional limitations or psychological issues. At this stage, it is recommended that interests and roles are maintained within and outside of the home including employment, social activities, and driving (Baker & Graham, 2004). Occupational therapy is most often required in the intermediate and later stages of the disease (Hoehn and Yahr [1967] stages 3 to 5). Evaluation should include a brief history and, in the intermediate stages, identify occupational performance problems related to reduced mobility, safety issues, swallowing, fine motor incoordination and dexterity, slowed movements, **cogwheel rigidity**, and depressed affect. Another area of evaluation concerns occupations that have been eliminated or where reduced time is spent (Gillen, 2000). Some examples of individual impairments and limitations in activities that may be included in screening are:

- Difficulties with coordination and manipulation in home, community, and work activities (writing, manipulating utensils/tools, and managing clothes fasteners)
- Difficulties with safe mobility, such as walking on even and uneven surfaces, stair climbing, driving, and moving from sit to stand, that limit home, community, and work tasks
- Bradykinesia, postural instability, and rigidity that limit chosen occupations
- Difficulties with ADL and IADL due to bradykinesia, rigidity, and cognitive function
- Difficulties with swallowing or other meal time problems that prolong eating and reduce intake
- Fatigue and cognitive problems that affect activities and competence
- Sexual activity limitations related to bradykinesia, rigidity, fatigue, depression, anxiety, and psychosocial problems
- Sleep disturbances

Occupational Therapy Intervention Process

Goal Setting

When setting goals with the client with PD and significant others, the occupational therapist must be mindful of and balance activity energy demands with motivation and frustration as well as caregiver time in the context of the

dependence-interdependence-independence continuum (Gillen, 2000). Participation of others in this process is frequently crucial to the viability and success of interventions.

Intervention Implementation

Interventions vary with the individual's and significant other's priorities and resources, stage of the disease, occupational difficulties identified through the evaluation, and activities in which they participate. In addition to the client, many of the procedures described in Procedures for Practice 40-1 should also be suggested to significant others to incorporate at home and in other relevant environments. Occupational therapy intervention for persons with PD has been evaluated in numerous studies showing an overall effectiveness of occupational therapy and other rehabilitation therapeutic interventions (Murphy & Tickle-Degnen, 2001).

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), popularly known as Lou Gehrig's disease, is a late-onset fatal neurodegenerative disease of upper motor neurons (UMN) and lower motor neurons (LMN). The prevalence of ALS is 5 to 8 cases per 100,000, and it occurs more often in men (Mitsumoto, Chad, & Piro, 1998). No special test is available to establish the diagnosis and the cause is unknown. Initial symptoms vary widely and diagnosis is a careful, multistep system of exclusion.

The average age at onset is 58 years, although adults as young as 20 have been diagnosed. Age-specific incidence and mortality rates in sporadic ALS increase until the eighth decade, with a peak between 55 and 75 years of age. Age at onset and the pattern of symptom development is useful for determining an individual's prognosis, with a younger onset of upper motor neuron origin having a somewhat better prognosis. It has also been shown that baseline scores on the *Short Form-36* are significant predictors of health status over time (Norquist et al., 2003). Generally the prognosis for individual patients is best left to neurologists with expertise in ALS.

In ALS, voluntary muscle control is affected, and early manifestations indicating UMN or LMN disease vary with the site of the initial disease process. UMN damage results in general weakness, spasticity, and hyperreflexia. LMN involvement results in weakness or muscle atrophy of the extremities, cervical extensor weakness, **fasciculations**, muscle cramps, and loss of reflexes. Speech, swallowing, and breathing may be affected by damage to the bulbar nerves. Early bulbar involvement and/or advanced age at time of diagnosis tend to indicate a quicker course of the disease (Mitsumoto et al., 1998). Speech impairment is common (Ball et al., 2004a). Generally people with ALS develop both UMN and LMN symptoms as the disease

PROCEDURES FOR PRACTICE 40-1

Occupational Therapy for PD

Interventions Related to Decreasing Isolation and Communication Problems

- Education about timing important activities to synchronize with medication regimen so that participation can occur when medications are at the height of effectiveness
- Modification of leisure activities to encourage participation and decrease isolation
- Information on support and advocacy groups
- Caregiver training for modifying communication and social activities
- Writing modifications, including enlarged felt-tip pen and writing when rested
- Communication aids, including speed dial, large-key telephones, dictating devices, and remote control systems for lights, television, and other frequently used devices
- Providing home exercise program to maintain facial movement and expression

Interventions Related to Safety

- Instruction in sit-to-stand techniques and bed mobility
- Instruction to manage “freezing” while walking, includes avoiding crowds, narrow spaces, and room corners; reduce distractions such as not carrying items while walking; reduce clutter in pathway; doing one activity at a time; not hurrying to answer the phone; focusing when changing directions; rhythmic beat or counting to maintain momentum
- Demonstration of equipment to increase independence and safety, such as a raised toilet seat, toilet grab bars, shower bench, sink chair, soap on a rope
- Prescribing walking aids (walker for festinating gait)
- If required, a wheelchair having a proper seating system, cushion, and adjusted foot/leg rests and arm rests that is appropriate for transporting within the community

- Good, uniform lighting, particularly in narrow spaces and at doorways
- Providing home and group exercises to maintain mobility, coordination, posture, and tolerance and reduce effects of festinating gait, bradykinesia, and postural instability
- Home assessment and modifications that might include alterations to the bathroom (e.g., non-skid surfaces, bath bench/chair) and flooring (e.g., eliminating throw rugs), horizontal strips on carpet where “freezing” episodes occur, and reducing furniture congestion (Gillen, 2000)

Interventions to Maintain Independence and Participation

- Modifying eating routine to include small portions, reduced distractions, more frequent meals that allow adequate time, and adapted equipment as required, such as non-slip surfaces for plates, built-up handles, and lids on cups
- Instruction in using adult absorbent underwear if necessary
- Demonstrating voice and facial exercise programs
- Advising on modifying sexual routine, such as to occur after resting and urination
- Instruction of energy effectiveness strategies in home, leisure, and work activities
- Modifications to reduce or eliminate the need for fine motor control, such as clothing with minimal fasteners or velcro closures
- To reduce impact of cognitive and perceptual limitations, use visual cues, rhythmic music, and a non-distracting environment; speak slowly and clearly; use simple instruction; provide one new concept at a time; and practice with repetition (Ward & Robertson, 2004)
- Home assessment

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Justifying a Home Assessment for a Client with Parkinson’s Disease (PD)

An occupational therapist considers it essential to complete a home assessment for someone with PD who lives alone and is falling and losing weight. Why does the therapist consider it necessary, and how could it be justified to a third-party payer?

progresses. Cognition may be affected, although this is relatively rare, whereas eye function, bowel and bladder control, and sensation are spared.

No known cure or effective pharmacological treatment is available for ALS, although riluzole (Rilutek), an antiglutamate agent, is the only Food and Drug Administration–approved medication for the treatment of ALS. Other medications can assist in the management of symptoms such as fasciculations, spasticity, anxiety, insomnia, and excessive saliva but do not affect the progression of the disease. Tracheotomies, gastrostomies, and assisted ventilation are used to ease problems with eating and breathing (Mitsumoto et al., 1998). Due to the progressive nature of ALS and vast array of symptoms

and potential interventions, a multidisciplinary health care team approach improves the quality of life for individuals with ALS (Van der Berg et al., 2005).

The Course of ALS

Six stages of ALS are recognized and described according to clinical features (Table 40-1). The median duration of life after diagnosis ranges from 23 to 52 months, but a significant proportion of patients survive 5 years or more (Mitsumoto et al., 1998). Focal weakness of the arm, leg, or bulbar area is a common initial symptom (Mitsumoto et al., 1998). Atrophy may begin in the hands, with wasting of the thenar and hypothenar eminences, as well as in the shoulder musculature. Finger extension is usually affected earlier than grip strength because of dorsal and palmar interossei wasting. Walking and bed mobility are affected, and falling is common with lower extremity weakness. Upper and lower extremity weakness makes transfers and getting up from the floor after a fall increasingly difficult. Speech and swallowing problems may arise early in the disease course.

Potential Emotional, Social, and Economic Consequences

ALS is a devastating disease for individuals and their families. Its relatively fast progression, frequently involving early loss of upper extremity function and possibly speech and swallowing, means that the disease quickly affects quality of life and the ability to perform ADL, IADL, and employment tasks. It has been shown that those with ALS, as compared to normal controls, have more depression,

external locus of control, and feelings of hopelessness (McDonald et al., 1994) and that this is not related to physical function or sociodemographic factors (Plahuta et al., 2002; Robbins et al., 2001).

People with ALS and their families have little time to make psychological adjustment to the diagnosis and its implications before having to deal with their loved one’s increasing disability. The acceptance by family members of the ALS diagnosis may affect willingness to be involved in planning, incorporating changes necessary to maximize the independence of the person with ALS, and making informed choices for intervention (Ball et al., 2004a).

People frequently withdraw from employment soon after the diagnosis and may also have to confront economic problems due to loss of income and possibly health insurance issues. Since the age group most commonly affected is often employed and actively involved in family and community activities, the abrupt change in status is devastating.

Occupational Therapy Evaluation

The specifics of the occupational therapy assessments should be based on clearly defined levels of function (see Table 40-1) and the individual’s needs and priorities. Early interventions should target the individual’s symptoms as these affect their occupations. As ALS progresses, interventions not only focus on individual function, but also on the physical environment and social network. This is supported by Neudert, Wasner, and Borasio (2004), who showed that the quality of life of a person with ALS with a supportive family and social network remains stable over time despite reduced health status.

Table 40-1. Rehabilitation of Patients with ALS at Various Stages

Stage	Characteristic Clinical Features	Activities to Maintain Motor Function	Equipment
I	Ambulatory, no problems with ADL, mild weakness	Normal activities, moderate exercise in unaffected muscles, active range-of-motion (ROM) exercise	None
II	Ambulatory, moderate weakness in certain muscles	Modification in living; modest exercise; active, assisted ROM exercise	Assistive devices
III	Ambulatory, severe weakness in certain muscles	Active life; active, assisted, passive ROM exercise; joint pain management	Assistive devices, adaptive devices, home equipment
IV	Wheelchair-confined, almost independent, severe weakness in legs	Passive ROM exercise, modest exercise in uninvolved muscles	Assistive devices, adaptive devices, wheelchair, home equipment
V	Wheelchair confined; dependent; pronounced weakness in legs, severe weakness in arms	Passive ROM exercise, pain management, decubitus prevention	Adaptive devices, home equipment, wheelchair
VI	Bedridden, no ADL, maximal assistance required	Passive ROM exercise, pain management, prevention of decubitus ulcers and venous thrombosis	Adaptive devices, home equipment

Information from Sinaki, M. (1980). Rehabilitation. In D. W. Mulder (Ed.), *The diagnosis and treatment of amyotrophic lateral sclerosis* (pp. 169–193). Boston: Houghton Mifflin. Reprinted with Permission from Mitsumoto, H., Chad, D., & Piro, E. (1998). *Amyotrophic lateral sclerosis. Contemporary neurology series*. Philadelphia: Davis.

To assist with the occupational therapy evaluation process, a number of measures are suggested such as the *ALS Functional Rating Scale* (Mitsumoto, Chad, & Piro, 1998). To determine ongoing functional ability, ADL and IADL assessments should be included in all evaluations. Functional limitations may be due to reduced upper extremity ability, and thus the *Purdue Pegboard* or other timed upper extremity function tests and standard range-of-motion and manual muscle testing are useful measures. Limitations may be due to fatigue, which has been shown to affect physical quality of life (Lou et al., 2003) and can be assessed with the *Multidimensional Fatigue Inventory*. As oral communication and swallowing function declines (Higo et al., 2004), assessment and intervention is required to ensure ongoing nutritional needs are met and social participation is maintained. As the disease is progressive, reevaluations should be done at repeated visits.

Occupational Therapy Intervention Process

Goal Setting

The progressive nature of the disease necessitates that rehabilitation in ALS be compensatory, focusing on adapting to disability and preventing secondary complications. Goals center on keeping the person as active and independent as possible for as long as possible. Here are some examples of occupational therapy goals for a client with ALS in the early stages:

- Optimize strength and range of motion using home exercise programs (Drory et al., 2001).
- Maintain function in ADL and IADL through use of assistive or adaptive devices.
- Decrease pain and fatigue in the neck and extremities through use of splints and orthotics.
- Employ joint protection, pain management, energy conservation, and work simplification techniques.

As motor function declines, mobility and self-care become increasingly difficult. Home evaluations and/or in-home therapy are important in the later stages of the disease, and intervention goals largely focus on enabling the caregiver to assist the client safely and effectively. The occupational therapist helps the caregiver-client team to do the following:

- Optimize safety, assess positioning, perform safe transfers, and maintain skin integrity
- Employ augmentative communication equipment (Ball et al., 2004a)
- Assess and manage dysphagia (Higo et al., 2004)
- Optimize social participation (Ball et al., 2004b)
- Identify and obtain equipment, such as a hospital bed, to allow continued mobility
- Employ environmental modification

Throughout the stages of the disease, the therapist remains sensitive to the client's, family's, and caregiver's needs and stresses as the demands of care giving perpetually change. Physical demands, financial concerns, and transformation of the home into a hospital-like setting produce enormous strain on the client and the caregivers (Mitsumoto et al., 1998). Open discussions and close collaboration with clients, caregivers, and the ALS team help to address and plan for the client's changing needs.

Intervention Implementation

When treating clients with ALS, therapists must be aware of the client's level of gadget tolerance, financial resources, and social and cultural context. Special considerations for exercise, equipment, assistive technology, and dysphasia management for this diagnostic group are briefly reviewed.

EXERCISE

Active and passive range-of-motion, strengthening, endurance, stretching, and home breathing exercise programs are all appropriate at various stages of the disease. Research indicates that they are effective for minimizing secondary complications (Mitsumoto et al., 1998). Attention to overexertion, potential secondary problems, muscle spasms, and careful monitoring of fatigue are important to a successful exercise program. A client may initially be able to perform an independent home stretching program, but as the disease progresses, the program may become too fatiguing or difficult. At that time, the caregiver may be asked to learn how to perform the program.

EQUIPMENT AND ASSISTIVE TECHNOLOGY

A variety of assistive and adaptive equipment may help the client achieve the highest possible level of independence at the various stages of ALS (see Table 40-1). Assistive equipment such as a neck collar or universal cuff may be helpful. Mobility equipment or aids, depending on level of function, may include a foot-drop splint, cane, and/or walker. In a study by Trail et al. (2001), 57% of a moderately disabled group used a mobility device in addition to a wheelchair. The occupational therapist's role is to inform clients and caregivers about potentially helpful adaptive equipment at the various stages of ALS.

As the disease progresses, home assessment and client caregiver consultation inform selection of a wheelchair. Since independent walking becomes difficult in a rapidly progressing disease such as ALS, ordering the wheelchair may need to be expedited. Desirable features for a manual wheelchair are lightweight frame, small turning radius, high reclining back, and supports for head, trunk, and extremities (Trail et al., 2001). As ALS progresses, ideally a power wheelchair has adaptable controls; maneuverability;

the ability to add tilt or recline features; supports head, trunk, and extremities; and enables the client to access the community (Trail et al., 2001). Transporting the wheelchair in a vehicle should be considered when making purchase decisions as well as ramps or elevators required to access home and public spaces.

If the social network is prepared to adapt to the use of such technology, environment controls are extremely useful as the disease progresses. This technology, for example, includes hands-free operation of phone, lighting, call alert systems, door (un)locking systems, computers, TV, radio, and other equipment and devices.

DYSPHASIA

Swallowing difficulties present at various stages, particularly when bulbar involvement is apparent. Interventions may include, but are not limited to, reducing distractions during mealtime (limit conversation and other activities), altering food consistency (i.e., thicken liquids), teaching manual techniques to swallow, and ensuring adequate time for meals. Early introduction of an alternate route of nutrition may be indicated if nutrition and weight maintenance become issues.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is an inflammatory disease resulting in axonal demyelination of peripheral nerves (Dematteis, 1996; Meythaler, DeVivo, & Braswell, 1997). Characteristics of GBS include a quickly progressing, symmetrical ascending paralysis starting with the feet; pain, particularly in the legs; absence of deep tendon reflexes; mild sensory loss in glove-and-stocking distributions; cranial nerve dysfunction with possible facial palsy; an autonomic nervous system response of postural hypertension and tachycardia; respiratory muscle paralysis; and pain, fatigue, and urinary dysfunction (Gregory, Gregory, & Podd, 2005; Hughes & Rees, 1997; Meythaler et al., 1997). Severity of symptoms varies from so mild that medical attention is unlikely to severe disease that may cause death reportedly in 1–10% of cases (Hughes & Rees, 1997; Carroll et al., 2003; Khan, 2004).

The cause of GBS is unclear. Its distribution is known to be worldwide, with an incidence of 1.3 to 2 per 100,000 (Hughes & Rees, 1997). Men are slightly more commonly affected than women, and GBS most often occurs in adults 20–24 years and 70–74 years of age (Hughes & Rees, 1997; Jiang et al., 1997). No evidence supports hereditary susceptibility or vaccinations as causes of GBS, although there are reports concerning previous viral infections (Hughes & Rees, 1997). Enteritis precedes GBS in 41% of cases, and respiratory tract infections and HIV or AIDS may also precede it (Hughes & Rees, 1997; Jiang et al., 1997; Carroll et al., 2003).

Diagnosing GBS

Diagnosis of GBS entails a detailed history of symptoms and a complete physical and neurological examination that includes nerve conduction velocity tests and cerebral spinal fluid analysis (Hughes & Rees, 1997; Muscular Dystrophy Association of Canada, 1997). The medical interventions for GBS attempt to lessen the severity and hasten recovery but do not cure the disease (Muscular Dystrophy Association of Canada, 1997). Treatments for GBS include intravenous immunoglobulin, plasma exchange otherwise known as plasmapheresis, and steroids (Rees et al., 1998).

The Course of GBS

GBS has three phases. In more than 95% of people with GBS, the onset, or acute inflammatory phase, manifests as an acute weakness in at least two limbs that progresses and reaches its maximum in 2–4 weeks with increasing symptoms (Hughes & Rees, 1997; Dematteis, 1996). Mechanical ventilation is required for 20–30% of individuals with GBS (Dematteis, 1996). This is followed by the plateau phase when the greatest disability is present, as are many symptoms described earlier. During this phase, which may last for a few days or weeks, there is no significant change. Finally, the progressive period of recovery, when remyelination and axonal regeneration occur, may last for up to 2 years, although the average length of this phase is 12 weeks (Jiang et al., 1997; Meythaler, DeVivo, & Braswell, 1997). The recovery generally starts at the head and neck and proceeds distally (Karavatas, 2005). The degree of recovery varies, with complete return of function in approximately 50% of patients, whereas 35% experience some residual weakness that may not resolve. The remaining 15% of patients experience more significant permanent disability (Dematteis, 1996). In a study by Parry (2000), fatigue was the most common residual problem for 93% of patients. Gregory, Gregory, and Podd (2005) suggest that subtle cognitive deficits may be present as limitations in executive functions, short-term memory, and decision making.

Potential Emotional, Social, and Economic Consequences

Emotional and psychological reactions are a response to the rapid onset of symptoms and the degree of disability. Shock, despair, fear, and anger may be consuming (Dematteis, 1996). At the height of the acute phase of the disease, should the individual be unable to speak or move, fear of the unknown and frustration are often overwhelming (Muscular Dystrophy Association of Canada, 1997). As recovery progresses and improvement is slow, the psychological adjustment, impatience, and frustration associated with residual disability may be daunting.

For young adults, the impact of GBS can have educational, employment, and/or economic implications. This age group is launching careers and may have debt with only small savings. For those who develop GBS in later years, particularly in retirement, the economic effect may be less. Should the recovery phase last several months, the burden on family, colleagues, and/or friends who may be required to absorb the roles previously held by the person with GBS may be profound. A New Zealand survey describes the marked psychosocial impact of GBS and the need for professional intervention (Gregory et al., 2005).

Occupational Therapy Evaluation

Referral to occupational therapy is common when the course of GBS is moderate to severe. Approximately 40% of all GBS patients require rehabilitation services (Meythaler et al., 1997).

Screening and assessment during the plateau phase typically occur in intensive care, when the individual is undergoing extensive medical procedures such as plasma exchange or intravenous immunoglobulin. During this period, occupational therapists evaluate communication, control of the environment as appropriate, comfort, and level of anxiety.

During the recovery phase, occupational therapists evaluate mobility, self-care, communication, leisure, and reintegration into the workplace as appropriate. During this phase, OT services can be provided in an inpatient rehabilitation facility, through an outpatient program, and/or at home or work (Karavatas, 2005).

Occupational Therapy Intervention Process

Goal Setting

As the natural course of GBS is improvement, patients and caregivers tend to be optimistic about recovery. The long-term goal is full recovery, so that the individual performs at the same level as prior to the onset of GBS with or without modification.

Intervention Implementation

Modifications during the plateau phase should be considered temporary. Examples of interventions include:

- Developing communication tools, such as sign or picture board
- Ensuring access to the nurse call button, TV, and lights by remote control, as appropriate
- Modifying the telephone for hands-free use
- Modifying lying and sitting positions for optimal function and comfort
- Positioning for trunk, head, and upper extremity stability
- Teaching about GBS and strategies to reduce anxiety

Recovery-phase interventions are oriented to the resumption of activities and roles. Examples of occupational therapy interventions include:

- Providing activities and dynamic splints to maintain range of motion, particularly of wrists, fingers, and ankle (hinged drop-foot orthosis)
- Instructing in safe mobility and independent transfers
- Training in modified self-care techniques and adapting other daily activities
- Adapting modes of communication according to the person's priorities
- Encouraging access to the community
- Modifying and encouraging reengagement in routine activities, as appropriate
- Adapting equipment and modifying behavior in home, leisure, and work activities
- Instructing in energy conservation and fatigue management strategies
- Modifying employment roles, tasks, and environment, as indicated
- Fine motor program to enhance strength, coordination, and sensation
- Home assessment and modifications, as appropriate, to facilitate return to home

EVIDENCE-BASED RESEARCH ON OCCUPATIONAL THERAPY FOR NEURODEGENERATIVE DISEASES

Although expert consensus (PVA, 1998) may agree that occupational therapy is effective in treating neurodegenerative diseases, little empirical evidence confirms these views. Consequently, occupational therapy described here is based on commonly held assumptions about treatment and not on well-designed randomized controlled trials establishing its effectiveness. Even in the randomized controlled trials that have been published, occupational therapy is frequently not studied alone but is one of several interventions with other rehabilitation therapies (Aisen, 1999; Baker & Tickle-Degnen, 2001; Solari et al., 1999), typically in an inpatient rehabilitation setting (Freeman et al., 1997). Most occupational therapy for persons with these diseases takes place in outpatient, home health, or long-term care facilities, and consequently, the generalizability of these team-based inpatient studies is questionable. The study by Mathiowetz et al. (2005) of the effectiveness of outpatient group occupational therapy in energy conservation strategies in MS is a notable exception. It remains useful, however, to refer to a meta-analysis in which 10 of 15 studies demonstrated the positive effect of occupational therapy

intervention on the capabilities and abilities of clients and 9 of 15 studies showed favorable outcomes in activities and tasks (Murphy & Tickle-Degnen, 2001). This analysis also showed that 63% of those with PD who received therapy improved as compared to 37% who did not receive therapy.

Problems, however, with existing research are the lack of attention to placebo groups, small sample size, selec-

tion bias, poor internal validity, and lack of control for medications. At a time when evidence-based outcomes are increasingly required for reimbursement, occupational therapists must carry out well-designed research studies of interventions and publish findings in peer-reviewed journals to support the effectiveness of interventions in achieving positive outcomes.

CASE

EXAMPLE

Mrs. K: Multiple Sclerosis

Occupational Therapy Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information Ms. K., a 37-year-old woman diagnosed with relapsing-remitting multiple sclerosis (MS) 2 years prior to her first visit to occupational therapy, had recently submitted her resignation to her employer of 15 years. Upset by having to quit her administrative job, she reported the following problems: (1) severe fatigue, which had increased in the past year and resulted in her inability to do her normal household tasks, perform her ADL, and work without becoming exhausted; (2) a marked increase in lower extremity weakness, with decreased ability to perform tasks requiring prolonged walking or standing; (3) a feeling of heaviness and stiffness in upper and lower extremities; (4) decreased manual dexterity; (5) frequent falling; (6) daily headaches; (7) dizziness; (8) bladder problems; (9) vision problems; (10) disturbed sleep; and (11) increased attention and memory problems. Her adaptive equipment at the time of her initial therapy visit included a manual wheelchair and a quad cane. She had quit driving. Her husband was very supportive and had recently stopped adoption proceedings because of her MS changes. Medications included a bladder medication and a MS disease-modifying drug.</p>	<p>Understand the patient’s diagnosis and context of OT services</p> <p>Know the person</p>	<p>“This is not a new diagnosis for Ms. K., though it is her first interaction with occupational therapy because she may not have needed services in the past.”</p> <p>“I will want to get to know how long Ms. K. has experienced her current problems and how she has tried to address them before her resignation from work. It appears that she has made some rather significant and life-altering decisions about her future. In my experience, some patients respond to the relapse of MS symptoms by fearing the worst, not really understanding MS and all the potential treatment options. Getting a sense of ‘where she is at’ will be my priority.”</p>
<p>Reason for Referral to Occupational Therapy Fatigue management and work evaluation.</p>	<p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>“Ms. K. is not working and is having difficulty at home. Since her husband is supportive, he will likely help to make any changes I suggest in therapy. She is probably using inadequate fatigue management strategies.”</p>

Assessment Process and Results

The occupational therapy evaluation showed the following areas of concern: decreased strength bilaterally in the lower extremities and her dominant upper extremity; increased tone bilaterally in the lower extremities; decreased sensation and manual dexterity in the dominant upper extremity; high levels of dizziness with head movement; head, neck, and shoulder muscle trigger points; and marked fatigue. Ms. K., determined not to give in to the disease, had made no adaptations to reduce energy expenditure in daily activities. She was scheduled to have a neuropsychological assessment to identify her current baseline function and problem areas. Her equipment was self-selected and inappropriate for her problems. She was not taking any medications to manage spasticity or fatigue. Her seating at home and work was not supportive. Ms. K. purposefully climbed the stairs in the morning and had a desk distant from the bathroom to get exercise, since she had no exercise program.

Consider evaluation approach and methods

“I think I will start with an interview to get to know Ms. K., her past coping strategies, and her primary concerns. Depending on that information and what I already know from the client information, I will use some specific assessments such as the *Modified Fatigue Impact Scale*, *Modified Ashworth Scale*, and the *Functional Independence Measure*.”

Interpret observations

“I’m thinking that fatigue underlies most of her occupational performance problems and that weakness and spasticity are adding to this. It also seems that her current equipment and environmental setup are not helping her. I am also very concerned about what (I think) is a premature resignation from her work and withdrawal from driving.”

Occupational Therapy Problem List

1. Use of inappropriate equipment
2. Minimal understanding and use of fatigue management strategies
3. Has recently resigned from work without knowledge of options
4. Is not involved in a home exercise program
5. Has stopped driving without investigating options

Synthesize results

“Her occupational performance problems are due to inadequate information and modifications related to fatigue, equipment, ergonomic layout, and exercise routine.”

Occupational Therapy Goal List

In collaboration with Ms. K., the following goals were established:

- Identify and obtain appropriate power mobility equipment
- Incorporate at least six energy-saving strategies into her day
- Withdraw resignation notice from employer
- Make changes in work area by obtaining a headset and ergonomic chair and move her desk closer to the bathroom
- Submit a request to her employer for power automatic door openers on bathroom
- Apply to vocational rehabilitation and work with therapist and vendor to install hand controls on her vehicle
- Demonstrate that she can independently perform head, neck, and shoulder stretching exercises

Develop intervention hypotheses

“I will sequence the intervention by focusing on what is most important to Ms. K. I hypothesize that education on energy effectiveness strategies will improve success in performing daily tasks and assessment and alteration of the work environment while appropriate equipment will make it possible for her to return to work. I advocate the use of hand controls to return Ms. K. to independent driving.”

Select an intervention approach

“I think the compensatory and educational approach will be most useful.”

Consider what will occur in therapy, how often, and for how long

“I recommend one outpatient treatment session a week for 6 weeks. We will work closely with the physical therapist who will attend to pain, gait, and exercise interventions.”

Intervention

The occupational therapy intervention included: (1) instruction in and adoption of energy conservation techniques at home, at work, and in community (Mathiowetz, Matuska, & Murphy, 2001; Mathiowetz et al., 2005); (2) identifying and obtaining powered mobility equipment (Mathiowetz and Matuska, 1998); (3) decreasing daily headaches with head, neck, and shoulder stretching and focal heat; (4) identifying and obtaining equipment to decrease energy consumption at home and work (Mathiowetz et al., 2005; PVA, 1998); (5) with

Assess the patient’s comprehension

“Ms. K. was motivated to participate in therapy sessions, particularly because there was a potential to return to work. From my experience, I realize the success of therapy depends on her ability (and her husband’s) to incorporate suggested techniques, access and use equipment appropriately, and implement ergonomic changes into her daily life.”

Understand what she is doing

Compare actual to expected performance

“When we started talking about fatigue, Ms. K. realized she was fighting the fatigue rather than managing it. At first, it was tough to incorporate the sug-

therapist assistance, identifying and obtaining ergonomic seating and workstation to decrease pain and energy consumption; (6) increasing independence in driving with hand controls; (7) continuing full- or part-time employment; (8) instruction in vestibular and strengthening home exercise program (Petajan et al., 1996); and (9) identifying and obtaining equipment and modifications to decrease cognitive problems at home and work.

Know the person
Appreciate the context

gestions like taking rests, but Ms. K. immediately began to reduce long walks in favor of a short home exercise program.”

“While she didn’t want a lot of equipment, Ms. K. was interested in getting appropriate items if it meant she could continue to do her usual activities at home and work.”

“Because both her husband and employer were supportive, modifications at home and work could be accommodated.”

Next Steps

Following the therapy evaluation, Ms. K. withdrew her resignation at her job and began making modifications in her work. She was also planning to resume driving with the appropriate hand control modifications.

Anticipate present and future patient concerns

“I will follow-up with Ms. K. when she has returned to work to assist with any concerns related to the ergonomic changes and to help problem solve difficult job situations. I think this is important so that she has a positive experience upon her return and does not begin to have reservations.”

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“After that, I will follow-up at the annual visit or earlier if there is a change in her function.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Work and Managing Symptoms of MS

In accordance with the outpatient occupational therapy evaluation and goals, Ms. K.’s therapist suggested that Ms. K. withdraw her resignation to her employer until she had tried to manage her MS symptoms. What factors influenced this advice, and why would the therapist make this recommendation?

Evidence Table 40-1 Best Evidence for Occupational Therapy Practice Regarding Intervention Related to Multiple Sclerosis (MS)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Efficacy and effectiveness of an energy conservation course on fatigue, quality of life (QOL), and self-efficacy for persons with MS	Community-based energy conservation course included but was not limited to importance of rest through the day, effective communication, proper body mechanics, and modification of environment.	N = 169 persons with MS; 140 women, 29 men; mean age = 48 years.	Energy conservation course for 2 hours a week for 6 weeks.	Level 1 randomized control trial with a crossover design.	The energy conservation course significantly reduced the impact of the fatigue, improved vitality, and increased self-efficacy for performing energy conservation strategies.	Results were established at $p < 0.05$. Moderate to large effect sizes were established for the fatigue subscales (0.52–0.74) and for 3 of the <i>Short Form-36</i> subscales (0.53–0.99).	Mathiowetz et al., 2005
Rehabilitation program for individuals with MS	Self-care activities using compensatory strategies and conditioning were evaluated on admission, at discharge, and 6 weeks post discharge.	N = 30 adults with MS; 27 women, 3 men; mean age = 45 years. Rating of less than 5 on at least 1 item on the <i>Research Institute of Chicago Functional Assessment Scale</i> .	5–7 days of intensive occupational and physical therapy.	Level 4 case series before and after repeated measures.	Improved in tub/shower transfers, toileting, feeding, grooming, and upper and lower extremity dressing; 100% had high or very high satisfaction with OT services.	Results were established at $p < 0.05$ or better.	Mathiowetz and Matuska, 1998

(continued)

Evidence Table 40-1 (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Efficacy of an energy conservation course on fatigue impact, self-efficacy, and QOL for persons with MS	Experimental intervention group received energy conservation course by trained OTs that addressed importance of rest, effective communication, proper body mechanics, and ergonomic principles. Control intervention group: support group involving discussion of MS topics.	N = 54 persons with MS; 36 women, 18 men; mean age = 50 years; 83% reported fatigue as a primary symptom; 11% reported taking medications for fatigue.	6 weeks, 2 hours a week of control intervention followed by 6 weeks, 2 hours a week of experimental intervention.	Level 3, repeated measures with control and experimental interventions.	Efficacy for the energy conservation course was demonstrated because participants had less fatigue impact, increased self-efficacy, and improved QOL.	Results were established at $p < 0.05$ or better. Moderate to large effect sizes were established for the fatigue subscales (0.53–0.66), self-efficacy (0.52), and 3 of the <i>Short Form-36</i> subscales (0.49–0.78).	Mathiowetz, Matuska, & Murphy, 2001
Aerobic exercise program and its effects on fatigue, mood, and daily tasks	Treatment group (n = 21) participated in combined arm and leg ergometry. Control group (n = 25) did not alter usual activities for 15 weeks.	N = 46; 31 females, 15 males; mean age = 40 years; <i>Expanded Disability Status Scale</i> score of less than 6.	40 minutes three times a week for 15 weeks.	Level 1; randomized control trial.	The treatment group showed significant improvement in aerobic capacity, physical work capacity, upper and lower extremity strength, ambulation, and self-care. Depression, anger, and fatigue were significantly reduced at 10 weeks.	Results were established at $p < 0.05$.	Petajan et al., 1996

SUMMARY REVIEW QUESTIONS

1. What are the various courses of MS?
2. What symptoms of MS may require occupational therapy intervention?
3. What are the main modifications that a therapist might recommend for a woman with severe MS fatigue who is working full time and has two young children?
4. How can an occupational therapist help a person with neurodegenerative disease stay employed?
5. What factors and symptoms should a therapist consider when ordering wheeled mobility for a patient with neurodegenerative disease?
6. What environmental modifications may be necessary in PD?
7. List the items you would check and primary modifications you might recommend during a home safety visit for a person with a neurodegenerative disease.
8. Why is it important to include the significant others when developing interventions?
9. Plan an outpatient therapy session to treat a person with PD who has akinesia, bradykinesia, and rigidity and who is falling regularly.

CHAPTER 41

Orthopaedic Conditions

Colleen Maher and Jane Bear-Lehman

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Identify the role of the occupational therapist in assessing and planning treatment for persons with occupational dysfunction secondary to injuries or diseases affecting the musculoskeletal system.
2. Select appropriate assessments and plan treatment according to the stages of recovery following a musculoskeletal injury or disease of the upper extremity.
3. Describe how to accomplish daily life tasks without causing adverse sequelae following fracture or surgery to the hip.
4. State the principles of body mechanics and describe how to apply them to activities and tasks of daily life.
5. Describe the phases of fracture management of the upper extremity and how to optimize occupational functioning at each stage.

Glossary

Clinical union—Evidence of bony callus on radiographic examination, although the fracture line is still apparent (Salter, 1999).

Codman's pendulum exercises—Exercises prescribed for most shoulder surgeries in early recovery. The standing or sitting patient bends over at the hips so that the trunk is parallel to the floor. The arm assumes a position away from the body and perpendicular to the floor, either with or without a sling. In this gravity-assisted position, the patient moves the arm passively or actively, depending on the surgical protocol, forward into humeral flexion and backward into humeral extension; across and away from the body for shoulder abduction and adduction; and then in a circle for circumduction (Salter, 1999).

Collar-and-cuff sling—Commercially available sling that supports the upper extremity in an adducted and internally rotated position against the abdomen.

Controlled range of motion—Active or passive movement within a predetermined safe arc. Often the allowed movement begins in the middle of the range and is gradually upgraded toward the full arc as healing occurs. A splint can be used to set the boundaries or block unwanted movement.

Deep pressure tissue massage—Firm manual pressure applied to the skin for about 5 seconds to blanch the underlying scar. This massage is initiated once sutures are removed. On a closed wound, lanolin or vitamin E can be used. Massage begins at the perimeter and gradually works toward and then over the surgical scar site.

Occupation-specific training—Occupation-as-means using the equipment and in the context specific to one's occupation (e.g., patient who enjoys golfing practices golf swings using golf clubs and ball, under supervision of the occupational therapist). Same as task-specific training.

Shoulder immobilizer—Used if strict immobilization is required. Adjustable elastic band that fits around the waist with two straps that position and secure the arm in internal rotation.

Skateboard—Wooden or plastic board with four ball-bearing wheels (one at each corner) that support the skateboard and reduce friction when the patient attempts to move the upper extremity. The forearm rests on the skateboard, and the patient moves it to active range of motion in gravity-lessened plane.

Theraband—Exercise bands that come in various levels of resistance (denoted by different colors) used to improve strength.

Trendelenburg gait—Gait pattern that results from a weakened gluteus medius muscle. The patient lurches toward the injured side to place the center of gravity over the hip. It is characterized by dropping of the pelvis on the unaffected side at heel strike of the affected foot.

Volkman's ischemia—Increased compartment pressure in one anatomic area of the extremity as a result of a fracture or crush injury. In the upper extremity, it is most common in the forearm. Closure of the small vessels results in increased pressure. The patient will experience severe pain, especially with passive stretching. Pressure greater than 30 mm Hg is considered a surgical emergency in which a fasciotomy would be performed (Bednar & Light, 2003).

Wall climbing, finger walking, palm gliding—Exercise to develop shoulder flexion. The patient faces the wall, places the injured shoulder's hand on the wall, and either finger walks or glides the palm toward the ceiling and then the floor. For shoulder and scapular abduction, the patient turns parallel to the wall and abducts the shoulder to place the fingers or palm on the wall for finger walking or palm gliding. Commercially available finger climbers can be mounted on the wall or used on a tabletop with set increments for the finger walk; some climbers can be adjusted to different angles to allow for varying degrees of movement.

Orthopaedic conditions include injuries, diseases, and deformities of bones, joints, and their related structures: muscles, tendons, ligaments, and nerves. These conditions can be caused by traumatic events, such as motor vehicle, recreational, or work-related accidents; by cumulative trauma; or by congenital anomaly. The rising incidence rate of musculoskeletal injuries is attributed to an increase in "individual participation in high-speed travel by land, sea, and air, complex industry, and competitive and recreational sports" (Salter, 1999, p. 417). Furthermore, more individuals are reaching old age, and as they age, the incidence of injuries from falls increases.

This chapter provides an overview of the occupational therapy assessments and treatments used with adult patients who have orthopaedic or musculoskeletal conditions. Specifically, it reviews upper extremity and hip fractures and their sequelae, hip surgery for trauma and disease, shoulder injuries and their effects on function, and pain with a focus on low back pain.

PURPOSE AND ROLE OF OCCUPATIONAL THERAPY IN ORTHOPAEDICS

The aim of occupational therapy in orthopaedic rehabilitation is to help the patient achieve maximal function of body and limb to restore occupational functioning. In the acute stage of recovery, the therapist's role is to help relieve pain, decrease swelling and inflammation, assist in wound care, maintain joint or limb alignment, and restore function at the injury site. The therapist teaches the patient to safely perform tasks and activities while protecting the injury site for healing. As healing progresses to **clinical union** and then to consolidation, the occupational therapist retrains the patient in activities of daily living (ADL) and other occupational tasks.

For individuals who have a chronic joint disease, such as osteoarthritis, or cumulative trauma, such as low back pain, the occupational therapist's role depends on the

stage of recovery and the directives of the treatment team. The occupational therapist may directly help relieve pain, realign structures, or reduce the stress on soft tissue. Or the occupational therapist may work closely with the physical therapist to relate the functional program to treatment offered in physical therapy to heal the wound. As the acute episode of pain calms, the occupational therapist focuses on an individually tailored education program to help the patient physically and psychologically make the required lifestyle changes to reach and sustain optimal occupational functioning.

skills and performance patterns, and impairments of capacities and abilities.

Participation in Life Roles

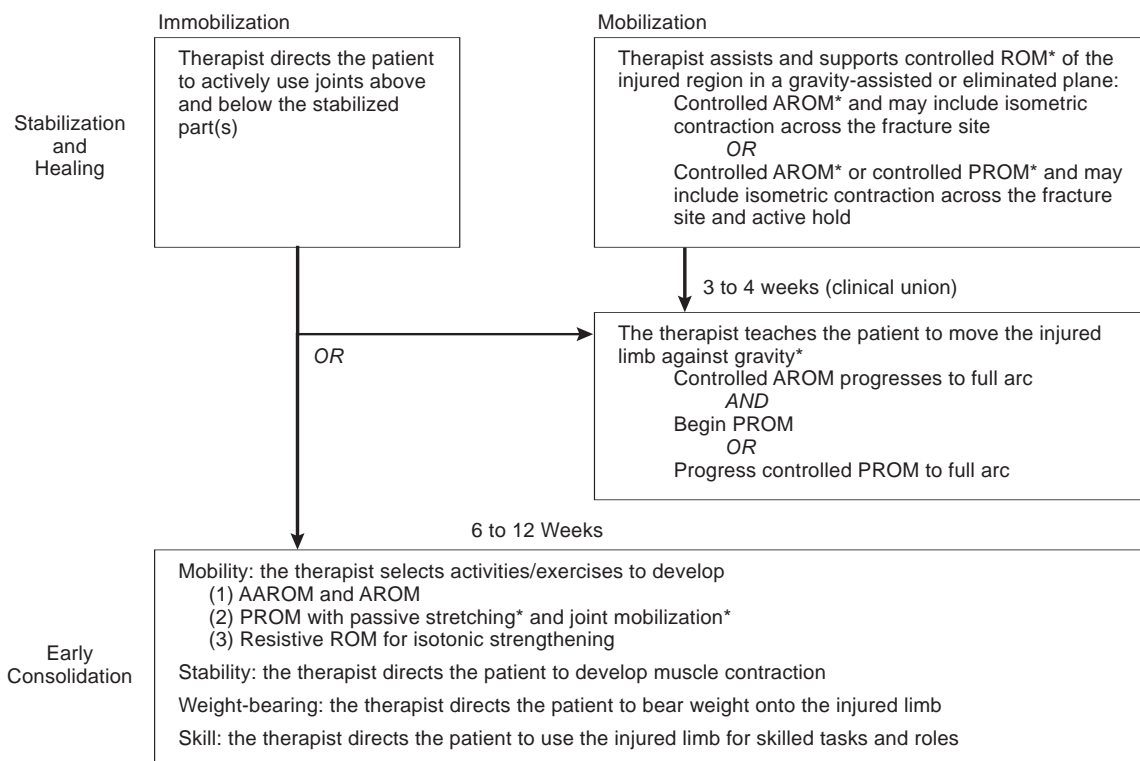

Although resumption of life roles may not be possible at the start of the aftercare program, life roles regulate the choices made during treatment planning and serve as the end point for treatment planning. In addition to noting the activities and tasks the patient can and cannot accomplish, using the assessment tools described in Chapter 5, the therapist observes whether the patient is magnifying the injury or appears to be adopting a sick role.

OCCUPATIONAL THERAPY EVALUATION IN ORTHOPAEDICS

Evaluation is an ongoing process that is carefully coordinated with the stage of recovery. The therapist selects assessments that will provide sufficient information to plan and to direct treatment but will not threaten the injured or inflamed structure during healing. The therapist chooses assessments that correspond to the level of bone healing, the chosen method of reduction and stabilization, and the plan for movement during healing or the acute inflammatory episode. The therapist assesses participation in life roles, areas of occupations, performance

Impairments of Abilities and Capacities

Physical impairments are directly measured by various assessment instruments. See Chapter 5 for assessment of pain, edema, range of motion (ROM), strength, and endurance. The surgeon’s protocol may stipulate no movement or no force at or near the fracture site, or it may require **controlled range of motion** beginning immediately or within the first 3–4 weeks after stabilization (Fig. 41-1). If the surgeon’s protocol requires complete rest of the injured bone or joint, ROM measurements are deferred until movement is permissible. If the patient is on

*Follow surgical plan and seek medical approval to proceed.

Figure 41-1 Guidelines for therapeutic intervention during fracture healing and consolidation.

a specific program, such as controlled range of motion, the therapist measures the joint, adhering to the precautionary boundaries, and does not allow the patient to exceed the limits of the directive. The adjacent joints are measured, and a treatment program is designed for any adjacent joint that demonstrates less than normal function. Detailed strength testing with applied resistance is deferred until there is bony consolidation or the acute inflammation has calmed. Due to the force required, grip and pinch testing are usually deferred for 2–4 weeks following cast removal in forearm fractures. Assessing strength after a fracture should only be performed when ordered by the orthopaedist. The occupational therapist not only focuses on direct measure of the injured and adjacent anatomical regions but also closely observes the patient’s total body response in terms of postural changes, pain responses, and psychological reactions.

OCCUPATIONAL THERAPY TREATMENT IN ORTHOPAEDICS

The most important treatment goal is the restoration of occupational functioning. To achieve this, the patient needs to be directed from the start of recovery to move and to use all joints that are not affected by the injury or the disease. For patients who have an upper limb fracture or a short-term inflammation, the therapist may recommend temporary use of the uninjured hand alone to perform some ADL, assisted by adaptations such as pump bottles for toothpaste and shampoo, a button hook, or a rocker knife. Other ADLs may require the temporary assistance of another person so as not to disturb the healing region. When the patient is medically ready, the occupational therapist, through careful activity analysis, ascertains how the patient can safely resume tasks that correspond with the achieved recovery status to reintegrate the injured or inflamed limb into activity safely. Attention is directed toward redeveloping the function of the injured limb to resume its capacity in mobility, stability, weight bearing, and ultimately skill (see Fig. 41-1). When a condition is chronic, such as status post total hip replacement or low back pain, the therapist recommends alternative methods, adaptive equipment, or environmental modification for safe task completion.

Acute Trauma: Fractures

As long as orthopaedic surgeons have been treating fractures, there has been a controversy between the “movers” and the “resters.” The surgeons prescribing rest as a fracture treatment keep their patients immobilized in traction, plaster, or fiberglass for long periods after stabilization. For many surgeons, however, the goal in

fracture treatment is to mobilize the injured structures as quickly as is compatible with healing and return the patient to work and leisure activities (Salter, 1999).

The goal of fracture treatment is to achieve a precise and effective stabilization for optimal recovery and resolution of function. Closed fractures that are relatively undisplaced and stable may be managed by protection alone, without reduction or immobilization. Fractures that are undisplaced but unstable do not need reduction but do require positioning and immobilization in a cast or a fracture brace. Surgical reduction is performed to reduce open fractures and those closed fractures where the bone fragments cannot be approximated accurately by closed manual reduction alone. The bone fragments are brought into a closer anatomical alignment during surgical reduction and are stabilized by insertion of an internal fixation device, such as a nail, pin, screw, rod, compression plate, or an external fixator. Surgical repair also can include prosthetic devices that are implanted to restore joint motion (Smith et al., 2003).

Fracture healing, when the part is immobilized by a cast, splint, or fracture brace (Figs. 41-2 and 41-3), is accomplished through the formation of immature woven bone or external callus. The woven bone then consolidates and remodels so that the fracture is repaired with lamellar bone (Smith et al., 2003). When internal fixation provides complete bone immobilization, external callus does not form, and direct healing occurs. When external callus forms first, more healing time is required. Fracture healing has a general timetable that is confirmed routinely by physical exam

and x-rays to reveal the healing status before advancing the rehabilitation program (Definition 41-1). Restoring bone to its optimal function is evident when consolidation or complete fracture repair has occurred when the callus is ossified, the fracture site is no longer tender and painful, and there is no movement when the fractured bone is manipulated (Krop, 2002; Smith et al., 2003).

Rehabilitation begins as soon as the plaster cast dries or within a day or two after reduction. The timing, amount, and kind of activity depend on the place and kind of fracture, the method of fracture reduction selected by the orthopaedic surgeon, and, in some instances, the age of the patient. Clinical experience has shown that early specific use of the injured limb during healing diminishes or eliminates the need for treatment after immobilization (Salter, 1999). Early movement prevents the unwanted side effects of immobilization: stiff joints, disuse atrophy, and muscle weakness.

Evaluation Process in Aftercare for Fractures

The evaluation is carefully designed and adjusted to the stage of recovery and the kind of fracture. This chapter presents the specialized focus for each fracture by the

stage of recovery: immobilization and early mobilization or early consolidation.

Immobilization or Early Mobilization (Zero–6 weeks)

The therapist identifies the tasks and activities for which the patient needs to learn an adaptation or obtain assistance during the temporary period of restricted movement so that the fracture site remains undisturbed. Measurements of ROM and circumference for swelling are conducted on adjacent joints. Assessment of ROM of the injured joints depends on the type of protection and stabilization used and the orthopaedic surgeon's protocol for aftercare, as discussed earlier. Patients with secure internal fixation of bone fragments may begin gentle ROM of the involved joints before the consolidation phase. This usually occurs at 2 weeks post-op under the close supervision of the surgeon.

Early Consolidation (6–8 weeks)

The therapist determines whether and to what extent the patient can safely reintegrate the injured limb into occupational tasks. The therapist continually assesses the patient's ability to use the injured limb for functional tasks to correspond with clinical progress. The therapist initially measures active ROM (AROM) of the involved joints with the exception of shoulder fractures, which are measured for AA/PROM (active assisted, passive range of motion). Edema and sensibility should be assessed. A 10-cm visual analog scale should be used to assess the patient's pain level. Grip and pinch measurements are not taken until the surgeon orders strengthening. Observe the patient for signs of infection: redness, heat, swelling, pain, loss of function, or changes in circulation. To do so, look at the limb's skin color: purple, dusky, or white coloration indicates alterations in circulation, as does a skin surface that is too warm or too cold to the touch. **Immediately report abnormal findings to the surgeon.**

Treatment Process in Aftercare for Fractures

Intervention strategies for addressing orthopaedic injuries are based on the stage of recovery and the orthopaedic treatment protocol. The therapist selects and applies intervention strategies that are consistent with the orthopaedic surgeon's immobilization or mobilization plan, the restrictions or precautions, and goals.

Immobilization or Early Mobilization

Early mobilization treatment programs have specific and focused protocols indicating the timing, type, and quantity of desired movement (see Fig. 41-1). Advancement of the therapeutic program is determined for each patient based on the stability of the fracture and radiographic signs of fracture healing (Brotzman et al., 2003). The

DEFINITION 41-1

Fracture Healing

The estimate of healing time for uncomplicated fractures in tubular bones, according to Apley and Solomon (1994), is as follows:

	Upper Limb	Lower Limb
Callus visible	2–3 weeks	2–3 weeks
Union	4–6 weeks	8–12 weeks
Consolidation	6–8 weeks	12–16 weeks

cautiously controlled movement usually begins in a gravity-assisted or gravity-eliminated plane. The movement may be active assistive range of motion (AAROM) or AROM restricted to midrange and gradually upgraded to full ROM. Under careful guidance and manual handling, isometric contraction of the muscles whose bellies extend across the fracture site is encouraged to facilitate circulation and bone healing. Some protocols require controlled PROM, often followed by an active hold pattern. That is, the therapist passively moves the injured part through the prescribed arc, and then the patient isometrically holds the achieved position briefly.

The therapist may have to fit the patient with a sling, shoulder immobilizer, splint, or fracture brace during healing either to add protective support or to begin early controlled movement. To add to a patient's comfort during stabilization in an external fixator, the therapist may recommend and fabricate a supportive static splint. Thermoplastic splinting alone is often used to achieve relative immobilization for fractures of the metacarpals and phalanges (see Chapters 16 and 42). Following the initial treatment of closed reduction of fractures in the shaft of long bones, the surgeon may prescribe a functional fracture brace as popularized by Sarmiento and shown in Figures 41-2 and 41-3 (Sarmiento, 2000). The lightweight thermoplastic fracture brace allows for motion above and below the fracture site and minimizes detrimental effects of prolonged immobilization. The metal hinge controls the amount of movement available. The patient is closely monitored for circulation, biomechanical alignment, and desired (controlled) movement. The therapist adjusts the shell to facilitate comfort, to respond to changes such as a reduction of limb volume, and to adjust the amount of movement the splint permits.

Early Consolidation

Therapy usually begins with focused, active use of the limb. Active therapy consists of activities and tasks to remediate the use of the muscles in the injured region. The therapist directs the patient in a graduated program to resolve the presenting impairments and to reintegrate the limb into normal and customary use for functional tasks and role performance. If secondary changes are noted in the adjacent body parts or if there is a change in body posture, therapy is also directed to resolving those impairments.

Should edema persist even with elevation and active muscle contraction, additional methods, such as compression gloves or sleeves, contrast baths and retrograde massage, or manual lymph drainage, are applied. To ameliorate stiffness and pain, the therapist may introduce modalities such as paraffin, fluidotherapy, or heat packs before or with exercise or activity (see Chapter 20). If stiffness prevails and the fracture is stable, joint mobilization and passive stretching are performed to fa-

cilitate the arthrokinetic accessory movements to increase the passive movement potential. Dynamic splinting, static progressive splinting, or the use of continuous passive motion may also increase passive mobility over time. Adherent or hypertrophic scar formation after open reduction or soft tissue repair can also limit movement, increase pain, and alter sensation. To prevent this, the therapist teaches the patient **deep pressure tissue massage** and applies continuous pressure to the scar with an agent such as silastic gel to facilitate scar remodeling (see Chapter 45).

FRACTURES

The care of fractures challenges both the surgeon and the occupational therapist to help the patient ultimately reincorporate the injured limb into functional performance tasks. To initiate the care of a patient who sustained a fracture, the therapist must understand the anatomy and biomechanics of the extremity and select intervention strategies that are consistent with the physiological process of fracture repair.

Shoulder Fractures

The shoulder complex is composed of the glenohumeral joint, scapulothoracic joint, sternoclavicular joint, and acromioclavicular joint. The shoulder complex provides a wide range of movements for hand placement but also provides the important functions of stabilization for hand use, lifting and pushing, reaching, and weight bearing (Greene & Roberts, 2005). The shoulder is considered the most challenging portion of the body to rehabilitate. After traumatic, degenerative, or surgical shoulder lesions, the therapy goals are delicately balanced to relieve pain, to restore movement and muscle strength, and to allow for callus formation and the approximation of the bony fragments in the injured region.

Immobilization of the shoulder results in stiffness and pain; therefore, non-operative and post-operative therapy programs call for a specific regimen of PROM, AAROM, or AROM within a controlled, guarded range. Shoulder fractures are closely monitored by radiographs as initial controlled PROM and AAROM begin. There is controversy with regard to PROM. Some argue that passive motion is contraindicated, particularly in the elderly (Goldstein, 1999). Others say that passive movement is safe if the provided range corresponds to the surgeon's prescribed limitations. Emphasis is on the patient resuming non-resistive functional activities and using the injured limb as soon as movement is allowed.

Since immobilization quickly results in stiffness, active shoulder motion begins as soon as the acute pain

diminishes in stable shoulder fractures. Unstable shoulder fractures usually require surgical intervention for fixation. The protocols are based on the classification of fracture, the type of surgical procedure, and age and activity level of the patient, and they often follow the guidelines as originally described by Neer (1990). Some post-operative protocols start isometrics for external rotation and shoulder abduction across the repair site immediately to facilitate stability. Assisted isotonic shoulder motions follow about 3–4 weeks later, once the shoulder fragments are approximated as confirmed by radiograph (Kelley & Clark, 1995). If shoulder stability is achieved with internal fixation, AROM or pain-free AAROM exercises may begin as early as 7–10 days after surgery (Kelley & Clark, 1995).

During the first 6–8 weeks, isometric exercises, a stimulant for fracture healing and callus formation, are performed along with **wall climbing**, non-resistive therapeutic activities, and **Codman's pendulum exercises**. Codman's exercises are performed with the patient bending over so that the injured upper limb is perpendicular to the floor. In this gravity-assisted plane, the patient does clockwise and counterclockwise circular movements and flexion, extension, abduction, and adduction. *Codman's exercises may be contraindicated if the upper extremity is edematous.*

Barring complications, when clinical union is achieved at approximately 6 weeks, progressive shoulder exercises for flexion, extension, abduction, and internal and external rotation are started (Kelley & Clark, 1995). Passive stretching, joint mobilization, and resistive exercises begin once there is established clinical union, the inflammation has decreased, and there is no fear of disrupting the fracture (Kelley & Clark, 1995).

Humeral head fractures that are unstable and significantly displaced are often medically treated with humeral head replacement, known as hemiarthroplasty. A total shoulder arthroplasty is often considered for patients with severe arthritis in combination with a proximal humerus fracture (Keenan & Waters, 2003). Therapy for total prosthetic joint replacement of the shoulder varies with the design of the prosthesis and the surgical procedure. The rehabilitation program begins within the first 2–3 days after surgery. The exercises should not cause any pain. The key to a satisfactory functional result is early achievement of shoulder forward flexion and external rotation in the plane of the scapula. Some protocols require the use of continuous passive motion for forward shoulder flexion immediately following surgery (Salter, 1999).

Codman's pendulum exercises, passive shoulder elevation done lying supine with the opposite hand assisting the affected limb, and use of an exercise wand to perform passive external rotation are introduced during the first 2–3 days after surgery (Tan, Leggin, & Williams, 2002). The patient is instructed to perform the exercises 4–6

times daily. Since the subscapularis tendon and the rotator cuff are violated during the surgery, some surgeons introduce external rotation slowly in the first 4 weeks; others incorporate passive external rotation on the second post-operative day. The preferred position for passive external rotation exercise is with the humerus adducted. For the first 4–5 weeks of rehabilitation, external rotation is often limited to what was obtained at the time of wound closure or the operative ROM value for external rotation (Kelley & Clark, 1995; Tan, Leggin, & Williams, 2002). During this phase, the patient is instructed to begin non-resistive occupational tasks, such as brushing teeth and self-feeding.

One to 2 weeks post-operatively, the patient is instructed to add passive internal rotation, extension, and horizontal adduction. The patient can progress to isometric strengthening of the rotator cuff at 4–6 weeks. If the subscapularis was detached during surgery, the surgeon may restrict strengthening of this muscle at this time. At 6 weeks, with medical advisement, the program is upgraded to include active resistive exercise and activities to strengthen the rotator cuff muscles and the three parts of the deltoid muscle (Tan, Leggin, & Williams, 2002). Theraband exercises, free weights, and occupational tasks that emphasize abduction and rotational movements are initiated. Weight bearing on the injured arm is not allowed for at least 6 months.

Management of humeral shaft or humeral neck fractures is divided into three phases. Phase I includes positioning, Codman's pendulum exercises, and passive assistive exercises. Fractures of the humeral shaft and humeral neck both respond well to early passive movement and positioning. Codman's pendulum exercises and passive assistive movement of the shoulder are performed several times a day to prevent stiffness. The occupational therapist may make a fracture brace conforming to the length of the humerus to provide the initial support after a humeral shaft fracture (see Fig. 41-2). The therapist must be careful to flare and roll the edges of the shell to prevent compromise to circulation and nerve impingement while allowing available movement. In the case of humeral shaft fracture, there is a risk of radial nerve damage due to the location of the injury relative to the course of the radial nerve. Radial nerve injury is characterized by the inability to extend the elbow, wrist, and digits. Other complications that are not uncommon with humeral shaft fractures are delayed union and non-union. These complications may occur as a result of an injury to the nutrient artery located at midshaft when the humerus is fractured (Macklin et al., 2002). A bone stimulator may be used to facilitate bone healing.

For phase II, the therapist encourages active assisted concentric and eccentric exercise, progressing to lightly resistive exercises. These patterns often begin with the patient supine and progress to seated, in which position the

weight of the extremity is first supported by the therapist or a **skateboard**.

Phase III addresses both stretching and strengthening. As healing permits, the patient can combine shoulder forward flexion with abduction with or without external rotation (Basti et al., 1994). Use of the injured extremity in occupation-as-end is encouraged.

Elbow Fractures

Elbow motion gives the individual the capacity to position the hand in space close to or far from the body for manipulation of objects and to function as a stabilizer for strength activities (Davila, 2002). These movements are accomplished by two degrees of freedom: flexion and extension at the ulnohumeral and radiohumeral joints and pronation and supination at the proximal radioulnar joint. Supracondylar fractures of the humerus are the most common and the most serious elbow fracture (Salter, 1999). These fractures are associated with a high incidence of malunion and have a risk of **Volkman's ischemia**, a compartment syndrome of the forearm. Ischemia, considered an urgent medical matter, can be caused by edema within a fascia-surrounded compartment or by acute elbow flexion that compresses an artery against bone. *Signs of ischemia include pale, bluish skin color; absence of forearm radial pulse; and decreased hand sensation accompanied by severe pain. Report these signs immediately.* Immediate action is important because the peripheral nerves can withstand only 2–4 hours of ischemia, although they do have some potential to regenerate. The muscle can withstand up to 6 hours of ischemia, but it cannot regenerate (Salter, 1999). Prolonged occlusion allows for the progression to a contracture as the necrotic muscle becomes dense, shortened, fibrous scar tissue.

The uncomplicated supracondylar fracture may be treated with immobilization in a removable plaster cast or thermoplastic splint following open reduction. The elbow is held in 90–100° of flexion, and the arm may be supported in a **collar-and-cuff sling** (Salter, 1999). After the first week, the splint is removed daily for gentle, non-resistive active movement in a gravity-eliminated position. Therapy for elbow fractures emphasizes active, not passive, movement and flexion rather than extension to minimize the risk of ischemia and excessive bone formation (heterotopic ossification) (Salter, 1999). Many patients achieve close to full movement after 6–12 months without specific treatment; some, however, do not achieve complete elbow extension even with therapy (Davila, 2002).

Complex elbow fractures are often treated with open reduction and well-secured fixation. Active motion begins 3–5 days after surgery. Similar to the supracondylar fracture, the elbow fracture is splinted in flexion rather than extension; flexion has a greater functional importance. If a

contracture occurs, the hand can be raised to the face for eating and hygiene (Davila, 2002). In the elderly, elbow fractures are often treated with a collar-and-cuff sling alone, and active movement begins early to prevent stiffness and pain. A functional arc of motion for daily activities can be regained, but full ROM is not always achieved.

Radial head fractures can be treated with closed reduction or, depending on the severity, may require radial head excision. Radial head fractures seldom require more than a sling for immobilization. Active pronation and supination exercises are encouraged early. Emphasis should be placed on regaining active supination. Full supination is more difficult and painful than pronation (Davila, 2002). Supination and pronation exercises should be performed seated or standing, with the shoulder adducted to the side and elbow flexed to 90°. Exercises should be performed 6 times daily, with a minimum of 2 sets of 10 repetitions. Exercises should be pain free. Continuous passive motion (CPM), dynamic supination splint, and static progressive splinting can be used to further encourage forearm rotation. See Chapter 42 for wrist and hand fractures.

ROTATOR CUFF PATHOLOGIES

The shoulder complex is the foundation of all upper extremity movements. The rotator cuff musculature plays an integral part in the function and control of the shoulder complex. The supraspinatus performs shoulder elevation, the infraspinatus and teres minor perform external rotation, and the subscapularis performs internal rotation. Besides the actions they produce, the rotator cuff musculature functions as a force couple to control the head of the humerus on the glenoid fossa. Its anatomical location at the subacromial space, between the coracoacromial arch and the head of the humerus, makes the rotator cuff extremely vulnerable to compression. The supraspinatus also has an area of hypovascularity known as the critical zone. This zone is where the supraspinatus tendon inserts on the greater tuberosity of the humerus. Due to its anatomical location and area of hypovascularity, the supraspinatus is the most commonly impinged rotator cuff tendon. Patients with rotator cuff pathology are often faced with the inability to perform the most personal self-care tasks. Activities such as toileting, hair care, and hooking a bra are all dependent on a normally functioning rotator cuff.

Shoulder Impingement Syndrome

Shoulder impingement syndrome is a compression of the structures found in the subacromial space. Structures found in the subacromial space (superior to inferior) include the subacromial bursa, supraspinatus, joint capsule, and long head of the biceps. Shoulder impingement

syndrome is most commonly caused by repetitive or sustained elevation of the shoulder above 90°. If shoulder impingement syndrome goes untreated, it can result in a rotator cuff tear. Charles Neer developed a classification system to better understand the progression of shoulder impingement syndrome. Stage I is described as edema, inflammation, and hemorrhage. In this stage the bursa and/or the tendons become irritated and inflamed. The symptoms can be reversed with occupational therapy intervention. The focus should be on activity modification. In stage II, the bursa and tendons become thick and fibrotic. At this stage, a person can be treated conservatively; however, recovery may take longer. In stage III, a person may present with bone spurs and partial or full thickness tears (Neer, 1990). A small tear is less than 1 cm, a medium tear is 3 cm, a large tear is less than 5 cm, and a massive tear is greater than 5 cm (Post, Silver, & Singh, 1983).

Rotator Cuff Tendonitis and Bicipital Tendonitis

A person may have rotator cuff tendonitis and or bicipital tendonitis but not shoulder impingement syndrome. The chief complaint of tendonitis is pain during humeral movement above 90°. In most cases, the patient is independent with activities of daily living; however, the patient will experience pain while performing these tasks. Common causes are repetitive overhead use, curved or hooked acromion, weakness of shoulder or scapula musculature, and capsular tightness. Tendonitis can be treated conservatively with pain modalities, activity modification, strengthening exercises, and **occupation-specific training**.

Bursitis

Shoulder bursitis is inflammation of the subacromial bursa. Bursitis can be differentiated from rotator cuff tendonitis if the patient has pain during passive shoulder elevation and is pain free during AROM and muscle testing of the rotator cuff. It is rarely the major source of pain and usually coexists with shoulder impingement syndrome (Malone, Richmond, & Frick, 1995). See the section on shoulder impingement for causes.

Calcific Tendonitis

Calcific tendonitis results from calcium deposits laid down at the insertion of the tendon on the bone. In the shoulder, calcific tendonitis most commonly occurs in the supraspinatus and infraspinatus tendons. The cause is unknown. This type of tendonitis usually heals on its own by spontaneous reabsorption. Reabsorption of the calcium can take several months. During this time, the person may

experience significant pain. Physical agent modalities, pain-free ROM, and activity modification are used to address the pain.

Rotator Cuff Tear

Tears of the rotator cuff can be partial or full thickness. See the section on shoulder impingement syndrome for description of size of tear. Causes include trauma, progression of impingement syndrome, and degenerative changes of the tendon. Patients with rotator cuff tears will present with difficulty performing activities above shoulder level and will often compensate by hiking the shoulder using the upper trapezius muscle. Rotational movements, such as reaching the small of the back to tuck a shirt in or remove a wallet from a back pocket, can also be limited. Rotator cuff tears can significantly limit a person's occupational functioning. Rotator cuff tears are diagnosed using magnetic resonance imaging (MRI) and magnetic resonance arthrography (MRA) (Toyoda et al., 2005). Some partial tears can be treated conservatively with activity modification and strengthening of scapula and rotator cuff muscles. Surgical options for those patients who don't benefit from conservative treatment include arthroscopic, mini-open, and open repairs. Post-operative therapy focuses on regaining full ROM, scapula and rotator cuff strengthening, practicing activities of daily living, and occupational tasks.

Evaluation (of the non-surgical patient)

The evaluation should begin with a thorough history. Discuss the mechanism of injury. Was it a sudden onset or gradual onset? If it was a gradual onset, try to determine what activity or sustained posture led to the rotator cuff problem. Also discuss the patient's level of pain (scale of 0–10). Is the pain localized or referred? What activities or occupations cause pain? Can the patient sleep on the involved side? The therapist should also observe the patient's posture and symmetry of the scapula at rest and during upward rotation. The physical assessments can then begin with asking the patient to perform various functional movements such as reaching the small of the back, reaching the opposite axilla, and touching the top of the head. See Chapter 5 for assessment of AROM and PROM and manual muscle testing of the shoulder. Active cervical ROM and sensory testing the C4 to T1 dermatomes (see Chapter 7) should be performed to eliminate the possibility of cervical involvement. Palpation of the rotator cuff tendons will assess tenderness and swelling. Special tests should be administered to determine all the involved structures. Special tests for rotator cuff pathology include the Neer impingement sign, Hawkins test, empty can test, drop arm test, and biceps speed's test (Procedures for Practice 41-1). Activities of daily living should be assessed by

PROCEDURES FOR PRACTICE 41-1

Special Tests for Rotator Cuff Injuries

1. *Neer Impingement Sign*: Forced forward flexion with the shoulder internally rotated. If the patient expresses pain, the sign is positive, indicating compression and/or inflammation of the supraspinatus and/or long head of the biceps (Fig. 41-4).
2. *Hawkins test*: Shoulder and elbow are flexed to 90° followed by forced internal rotation. If the patient expresses pain (Fig. 41-5), the test is positive, indicating compression and/or inflammation of the supraspinatus and long head of the biceps.
3. *Empty can test*: Shoulder elevation to 45° and internal rotation (thumb facing down). Therapist applies resistance to abduction (downward force) (Fig. 41-6). Positive sign is weakness or pain. This test indicates a tear of the supraspinatus tendon. Repeat the same test at 90°. If pain is only experienced at 90° position, suspect bursitis.
4. *Drop arm test*: Patient's arm is positioned in 90° of abduction. The patient slowly lowers his or her arm to the side. The test is positive if the patient drops the arm to the side, indicating a supraspinatus tear (Fig. 41-7).
5. *Biceps speed's test*: Shoulder flexed to 90°, forearm supinated, and elbow extended. Resistance is applied to flexion (downward force using a long lever arm). Positive sign is pain over bicipital groove (Fig. 41-8).

observing the patient using the involved extremity during activities that are within low range (waist level), mid range (shoulder level), and high range (above shoulder level). The therapist should note any compensating or expressions of pain while performing the activities. Numerous shoulder questionnaires can also be administered to address pain,

Figure 41-4 Neer Impingement Sign.

Figure 41-5 Hawkins test.

function, and activity. Examples of these questionnaires include *The Disabilities of the Arm, Shoulder and Hand (The DASH)* (Hudak, Amadio, & Bombardier, 1996) and the *Western Ontario Rotator Cuff Index* (Kirkley, Alvarez, & Griffin, 2003).

Evaluation (of the post-surgical patient)

The evaluation for the post-surgical patient will be guided by the surgeon. Request for occupational therapy services can begin as early as 24 hours after surgery. Assessments of pain, PROM, and activity adaptation are the usual orders post-operatively. Depending on the type of repair, AROM can be assessed at 4–6 weeks, and strengthening can be tested at 8 weeks.

Treatment (of the non-surgical patient)

Conservative treatment should begin with educating the patient on activity modification. The patient should be instructed to avoid above shoulder level activities

Figure 41-6 Empty can test.

Figure 41-7 Drop arm test.

Figure 41-8 Biceps speed's test.

until pain subsides. Sleeping postures should also be addressed. The patient should avoid sleeping with the arm above shoulder level or in an adducted and internally rotated position. Combined adduction and internal rotation for a long period of time can further compromise the blood supply of the supraspinatus tendon. Exercise

should focus on pain-free ROM. Begin with PROM. As pain decreases, progress to AROM. Strengthening should include isometric and isotonic exercises for the rotator cuff and scapula musculature. Also improve ROM and strengthen through functional activities such as dressing (Fig. 41-9, A-C). Investigate what

occupations are most important to the patient and have him or her bring in the necessary equipment such as a golf club or tennis racquet. The long-term goal is to return the patient to unrestricted, pain-free occupational functioning.

Treatment (of the post-surgical patient)

Immediately following rotator cuff repair, the patient will begin with PROM/AAROM for the next 4–6 weeks. The movements emphasized should include pain-free Codman's pendulum exercises, passive shoulder elevation, and internal/external rotation in the adducted or slightly abducted position. An ice pack should be used before, during, and after exercise to decrease pain and swelling. The patient should be instructed to perform these exercises at home using the uninvolved arm to supply the power. Internal and external rotation is performed with the patient supine and the shoulder adducted to the side and elbow flexed to 90°. A cane or stick is held in both hands, while the uninvolved arm supplies the power to move the involved extremity toward the stomach (internal rotation) and away from the stomach (external rotation). Pulleys are only used if requested by the surgeon because repetitive shoulder elevation may irritate the repair. During this time, the patient should be instructed in one-handed techniques to perform activities of daily living. The involved shoulder should not be used for any activity at this time, unless indicated by the surgeon. In between exercise sessions, the shoulder is often protected in a **shoulder immobilizer**. At 4–6 weeks the patient progresses to AROM. Begin in gravity-lessened positions and progress to against-gravity movements. Shoulder extension and internal rotation to the small of the back are added. Encourage the patient to achieve functional ROM. Engage the patient in light activities of daily living. Avoid compensatory movements such as hiking the scapula or lateral bending of the trunk. When performing against-gravity activities of daily living, progress from waist level to above shoulder level activities. Strengthening can be initiated at 6 weeks to prepare the patient for functional activities. Initially the strengthening program begins with isometric exercises for the rotator cuff and scapula stabilization exercises.

Eight weeks after surgery, the patient progresses to isotonic exercises using **Theraband** and free weights. Activities of daily living above shoulder level should be emphasized, including cooking and laundry. At 12 weeks, the patient can begin resistive occupational tasks. Again, the long-term goal is to return the patient to normal pain-free occupational functioning. These treatment protocols are only guidelines. Communication with the surgeon should be ongoing throughout the patient's rehabilitation.

HIP FRACTURES

Intertrochanteric hip fractures are very common in adults over 50 years of age and are more common in women than in men (Altizer, 2005). These fractures occur in bone that is markedly weakened by osteoporosis (Salter, 1999). Many of these patients have comorbidities, including congestive heart failure, coronary artery disease, hypertension, chronic obstructive pulmonary disease, or diabetes, that affect the duration and potential of the rehabilitation program (Altizer, 2005).

Hip fractures are treated with closed reduction and immobilization in plaster or open reduction with internal fixation using pins, nails, screws and plate, or rods (Keenan & Waters, 2003). Partial joint replacement is the treatment for some fractures of the neck and head of the femur. In partial joint replacement, the femoral head and neck are replaced by a prosthesis composed of a metal head and stem. After excision of the femoral head, the stem of the prosthesis is inserted distally into the medullary canal of the femur so that its head articulates with the normal acetabulum. If destructive changes have taken place in both the femur and the acetabulum, a total hip arthroplasty is necessary (Keenan & Walters, 2003).

Occupational Therapy Following a Hip Fracture and Surgery

The restrictions for weight bearing and hip movement on the operated leg are directly related to the severity and location of the fracture, the surgical approach, the ability of the fixation device or prosthesis to withstand stress, the integrity of the bone, the weight of the patient, and the patient's cognitive status (Goldstein, 1999; Smith et al., 2003). The physical therapist teaches the patient to use a walker or crutches, depending on percentage of body weight allowed on the operated limb (Definition 41-2). The occupational therapist teaches the patient to complete ADL safely, corresponding to the medical orders and the physical therapy progression for post-operative weight bearing. For some patients, pre-existing factors or the risk of dislodging the new hip joint may necessitate the assistance of another person for lower extremity dressing and for bathing.

The rate of progression of weight bearing and mobility is individually tailored for the patient by the rate of fracture healing and the patient's response (Goldstein, 1999). Close communication among the rehabilitation team is imperative to provide the patient with the best quality of care and consistency in learning how to function after surgery. Essential to the planned discharge following a hospital stay of less than a week for most is the therapist's

DEFINITION 41-2

de·fin·i·tion

Progression of Weight Bearing After Hip Surgery (Goldstein, 1999)

Weight-Bearing Status	Percentage of Body Weight on Operated Limb	Ambulatory Device
Non-weight bearing	0	Walker or crutches
Touchdown weight bearing	10–15	Walker or crutches
Partial weight bearing	30	Walker or crutches
50% weight bearing	50	Cane
Full weight bearing	75–100	Cane or no device

evaluation of the patient's ability to perform basic and instrumental ADL safely and independently and the need for adapted equipment and/or assistance of others (Bargar, Bauer, & Borner, 1998).

It is best to teach the patient who is restricted to non-weight bearing or touchdown weight bearing to sit to perform ADL to conserve energy and increase safety. Once the patient can do partial weight bearing, he or she can safely stand while grooming. For some, this may be as early as the first week, and for others, it may be as late as the third or fourth week (Goldstein, 1999). For at least 6 weeks, and for some patients longer, movement is re-

stricted. As these restrictions preclude bending over or bringing the foot closer to the hands, adaptations (Procedures for Practice 41-2) are required to resolve problems in bathing, dressing, functional mobility, and home management.

The patient must be reminded that the operated hip is not to be flexed actively or passively or the leg adducted beyond the midline (Safety Note 41-1). Long-handled dressing and grooming devices are provided, and the therapist teaches the patient to bathe and dress the operated side using these devices to avoid bending over (flexion) or crossing the operated leg (adduction). For bathing, if permitted, some patients shower standing and require a grab assist bar and non-skid bath mat in the tub area for safety. Others prefer to sit to conserve energy or feel secure, and they require a bath bench. The bath bench must be high enough so the hip does not flex more than 80–90°. These patients also require a non-skid bath mat and grab assist rail. Procedures for Practice 41-3 describes the procedure to get into and out of a bathtub after hip surgery.

To reduce hip flexion during sitting and rising, the patient is instructed to use a raised toilet seat, bed, and chair. Bed and chair heights are raised by putting wooden blocks under the legs. To increase mattress and chair cushion

PROCEDURES FOR PRACTICE 41-2

Adaptations for ADL After Hip Replacement Surgery

Problem	Adaptation
Bathe feet	Long-handled bath sponge
Get in and out of tub	Non-skid bath mat; grab bar; tub bench
Don, doff shoes	Extended-handled shoe horn; elastic laces
Don, doff socks	Sock aide
Don pants	Reacher or dressing stick
Transfer to and from toilet, tub, and bed	Raised toilet seat, increased height of chair and bed
Sit in and rise from a chair	Wedge cushion with thick end of the wedge at the back of the chair
Open and close cabinets	Relocate frequently used items to eliminate the need to bend; use a reacher

SAFETY NOTE 41-1

Movement Restrictions After Hip Surgery

- No hip flexion beyond 90°
- No hip rotation (avoid internal rotation for posterolateral approach and external rotation for anterolateral approach)
- No crossing the operated leg over the unoperated leg
- No adduction of the operated leg

PROCEDURES FOR PRACTICE 41-3

Transferring Into and Out of a Bathtub After Hip Surgery

To Get into the Bathtub

1. Stand with feet parallel to the tub with the operated leg next to the bathtub.
2. Shift body weight to unoperated leg.
3. Hold onto a grab assist rail for support.
4. Position the operated leg into hip extension and knee flexion; then abduct the hip to allow the leg to go over the edge of the bathtub.
5. Extend the knee on the operated side once the leg is over the tub edge.
6. Place the foot on the non-skid bath mat inside the tub.
7. When balance is secure, transfer the body weight to the operated leg.
8. Lift the unoperated leg over the edge of the tub and place the foot on the bath mat.

To Get out of the Bathtub

1. Position self so feet are parallel to the side of the tub and the operated leg leads (goes out of the tub first).
2. Use the same procedure as for getting into the tub.

firmness and prevent passive hip flexion, plywood is inserted between the mattress and box spring or between the chair cushion and its frame. The patient is encouraged to sit in a reclined position enhanced by a wedge cushion or a small rolled pillow or towel at the junction of the chair's seat and back, as originally described by McKee (1975).

The patient who must sit in a regular-height chair is taught to stand up without over flexing the operated hip. In a chair with armrests, the patient scoots to the front edge of the seat, keeping the operated hip extended, and uses the armrests to push straight up without bending the trunk forward. In a chair without armrests, the patient moves to the side of the chair so that the operated thigh is over the edge with the foot placed at the midline of the chair. This places the operated hip in extension, puts the foot close to the center of gravity, and enables the person to gain momentum to stand without excessive hip flexion. With this technique, the unoperated hip, knee, and ankle are in position for weight bearing.

By 6 weeks, almost all patients walk with a cane, and some walk unassisted; most can return to driving a car, swimming, and work (Goldstein, 1999). Physical restrictions against bending to put on shoes or socks, sleeping on the operated side, and using a regular-height toilet seat are often lifted 8–12 weeks after surgery.

CHRONIC CONDITIONS

Some orthopaedic conditions are chronic. One is progressive hip pain from degenerative disease. When that pain interferes with activities and tasks of daily life despite medication, rest, reduction in lower extremity loading by the use of a cane, walker, or crutches, and physical therapy, hip surgery is indicated (Salter, 1999). After hip replacement surgery, therapists teach the patient to move the operated leg within the ordered weight-bearing and movement restrictions. Another chronic condition seen by therapists who practice in orthopaedics is low back pain. Medical costs for low back pain range between \$20–50 billion annually (Hu et al., 2003). This section discusses occupational therapy both after hip replacement surgery and to relieve low back pain to enable occupational performance.

Occupational Therapy After Elective Hip Surgery Resulting from Disease

A number of surgical procedures are used for reduction of hip pain. They include osteotomy; arthrodesis, or hip fusion; hip resurfacing; and partial or total hip arthroplasty. To select the procedure, the orthopaedic surgeon considers not only the patient's age and physical status but also his or her occupational requirements and lifestyle.

Osteotomy is a procedure to correct the alignment of the femur to relieve weight bearing on the hip joint. When the osteotomy is done, compression plates stabilize the bone, and the patient can begin early post-operative mobilization with passive movement. Only partial weight bearing on the operated leg using crutches is allowed for 6 months, until the bone is healed. Osteotomies are not the treatment of choice for treating hip pain as a result of arthritis (Namba, Skinner, & Gupta, 2003).

Hip joint arthrodesis fuses the acetabulum with the femoral head at about 25–30° of flexion and in neutral abduction and rotation. Arthrodesis is considered for patients under age 60 years who are in good physical condition and who have only one painful hip. A candidate is a person who is not a candidate for a prosthetic hip implant because of heavy physical demands at work or recreational pursuits that are beyond the tolerances of an implant. This is also considered a salvage procedure for those whose prosthetic hip implant has failed. The patient is mobilized a week after the hip fusion and is allowed gradual weight bearing up to full weight in 2 months. Some patients do use a cane for a long time after surgery. The patient requires long-handled devices to assist with reaching the feet during bathing and dressing because of early post-operative flexion restrictions (Dalseth & Lippincott, 1991). In 6 months, when complete healing is established, the patient may be able to put on a sock and shoe when seated by flexing the

knee to the side of the chair and reaching behind, using touch without visual guidance. The arthrodesis does leave the patient with a residual disability, but the hip is strong, stable, and pain free, and the patient has adequate endurance for standing at work and participating in active sports, such as walking, hiking, sailing, and horseback riding (Kostuik, 1991).

A total hip arthroplasty (THA) surgically replaces the entire hip joint destroyed by disease or trauma. The main benefit of hip replacement is to resolve arthritic pain. Joint replacement surgery can also restore the length of the limb and its alignment, which has the potential to improve ROM and function (Drake, Ace, & Maale, 2002). This surgery replaces the arthritic acetabular cup with a metal cup and polyethylene plastic liner. The femoral head is replaced with a femoral head implant and stem component. Other typical joint-bearing surface materials include plastic and ceramic balls and sockets. The surgical approach to perform the THA varies among surgeons. The most common is the posterolateral approach (Youm et al., 2005). With this approach, there is no disruption to the gluteus medius and minimus muscles, and therefore, hip abduction is not compromised. The risk of the posterolateral approach is posterior dislocation. To avoid dislocation, immediately following surgery the patient is placed in an abduction pillow. Some surgeons also opt to place the ipsilateral knee in a knee immobilizer to further decrease the risk of dislocation. The patient is instructed to avoid hip flexion beyond 90°, adduction, and internal rotation. The second most common approach is the anterolateral approach (Youm et al., 2005). Although this approach decreases the risk for posterior dislocation and does not require an abduction pillow, the surgery requires division of the gluteus medius and minimus muscles and could disrupt the superior gluteal nerve, which leads to hip abductor weakness (Bertin & Rottinger, 2004). This weakness can result in a limp. The patient is instructed to avoid flexion beyond 90°, adduction, and external rotation.

Another decision the surgeon must make when performing a THA is what type of implant fixation he or she will use. The choices are cemented, cementless, or hybrid prostheses (Namba, Skinner, & Gupta, 2003). The cemented total replacement usually requires 4–6 weeks of weight bearing to tolerance (WBTT) using a standard or rolling walker, and then the patient progresses to straight cane. The cementless prosthesis, which depends on ingrowth of porous bone for stability, requires 6–12 weeks of partial weight bearing before a cane is used. Some surgeons may initially order non-weight bearing. In the case of the hybrid prosthesis, in which the femoral portion is cemented and the acetabulum is uncemented, 4–6 weeks of partial weight bearing precedes introduction of a cane (Youm et al., 2005).

Pre-operative education should be the first phase of occupational therapy for the patient receiving a THA. Hip pre-

cautions, demonstration of long-handled equipment, and medically necessary durable medical equipment should be presented. Pre-operative education has been linked to reducing anxiety (Spalding, 2003). The first 2 months after total hip arthroplasty is critical for protection and function of the new hip joint. The post-surgical program is designed to allow for healing of the trochanter and soft tissues and for development of a capsule around the joint for future stability. *Until soft tissue is healed, hip flexion beyond 90°, hip adduction, and hip rotation (internal rotation for posterolateral approach and external rotation for anterolateral approach) are avoided.* The extremes of these movements during the first 2 months can dislocate the prosthesis. If dislocation occurs, the hip must be treated with closed reduction or be surgically realigned. The patient may be placed in a hip spica cast or knee immobilizer, delaying rehabilitation (Best, 2005). To protect the prosthesis, the occupational therapist instructs the patient in adaptive procedures and in methods to modify the environment to allow for safe performance of ADL and homemaking (Definition 41-2). The techniques used to help the patient following a total hip arthroplasty parallel those described earlier under hip fracture surgery: hip flexion and adduction are discouraged, and weight-bearing guidelines are carefully adhered to. Rehabilitation starts as early as the third day after surgery.

For at least 3 weeks and, for some patients, up to 8 weeks after surgery, the operated hip is positioned in extension and abduction. A splint or a foam abduction wedge is used with the patient lying down or sitting to encourage hip abduction. Once the patient achieves 55° of hip flexion in physical therapy, the patient can sit reclined on a raised chair using a rolled pillow or wedge cushion between the seat and the back of the chair and a foam abduction wedge between the legs. The patient learns to transfer from supine to standing without flexing the operated hip beyond 90° by keeping the knees apart (hips abducted) and sliding out of a raised bed to take weight on the unoperated leg. Some patients use an overhead trapeze bar to assist this transfer. The patient also needs to practice transferring from a variety of surfaces such as high chair (Fig. 41-10, A-C), tub bench, raised toilet seat, and a car seat.

The patient with a cemented or hybrid total hip prosthesis usually begins partial weight bearing with a walker or crutches immediately after surgery. In some instances, these patients can withstand full weight bearing within the first 3 days; however, many orthopaedic surgeons wait 3 weeks before ordering full weight bearing (Goldstein, 1999). The ADL program, which can be taught with the patient standing, uses the bathing and lower extremity dressing techniques described for fractures (Procedures for Practice 41-2 and Safety Note 41-1). The patient with a cementless total hip arthroplasty is usually touchdown weight bearing for the initial recovery phase and is conservatively progressed to partial weight bearing (Goldstein, 1999). This necessitates learning ADL from the seated position (Fig. 41-11). Once

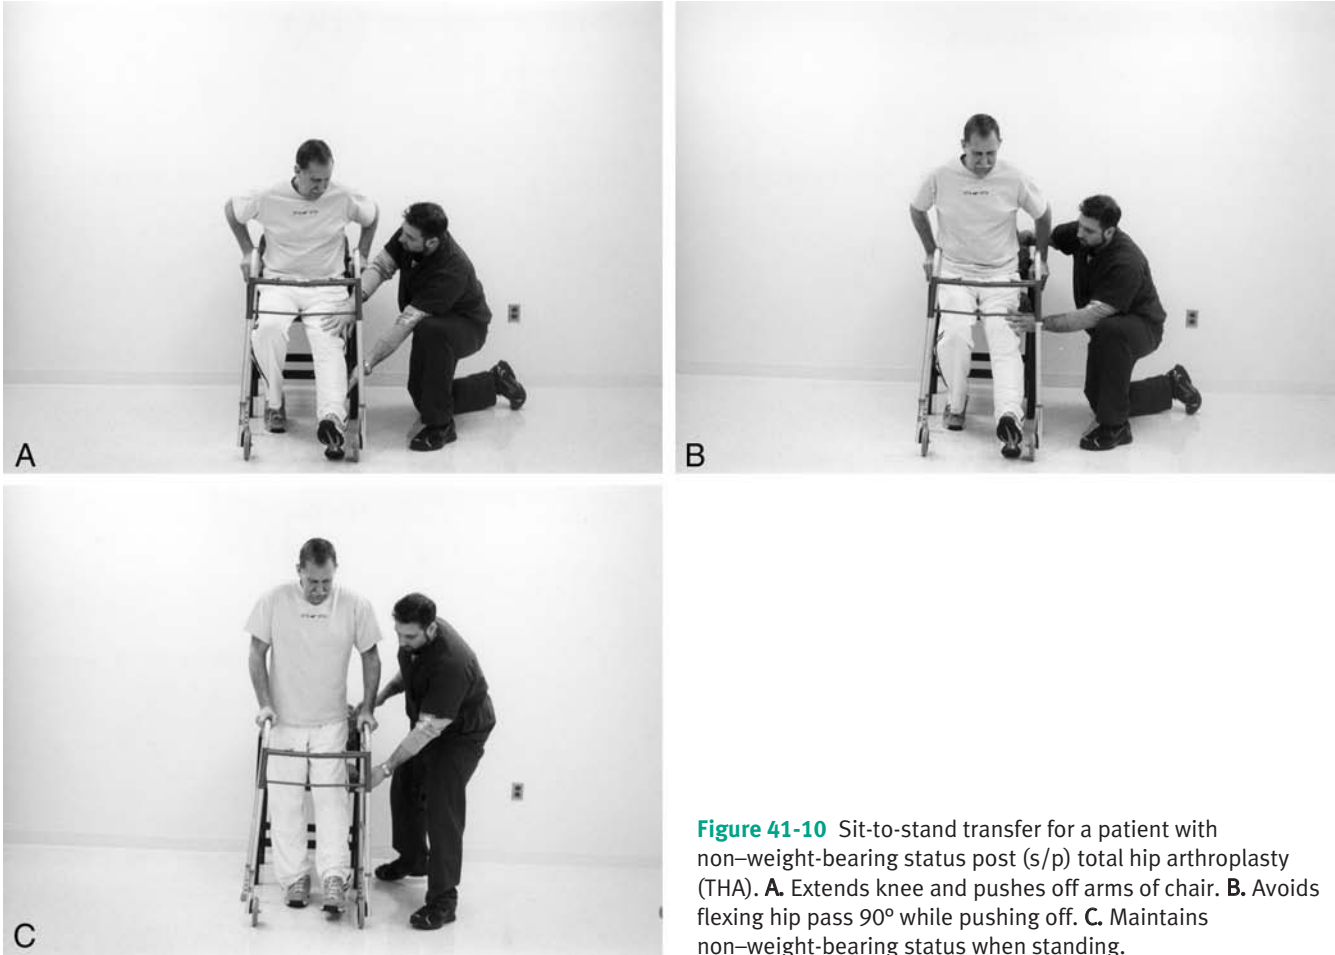

Figure 41-10 Sit-to-stand transfer for a patient with non-weight-bearing status post (s/p) total hip arthroplasty (THA). **A.** Extends knee and pushes off arms of chair. **B.** Avoids flexing hip past 90° while pushing off. **C.** Maintains non-weight-bearing status when standing.

Figure 41-11 Removing shoe status post total hip arthroplasty (THA). Approach medial aspect of shoe with long-handled shoe horn to prevent internal rotation.

50% weight bearing is ordered, the ADL program is upgraded to allow for standing with a cane. The cane is used until the **Trendelenburg gait** disappears.

Usually, after a total hip arthroplasty, patients do not receive outpatient therapy following inpatient rehabilitation, although many may receive home care occupational and physical therapy for safety assessment and/or treatment. Between the second and third month after surgery, patients usually resume all routine daily activities, with the restrictions listed in Safety Note 41-1 still applicable. For some, this restriction may persist for a long time, even for life. Mayo Clinic has recommended the following low-impact sport activities permissible at >12 weeks after surgery: golf, swimming, cycling, bowling, sailing, and scuba diving (Healy, Iorio, & Lemos, 2001). Tennis, skiing, and jogging are discouraged.

Low Back Pain

“Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage” (International Association for the Study of Pain, 2004).

Acute pain is proportional to the physical findings. It is often an indication that the patient has traumatized or damaged tissue. Physical and psychological responses to acute pain may include muscle guarding, anxiety, and increased pain behaviors (Healy, Iorio, & Lemos, 2001). Chronic pain is described as pain that extends beyond 3 months post injury (International Association for the Study of Pain, 2004). Patients with chronic pain often become preoccupied with their symptoms, experience sleep deprivation, and have difficulties performing their activities of daily living (Cieza et al., 2004). The goal is to alleviate the pain early to prevent psychological changes (Andersson, 1992).

Low back pain has been reported by approximately 80% of the adult population (World Health Organization, 2003). Postural stress is the most common cause of low back pain. Examples of postural stressors include poor sleeping and seated postures, lifting or reaching with a rounded back, and prolonged standing and seated postures (McKenzie, 2005). Other causes of back pain include spinal stenosis, vertebral fracture, tumor, infection, spondylolisthesis, and arthritis. Most episodes of low back pain are self-limiting; 90% of patients return to work within 6 weeks. One percent of patients, however, have chronic pain and are out of work for more than 6 months (Hu et al., 2003).

The primary goal in medically managed back care is to prevent the patient from developing chronic pain. Continued pain, distress, and illness behavior combine to reduce the patient's overall physical activity level, which leads to disuse syndrome, deconditioning (Waddell, 1992), and occupational dysfunction. If pain is not alleviated, the objective findings over time may have little or no association to a nociceptive stimulus. Chronic pain and disability become increasingly associated with emotional distress, depression, disease conviction (convince self and others that the disease exists), failure to cope, catastrophizing (feelings of total misfortune), and adaptation to chronic invalidism. This situation becomes self-sustaining and is often resistant to traditional medical management alone (Waddell, 1992).

The primary focus when treating patients with acute or chronic low back pain is to return them back to work and to resume their daily activities as quickly as possible. All efforts should be made to prevent the development of chronic pain syndrome by adopting practices used in sports medicine treatment to calm the pain and relax the muscles. Bed rest is replaced with early application of physical therapy, a flexibility program, and active involvement in a graduated program of occupation-as-end. Studies have shown that exercise can significantly reduce sick leave in patients with low back pain (Kool, 2004). As physical therapy helps the patient develop dynamic control of the lumbar spine through flexibility training, stretching, and ROM exercises, the occupational therapist directs the patient in performance of activities in a neutral

lumbosacral position (the midpoint of available range between anterior and posterior pelvic tilt). The occupational therapist teaches the patient to understand, manage, and protect the low back by using proper body mechanics and alternative techniques to perform activities at home and at work (Sanders, 2004). As endurance training progresses in physical therapy, the occupational therapist upgrades the type and quantity of ADL and work-related task challenges. When return to usual and customary activities is imminent, the treatment addresses safety and prevention of recurrence.

Teaching patients about their back and body mechanics has been part of rehabilitation for many years. The multidisciplinary team usually consists of a physician, a physical therapist, an occupational therapist, and, in some instances, a social worker or psychologist. The philosophy is that education in anatomy, spine function, and proper body mechanics for daily living and leisure activities will help patients with low back pain take responsibility for long-term management of their back. Patients are taught to live well despite back pain and to prevent recurrence or aggravation of symptoms by working and behaving correctly (Kumar & Konz, 1997). The multidisciplinary approach to treating patients with low back pain can significantly reduce pain and improve occupational functioning (Guzman et al., 2001).

Evaluation of the Patient with Low Back Pain

In the initial interview, the therapist asks about the pain history and pain reaction during activity. Patients are asked to describe their pain in relation to location, intensity (using a 0–10 pain scale), quality (is pain sharp, throbbing, burning, etc.), and duration. Inquiry into occupational function determines the person's extent of accommodation and methods for task completion. Observation of actual or simulated performance of tasks may be indicated to reveal the patient's functional limitations and decision-making process.

Treatment of the Patient with Low Back Pain

The occupational therapist facilitates the patient's active participation in tasks and activities that correspond to the medical stage by teaching body mechanics and how to perform activities safely. Use of relaxation techniques for stress reduction, biofeedback for muscle control, and group educational sessions may also be included in the occupational therapy program. Body mechanics are taught relative to static and dynamic postures and transition patterns (e.g., sit to stand, stand to stoop). The occupational therapist demonstrates body mechanics with commonly performed tasks to show the patient how to apply the principles to everyday tasks. Emphasis is on both cognitive and motor learning to develop the patient's understanding and ability to self-regulate motor activity safely. Therapeutic activity, including

PROCEDURE FOR PRACTICE 41-4

Principles of Body Mechanics (Fig. 41-12, A–C)

The patient is taught to do the following:

- Incorporate a pelvic tilt during static sitting or standing to unload the facet joints, aid in pelvic awareness, and decrease muscular tension in the low back.
- Position the body close to and facing the task. This aids in balance by getting the objects as close to the center of gravity as possible. Objects held away from the body require increased force of all muscles to lift or hold them. Getting closer also helps to avoid twisting or bending the spine.
- Avoid twisting. Twisting causes stress on the ligaments and small muscles of the spine. Instead, turn the body by stepping with both legs to face the activity.
- Use the hip flexors and extensors to lower and raise the body. These are large muscles with leverage and power to handle heavy loads. The joints and muscles of the spine are much smaller, with less leverage and power.
- Avoid prolonged repetitive activity or static positions. Take microbreaks and walk briefly or stretch every hour.
- Balance activity with rest to facilitate endurance and safety. Incorporate rest periods into the course of a particular activity or alternate between two work patterns that challenge different muscle groups.
- Use a wide base of support. Stability while lifting is increased when the feet are at least hip distance apart. One foot slightly in front of the other provides additional support.
- Keep the back in proper alignment, ear over shoulder, shoulder over hips, and hips over knees and feet to maintain the natural curves of the back. Practice in front of a mirror.
- Test a load before lifting to decide whether the lift should be modified. Describe how to modify the lift: get help, split the load into more than one lift, or put the object on wheels.
- Stay physically fit. Strong muscles and flexible joints are the best defense against injury or recurrence of an injury.

games, crafts, ADLs, and work tasks, are selected for practice. Through feedback, the therapist guides the patient's performance during the activities and encourages development of self-regulation.

Body Mechanics

Good body mechanics entails practices to reduce the load or stresses on the spine in various positions or when

moving objects. Compression and twisting of the spine are avoided, as are attempts to exert force in positions that poorly support the spine (Procedures for Practice 41-4). Suggestions for application of principles of body mechanics in various postures are as follows:

- While standing, for example to cook or wash dishes in the kitchen or to brush teeth at the bathroom sink, the patient places one foot on the shelf under the sink

Figure 41-12 Lift using proper body mechanics. **A.** Move close to object being lifted. **B.** Lift with legs and maintain lumbar curve. **C.** Maintain lumbar curve throughout lifting activity.

or on a low stool to achieve posterior pelvic tilt. This technique is used whenever prolonged standing is a requirement.

- To sit, the patient lowers the body by flexing the knees and hips without bending the spine. To do so, the patient places the hands on the chair’s armrest, both to guide the descent and to provide support through the transition. A raised seat is recommended because it requires less muscle power, which reduces pain and stress on the back. A slightly reclined sitting posture is preferred for prolonged sitting. When seated to work at a table, the patient avoids bending over the work by moving the chair close to the work and raising or inclining the work surface as needed.
- For tasks that ordinarily require excessive reaching and bending of the spine, such as sweeping, vacuuming, or raking, the patient is taught to move the body close to the task, that is, to walk with the broom or rake rather than reaching with it.
- For lifting objects from the floor, the choice of position depends on the size and weight of the object. To pick up a lightweight object, such as a newspaper, the patient faces the newspaper and lowers both knees in a

semisquat (or a ballet position of plié) toward the floor while keeping the back straight and maintaining posterior pelvic tilt. When lifting a large or heavy object or a small child, the patient adds more central support by lowering one knee to the floor (half-kneeling) so that the body is close to and facing the object. The goal is to bring and keep the weighted mass as close to the body’s center of gravity as possible. A small child is encouraged to climb up into the lap. Once the object or child is grasped securely, the knee on the floor helps push the body up, and then both legs extend to lift the weight. The patient should be instructed to lift to an intermediate height, such as a chair, if possible, rest briefly, and then lift to carry.

- The patient is taught to carry light, well-balanced loads of laundry, groceries, and parcels close to the body. Infants are best transported in a front or back baby carrier or a stroller. Through practice sessions, the patient learns his or her safe load tolerances over given distances and time. It is important that practice employ common items, such as half a gallon of milk, which weighs 4 pounds, or a gallon of bottled water, which weighs 8 pounds.

CASE

EXAMPLE

Mrs. B.: Total Hip Replacement

Occupational Therapy Process

Patient Information

Mrs. B. is a 72-year-old married female who fell on ice 3 days ago when she walked from her house to her car. She was admitted to the hospital on the same day with a diagnosis of a right intertrochanteric hip fracture. Due to the severity of the hip fracture, Mrs. B. required surgical intervention the same day. She received a cemented total hip replacement. Mrs. B. anticipates returning home to be with her husband and eventually resuming her family and volunteer roles.

Clinical Reasoning Process

Objectives

Examples of Therapist’s Internal Dialogue

Understand the patient’s diagnosis or condition

“Most patients status post cemented total hip replacement can begin weight bearing as tolerated, and so I am hopeful that Mrs. B. will be given the same weight-bearing orders. The surgeon performed the total hip replacement using a posterolateral approach, so precautions must be taken to avoid dislocation.”

Know the person

“Mrs. B. has a history of osteoarthritis in both hips; however, she has been able to manage the pain with Advil.”

“Mrs. B. obviously values her home life and being active in the community.”

Reason for Referral to Occupational Therapy

Mrs. B. was referred to occupational therapy (OT) for the duration of her acute-care post-operative hospital stay, approximately 5 days, to learn how to move safely while adhering to hip precautions, to practice transferring, and to begin to resume personal activities of daily living. She was also referred to physical therapy.

Appreciate the context

Develop provisional hypotheses

“Mrs. B. will have to follow the hospital’s total hip replacement critical pathway, which allows a 5-day stay. I am glad she was referred to physical therapy, as we will be able to coordinate our services as well as co-treat during some of our sessions. I anticipate at the end of her 5 day stay that Mrs. B. will have improved occupational functioning by understanding hip precautions and practicing with long-handled equipment. The co-treatments with physical therapy will help to improve her confidence and ability to transfer.”

Assessment Process and Results

- The evaluation began with an interview concerning the patient’s home environment. Mrs. B. reports that she lives with her husband in a one-story ranch-style home. There are four steps to enter her home. The bathroom has a combined tub and shower.
- Bed mobility and transfers were assessed. Mrs. B. required minimal assistance for bed mobility and contact guard (CG) with verbal cues for tub and toilet transfer (using standard walker).
- Self-care: Dressing: hip precautions were reviewed and use of long-handled adaptive equipment was demonstrated prior to the assessment. Mrs. B. was independent with upper body dressing but required moderate assistance for lower body dressing. Mrs. B. required constant verbal cueing on hip precautions during dressing assessment. Bathing: Mrs. B. is (I) sponge bathing (bedside) her upper body and requires moderate assistance bathing her lower body (with aide of long-handled sponge).
- Upper extremity ROM: AROM is within functional limits (WFLs) throughout both upper extremities.
- Manual Muscle Test (MMT): 4/5 muscle strength throughout both upper extremities.
- Pain (scale 0–10): Mrs. B. reported a 7/10 for her right hip. Mrs. B. reports her pain is constant and interferes with her sleep and any movements she has been requested to do by nursing.

Consider evaluation approach and methods

Interpret observations

“Due to the orthopaedic nature of Mrs. B.’s injuries, a biomechanical approach that focused on her impaired occupational functioning was used to assess her impaired abilities and capabilities.”

“Pain was reported throughout the entire evaluation, which I was concerned might interfere with her progress. I contacted the patient’s surgeon, and pain medications will be increased and administered to coordinate with occupational and physical therapy treatment sessions. ROM and muscle strength of both upper extremities were assessed to determine their ability to assist with transfers. Her major limitations are with her ADLs and mobility activities.”

Occupational Therapy Problem List

- Pain that interferes with sleep and movement
- Impaired ADL status
- Unsafe transfers and mobility due total hip replacement (THR)
- THR restrictions

Synthesize results

“Mrs. B. has the typical problems one faces following a THR.”

Occupational Therapy Goal List

1. Mrs. B. will have a pain level of 3/10 during all self-care activities.
2. Mrs. B. will be able to transfer to and from a chair, bed, tub bench, and toilet while adhering to the hip precautions.
3. Mrs. B. will demonstrate how to use long-handled equipment to independently perform functional tasks in the kitchen, bedroom, and bathroom while adhering to hip precautions.

Develop intervention hypotheses

Select an intervention approach

Consider what will occur in therapy, how often, and for how long

“I feel Mrs. B. will have improved occupational functioning by learning total hip replacement precautions. The structured daily therapy will also build her confidence for performing mobility and transfer tasks.”

“The occupational therapy intervention will use a combined compensatory approach and biomechanical approach.”

“Following the critical pathway, Mrs. B. will have five individualized treatments from occupational during her inpatient stay. An additional 3 co-treatments with physical therapy will be added to address mobility and transfers.”

Intervention

Mrs. B. participated in 8 treatments over a 5-day inpatient stay. Her pain medication was coordinated with OT visits. Both the occupational therapist and physical therapist taught Mrs. B. postures and movements that would be safe for her operated hip during transfers, sitting, standing, lying in bed, and bending and reaching during ADLs and IADLs. Transfers were performed using a standard walker. She practiced with long-handled equipment while adhering to hip precautions. Tasks or components of tasks that she could not complete satisfactorily were identified. Mr. B. attended all of the OT sessions with his wife, and he agreed to assist his wife with those activities identified as being difficult for Mrs. B. The therapist taught Mrs. B. energy conservation techniques to be used during ADLs and IADLs. Mrs. B. was given a written and illustrated brochure concerning restrictions related to ADL. The therapist determined that Mrs. B.'s husband, with the assistance of a home health aide, could provide the necessary care for ADL and IADL that she could not manage because of hip precautions. Therefore, the recommendation was to discharge her home rather than to a skilled nursing facility.

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance

Know the person

Appreciate the context

“Mrs. B. made significant improvement in her occupational functioning with intensive therapy that used a team approach and family support.”

Next Steps

Discharge to home with assistance of home health aide. Recommend home care OT.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Mrs. B. is a highly motivated individual who will benefit from home care occupational therapy to further maximize her occupational functioning. She understands the importance of her home program as well as continuing with structured supervised occupational therapy. I feel confident that, in 6 months, Mrs. B. will be successfully participating in those occupational roles that she identified as valuable in her life (wife, homemaker, and volunteer).”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of Surgical Approach on ADLs

During her inpatient stay, Mrs. B. required multiple verbal cues to avoid flexing beyond 90°. Mr. B. informed you that he ordered an over-the-toilet commode for when Mrs. B. is discharged home. What adjustments can be made on the commode to ensure she does not flex beyond 90° or dislocate? Would you recommend the same adjustments for Mrs. B. if she had an anterolateral approach?

Evidence Table 41-1 Best Evidence for Occupational Therapy Practice Regarding Pain Management

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Multidisciplinary Pain Management Program	The program included physical, psychological, activity-based, and social interaction-based training and education. The team consisted of occupational therapist, psychologist, physician, physiotherapist, and social worker. Group-oriented program (8–9 patients per group) but with individually tailored treatment for each patient.	188 patients with pain diagnoses (fibromyalgia, low back, whiplash, and myalgia). Males: 42; females: 146. Mean age = 41 years. Mean pain duration was 7.6 years for females and 5.8 years for males.	5–7 hours each session, once a week for 5 weeks.	One group, repeated-measures design. IIIA2a	Yes. There was significant improvement in occupational performance and performance satisfaction as measured by the <i>Canadian Occupational Performance Measure (COPM)</i> ; 30–37% of patients increased 2 or more points on the <i>COPM</i> ; 44–56% increased more than 1 point in performance and satisfaction.	$p < 0.001$; insufficient data to allow calculation of the effect sizes.	Persson, Rivano-Fischer, & Eklund, 2004

Evidence Table 41-2 Best Evidence for Occupational Therapy Practice Regarding Regarding Hip Fracture

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Early Post-Operative Individualized Occupational Therapy (OT)	OT group: individual daily ADL and IADL training, including the use of technical aids. Control group (conventional care).	100 eligible patients aged ≥ 65 years with independent residence. Did not use walking or technical aids prior to hospitalization.	After the 3rd to 4th post-operative day, the OT group received 45-60 minutes of individualized training (including technical aids) each weekday morning for 3-33 days. The control group received conventional care from the nursing staff for 3-23 days. All patients received instruction in walking with mobility aids.	Randomized controlled trial. IB1b	Yes. OT sped up the ability of patients to perform ADL, enhancing probability of discharge home. At discharge, the OT group had significantly better ability to dress, to take care of personal hygiene, to toilet, and to bathe independently compared with the control group. No other factors (e.g., age, sex, type of fracture, etc.) explained the outcome. After 2 months, all patients had regained their ADL and IADL abilities.	<i>Klein-Bell ADL Scale</i> subtests: Dressing: $F_{(2,91)} = 79, p = 0.0001, r = 0.31$. Toileting: $F_{(2,90)} = 5.97, p = 0.02, r = 0.20$. Bathing/hygiene: $F_{(2,91)} = 17, p = 0.0001, r = 0.31$. Mobility: $F_{(2,91)} = 2.20, p = 0.1, r = 0.13$. 52% of the OT group (only group evaluated) needed technical aids and adaptation of their homes. Preventative changes (remove loose rugs, etc.) were needed in 90% of the homes.	Hagsten, Svensson, & Gardulf, 2004

SUMMARY REVIEW QUESTIONS

1. What are the unwanted side effects of immobilization of any fracture?
2. How would you direct your patient to prevent adverse side effects of prolonged immobilization?
3. What is a major treatment goal for any patient with an upper extremity fracture?
4. Why is passive motion not used in the treatment of fractures of the elbow?
5. What are the guiding principles for advancing a patient in the aftercare therapy program following orthopaedic surgery?
6. What is clinical union, and why is it significant in terms of the therapy program?
7. Why are isometric contractions across the fracture site encouraged?
8. Describe the type of exercise performed at 6, 8, and 12 weeks post-op rotator cuff repair.
9. What is the occupational therapist's role for the patient who underwent hip replacement surgery after a fractured hip?
10. After a hip fracture or total hip joint arthroplasty, the therapist directs the patient to perform occupational performance tasks safely. What specific tasks may threaten the integrity of the surgical procedure? Why?
11. List precautions that must be taught to a patient with a total hip arthroplasty (posterolateral and anterolateral approaches).
12. Describe how lower extremity dressing should be taught to a patient with low back pain, using all applicable body mechanic principles. Do the same for the tasks of sweeping the floor and working at a computer.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. State principles and general precautions of hand therapy evaluation and intervention.
2. Select splint positions that minimize, prevent, or correct hand deformity.
3. Describe clinical features of common hand impairments.
4. Recognize and foster favorable tissue responses to hand therapy interventions.
5. Promote pain-free occupational functioning of persons with hand impairment.

CHAPTER 42

Hand Impairments

Cynthia Cooper

Glossary

Anti-deformity position, intrinsic-plus position—Position of digital MP flexion and IP extension that maintains the length of the collateral ligaments and volar plate.

Buddy straps—Straps between an injured and an adjacent digit to protect or to promote movement.

Carpal tunnel syndrome—Nerve entrapment involving compression of the median nerve at the wrist causing sensory symptoms typically involving the thumb, index, and long finger and radial half of the ring finger.

Cervical screening—Proximal screening assessment of neck and shoulder to identify causes of or contributors to distal symptoms.

Claw deformity—Position of MP hyperextension and PIP flexion associated with muscle imbalance in ulnar-innervated structures.

Complex regional pain syndrome (CRPS)—Previously called reflex sympathetic dystrophy. CRPS is characterized by pain that is disproportionate to the injury, along with swelling, stiffness, and discoloration. Sudomotor (sweating) changes are often seen.

Contracture—Lack of passive motion due to tissue shortening.

Counterforce strap—Support or strap used over flexor or extensor muscle wads to support muscles and prevent maximum muscle contraction, decreasing load on the tendon. Often used to reduce symptoms of lateral or medial epicondylitis.

Cubital tunnel syndrome—Nerve entrapment involving compression of the ulnar nerve at the elbow between the

medial epicondyle and olecranon. Sensory symptoms affect the small finger and ulnar half of the ring finger. Motor symptoms affect the FCU, FDP of the ring and small fingers, AP, and interossei.

de Quervain's disease—Tenosynovitis involving the abductor pollicis longus and EPB tendons at the first dorsal compartment.

Extensor lag—Inability to extend a joint actively while passively being able to.

Hard end feel—Unyielding quality of joint motion at end range passively. Indicates an established joint restriction.

Kirschner wires—Fixation devices used alone or in conjunction with other forms of fixation to treat unstable fractures of the hand.

Neuroma—Disorganized mass of nerve fibers that can occur following nerve injury. Significant nerve pain with associated hypersensitivity is elicited by tapping over the neuroma.

Oscillations—Rhythmic movements that may be helpful to reduce guarding and pain.

Place-and-hold exercises—Passive motion used gently to achieve a position, with the patient then actively sustaining or holding that position.

Soft end feel—Spongy quality of joint motion at end range passively. Indicates favorable potential for tissue remodeling.

Tenolysis—Surgical procedure to release tendon adhesions that restrict movement.

Hand problems, which may be cosmetic or functional or both, are hard to hide. Hands function exquisitely to gesture and express, touch and care, dress and feed (Tubiana, Thomine, & Mackin, 1996). Impairment can be devastating. The purposes of this chapter are to introduce readers to the elements of hand therapy, to highlight the breadth of material that hand therapy encompasses, and to identify resources for further study.

The complex arrangement of the hand, with its intimate anatomy and multiarticulate structures, is unforgiving of stiffness, scar, or edema. Injury at one site can lead to stiffness of other parts of the hand. To test this for yourself, passively hold your ring finger in extension and then try to make a fist. This example, called the quadregia effect, demonstrates the interconnectedness of digits, whereby limited movement of one digit may cause restricted motion in uninjured digits (Burkhalter, 1995). For this and other reasons, hand therapists must look at more than the

isolated site of injury and must continually reexamine the patient's performance in the areas of occupation.

Hand therapy originated during World War II. Devastating upper extremity injuries of that era and of subsequent wars prompted a team approach to medical care (Hunter, 1986). Today, members of the rehabilitation team in hand therapy can include physicians and physician assistants, nurses, occupational therapists and occupational therapy assistants, physical therapists and physical therapy assistants, and aides or technicians. Workers' compensation representatives or case managers representing payers may also be involved.

Certified hand therapists are occupational therapists or physical therapists with advanced clinical skills who have passed the examination for certification in hand therapy. A minimum of 5 years of clinical experience and other criteria are prerequisites to taking the examination. It is advisable to establish a strong generalist background in occupational therapy before specializing in hand therapy.

Hand therapy differs from other occupational therapy specializations, such as pediatrics or gerontology, because it merges occupational therapy and physical therapy, and it has its own professional organizations. Although most hand therapists are occupational therapists, actual clinical practice may often look more like physical therapy than occupational therapy. Occupational therapy hand therapists should embrace an occupational therapy identity by grounding intervention in core concepts of our profession. To this end, hand therapists should not become so focused on specific anatomical structures that they overlook the person attached to the hand. They should treat the hand and should also address performance skills and performance patterns of the occupational human whose hand it is.

PSYCHOSOCIAL FACTORS AFFECTING THERAPEUTIC OUTCOMES

Why do some people with minor hand injuries wind up with large disabilities and others with devastating injuries have only small disabilities? Adaptive responses to hand

impairment are influenced by body image as well as individual functional needs and contextual elements. The personal or symbolic meaning of the hand, self-esteem, family and friend support systems, and coping strategies all influence outcome (Grunert et al., 1991). Whenever possible, encourage patients to participate in their care. Introduce yourself, maintain eye contact, listen well, use non-medical terminology and instructional diagrams, and encourage some amiable conversation as appropriate (Moskowitz, 1996). It can be helpful to touch patients' hands supportively and to make positive remarks (see Chapter 15).

Motivation is the most important variable favorably influencing recovery (Chin et al., 1999). Realistic expectations and appropriate communication that emphasizes education are also important (Bryan & Kohnke, 1997; Moskowitz, 1996). Psychological symptoms related to hand trauma resolve best when intervention occurs early (Grunert et al., 1991).

HAND THERAPY CONCEPTS

The following concepts are keys to clinical reasoning for all diagnoses of hand impairment. Intervention should not be determined by diagnosis per se. Rather, hand therapy relies on an understanding of anatomy and physiology, wound healing, biomechanics, tissue tolerances, psychosocial issues, and probable outcomes. Given the infinite variations among people, no two intervention plans should be the same.

Tissue Healing

Tissue heals in phases as follows: inflammation, fibroplasia, and maturation or remodeling. The inflammation phase lasts several days. It includes vasoconstriction followed by vasodilation, with white blood cell migration to promote phagocytic removal of foreign bodies and dead tissue. Depending on the diagnosis, immobilization to provide rest is often advised during the inflammation phase (Smith & Price, 2002).

The fibroplasia phase starts at approximately day 4 and continues for 2–6 weeks. In this phase, fibroblasts synthesize scar tissue. The wound's tensile strength increases gradually with the increase in collagen fibers. At this time, active range of motion (AROM) and splints may be appropriate to protect healing tissues and promote balance in the hand (Fess & McCollum, 1998).

The maturation, or remodeling, phase may last for years, but tissue is usually more responsive early rather than late in this period. The remodeling phase reflects the changing architecture and improved organization of collagen fibers, and the associated increased tensile strength. Gentle resistive activity may be appropriate during maturation,

but it may also generate inflammatory responses, which should be avoided. Gentle application of corrective dynamic or static splinting may also be appropriate (Fess, 1993). Tolerance of tissues to controlled stress requires monitoring throughout all phases of intervention.

As tissue continues to heal, the wound contracts, and the scar shrinks. Collagen continues to remodel, as it is constantly doing in uninjured tissue (Smith & Price, 2002).

Anti-Deformity Positioning

Upper extremity injury and disuse are associated with predictable deforming hand positions. Edema, which typically

accompanies injury, creates tension on extrinsic extensor structures. This leads to a zigzag collapse with a resulting deformity position of flexed wrist, hyperextended metacarpophalangeals (MPs), flexed proximal interphalangeals (PIPs) and distal interphalangeals (DIPs), and adducted thumb (Pettenigill, 2002).

Hand joints are anatomically destined to stiffen in predictable positions. Specifically, the MP joint is prone to stiffen in extension. This is because the protruding or cam shape of the metacarpal head causes the collateral ligament to be slack in MP extension and taut in MP flexion. Conversely, the interphalangeal (IP) joints are prone to become stiff in flexion because the volar plate folds on itself (Tubiana, Thomine, & Mackin, 1996).

When prolonged or constant immobilization is necessary and range of motion (ROM) is at risk, it is usually best to splint the patient's hand in the **anti-deformity position**, also called the intrinsic-plus position (Fig. 42-1). This position places the wrist in neutral or extension, the MPs in flexion, the IPs in extension, and the thumb in abduction and opposition. The anti-deformity position allows the collateral ligaments at the MP joints and the volar plate at the IP joints to maintain their length, which counteracts the forces that promote zigzag collapse. Certain diagnoses, such as flexor or extensor tendon repair, are not compatible with anti-deformity positioning. The physician can assist in this determination.

The Myth of No Pain, No Gain

Regarding tissue tolerances, the myth of no pain, no gain must be dispelled in hand therapy. A better mindset would be no pain, more gain. Well-intentioned therapists and overzealous family members of patients have too often caused irreversible damage by applying passive range-of-motion (PROM) forces beyond the tissues' tolerances (Fess, 1993). Pain induced by therapy can also cause

RESEARCH NOTE 42-1

Zhao, C., Amadio, P. C., Tanaka, T., Yang, C., Ettema, A. M., Zobitz, M. E., & An, K. N. (2005). Short-term assessment of optimal timing for postoperative rehabilitation after flexor digitorum profundus tendon repair in a canine model. *Journal of Hand Therapy, 18*, 322–329.

Abstract

The purpose of this study was to compare the short-term outcome following flexor tendon repair for postoperative rehabilitation commencing on day 1 (a common clinical choice) versus day 5 (the day on which, with postoperative immobilization, the initial gliding resistance is least in this model) in an in vivo canine model. Work of flexion (WOF) and tendon strength were evaluated following tendon laceration and repair in 24 dogs sacrificed 10 days postoperatively. Starting postoperative mobilization at day 5 resulted in no tendon ruptures compared with tendon ruptures in four of the dogs (33%) in the group subjected to mobilization starting at day 1. Although no statistically significant difference was found in WOF between groups at day 10, there was a trend toward lower resistance favoring the day 5 start group, and the statistical power to detect a difference in WOF was diminished by the ruptures in the day 1 group. We conclude that starting rehabilitation on day 5, when initial gliding resistance is lower, may have an advantage over earlier starting times, when surgical edema and other factors increase the initial force requirements to initiate tendon gliding. We plan further studies to evaluate the longer-term benefits of this rehabilitation program.

Implications for Practice

- Initial gliding resistance is lower on post-operative day 5 than on post-operative day 1 due to the effects of surgical edema and other factors.
- This study validates previous studies and confirms that post-operative mobilization of flexor tendons is safer to initiate on day 5 instead of day 1.

Figure 42-1 Anti-deformity or intrinsic-plus position: Wrist in neutral or extension; MPs in flexion; IPs in extension; and thumb in abduction and opposition.

complex regional pain syndrome (CRPS), which is discussed later.

People with upper extremity problems often arrive at therapy prepared for painful intervention. Some patients do not tell the therapist when intervention hurts. It is essential to educate patients about this. In addition, watch the patient's body language and face for signs of pain. Wincing and withdrawing the upper extremity are obvious signals. Proximal guarding is another revealing response. Change the intervention accordingly, and if necessary, try a hands-off approach wherein the therapist coaches and instructs while the patient self-treats.

Passive Range of Motion Can Be Injurious

PROM can be injurious to the delicate tissues of the hand. Specifically, PROM can disturb healing tissues and incite further inflammatory reactions, resulting in increased scar production. PROM can damage articular structures and can even trigger CRPS (Fess, 1993). Tissue's timeline for remodeling is maximized by non-inflaming intervention and is cut short by intervention that is inflaming or provoking. For all of these reasons, if PROM is clinically appropriate, be sure it is done gently and in a pain-free manner. The potential for harm may be compounded if PROM is performed following external application of heat. Instead, low-load, long-duration splinting is a safer and more effective method for remodeling tissue and increasing PROM (Fess & McCollum, 1998).

Judicious Use of Heat

External application of heat, such as a hot pack, is a popular way to prepare tissues for stretching. Unfortunately, the clinical concerns of externally applied heat have received less attention than they deserve. Heat increases edema, which acts like glue. Heat may degrade collagen and contribute to microscopic tears (Miles, Burjanadze, & Bailey, 1995). Heat may also incur a rebound effect, with stiffening following its use. *Do not use heat on patients who have edema or whose limb appears inflamed.* Overall, it is safer to use aerobic exercise to warm up the tissues of people with hand impairments. If external application of heat is used, elevate the upper extremity, be gentle with exercise, and promote active movement in conjunction with the heat. Continue to monitor for immediate and subsequent signs of inflammation.

Isolated Exercise, Purposeful Activity, and Therapeutic Occupation

Technically, it is necessary to treat hand impairments with a structure-specific approach to isolate and care for the

discrete components that are involved. It may seem easiest to accomplish this type of exacting intervention in the form of isolated exercise. Traditional valuing of the appearance of highly technical clinical environments, medical model indoctrination, busy schedules, and financial or material constraints may contribute to the perpetuation of hand therapy identifying itself within an environment that looks like an exercise gymnasium. Although some hand therapists do incorporate purposeful activity into intervention, more support is needed for an alternative approach to hand therapy that leads with concepts of therapeutic occupation (Cooper & Evarts, 1998). One way to achieve this is to integrate patient-directed goals and activities of daily living (ADLs) into hand therapy intervention planning and implementation. Whenever possible, encourage upper extremity use in ordinary daily activities as appropriate to the diagnosis. Explore the capabilities in the clinic and then teach patients to do so at home. For example, folding socks and underwear can be upgraded to folding heavy towels and jeans, which require greater strength and endurance.

Occupation elicits adaptive responses that do not occur with exercise alone. Compared to isolated exercise, purposeful activity or occupation promotes more coordination and better movement quality (Nelson & Peterson, 1989). An example of isolated hand therapy exercise to increase grip strength is gross grasp with therapy putty or exercise grippers. An example of purposeful activity to increase strength would be putting away groceries, starting with light items and progressing to heavier objects.

Occupation-as-means instills occupational therapy's heritage in what might otherwise be a less function-oriented context (Trombly, 1995). The examples cited earlier become therapeutic occupation with the use of activity that is meaningful to the particular person to accomplish the therapeutic goal. If the patient enjoys baking, then rolling dough with a rolling pin would be a therapeutic occupation to promote grip function.

EVALUATION

History

History taking as part of the occupational profile offers an excellent opportunity to establish therapeutic rapport (Bryan & Kohnke, 1997). Review medical reports, including radiographs, when possible; learn hand dominance, age, occupation, and avocational interests (Aulicino, 2002). Assess deficits in the areas of occupation by asking what the patient cannot do that he or she wants to do, needs to do, or is expected to do. Also, discuss the case with the physician.

For trauma, learn the date of injury, dates of any surgery, where and how injury occurred, mechanism of injury, posture of the hand when it was injured, and any previous

intervention. For non-traumatic problems, learn the date of onset, whether the symptoms are worsening, sequence of onset of symptoms, functional effects, and what worsens and/or lessens the symptoms (Aulicino, 2002).

Pain

Pain may be acute or chronic. Acute pain has a sudden and recent onset, usually has a limited course with an identifiable cause, and can last a few minutes to 6 months. Acute pain serves a physiological purpose, signaling the need to protect tissue from further damage. Chronic pain lasts months or years longer than expected and may not serve a physiological purpose (Maurer & Jezek, 1992). Myofascial pain, which may be chronic or acute, stems from local irritation in fascia, muscle, tendon, or ligament. It has specific reproducible pain patterns and associated autonomic symptoms (Travell & Simons, 1983). Evaluation of pain may include a graphic representation of pain, in which the patient marks painful areas on a drawing of the human body; analog pain rating scales (see Chapter 5); joint or muscle palpation to identify areas of local pain or qualitative changes in soft tissue; and trigger point sensitivity (Maurer & Jezek, 1992).

Physical Examination

It is helpful to observe the positioning and use of the patient's upper extremity in the waiting area before the meeting. On examination, look at the entire unclothed upper extremity for posture, guarding and gesturing, atrophy, and edema (Aulicino, 2002). Since distal symptoms are often caused by proximal problems, it is important to perform a **cervical screening**, which is a proximal screening assessment of the neck and shoulder, to identify additional areas requiring intervention. For more detail on cervical screening, see Cyriax (1982).

Wounds

Always follow universal precautions (Chapter 49). Evaluate wound size in terms of length, width, and depth. Wound drainage (exudate) is bloody (sanguinous), serous (clear or yellow), purulent (pus), or deep or dark red (hematoma). Wound odor is absent or foul (Baldwin, Weber, & Simon, 1992).

The three-color concept (red, yellow, or black) dictates wound care. Wounds can be one of or a combination of these three colors. A red wound is healing, uninfected, and composed of revascularization and granulation tissue. A yellow wound has an exudate that requires cleansing and debridement. A black wound is necrotic and requires debridement. The goal of wound care is to convert yellow and black wounds to red wounds (Evans & McAuliffe, 2002).

Scar Assessment

Observe scar location, length, width, and height. Hypertrophic scars stay confined to the area of the original wound and usually resolve within a year. Keloids proliferate outside the area of the original wound and do not usually become smaller or less pigmented with time. Note any scar tethering or adherence of skin and tendon causing restricted movement. Any wound or scar crossing a joint may form a **contracture**, which restricts passive motion. Immature scar has a red or purplish color imparted by its vascularity. It blanches to touch. Mature scar is flatter and softer. It has neutral color and does not blanch to touch (Baldwin, Weber, & Simon, 1992).

Vascular Assessment

Cyanosis, erythema, pallor, gangrene, or grayish color indicates vascular compromise. To test digital capillary refill, apply pressure to the fingernail or distal pad of the involved digit. Color should return within 2 seconds of release of pressure. Compare the refill time to that of uninvolved digits (de Herder, 1992).

Edema

Circumferential measurement is quick to perform and provides a good alternative when it is not possible to use a volumeter (Fess, 2002a). Be consistent with measuring tape placement and tension. Volumetric measurement is contraindicated over open wounds, percutaneous pinning such as Kirschner wires, plaster casts, or vasomotor instability (Fess, 1993). See Chapter 5 for volumetric measurement procedures.

Range of Motion

In hand therapy, ROM is measured as AROM, PROM, or torque range of motion (TROM), which is a more consistent and objective type of PROM in which the therapist documents the amount of force applied externally to achieve maximal PROM (Breger-Lee, Bell-Krotoski, & Brandsma, 1990). At a minimum, both AROM and PROM should be evaluated and compared to the uninjured extremity (Adams, Topoozian, & Greene, 1992) (see Chapter 5). Facilities usually have their own guidelines for measuring ROM. As expected, consistency of retesting is important.

Total active motion or total passive motion measures the sum of composite digital flexion and extension. This measurement is used in some studies. Normal total active motion and total passive motion are 270° (Fess, 2002a) (Procedures for Practice 42-1).

PROCEDURES FOR PRACTICE 42-1

Total Active Motion and Total Passive Motion

- Add the measurements for flexion of the MP, PIP, and DIP joints.
- Subtract the combined deficits in extension for those joints.

Grip and Pinch

When properly calibrated, the Jamar dynamometer is one of the best instruments to assess grip strength because of its reliability, face validity, and accuracy (see Chapter 5). Hand therapy authorities recommend comparing scores to those of the contralateral extremity rather than using norms (Fess, 2002a). Goals for grip and pinch strength depend on occupational factors and dominance. There may be approximately 10–15% difference in strength between dominant and non-dominant hands, with dominant hands usually being stronger. Interpretation of maximal effort with grip testing exceeds the scope of this chapter. However, grip testing at all five notch settings of the dynamometer typically reveals a bell-shaped curve when consistent effort is used. For more on this subject, see Smith et al. (1989). It is routine to measure three pinch patterns: lateral, three-jaw chuck, and tip. As with grip, compare pinch scores to those of the contralateral extremity.

No linear relationship exists between improvement in grip and pinch strength and improvement in function. Rice, Leonard, and Carter (1998) noted that even debilitated, deformed hands could be surprisingly functional. These authors found only weak relationships between grip and pinch strength and the forces required to open six containers used commonly in the home. Thus, grip and pinch testing are not substitutes for ADL assessment with contextual relevance (Rice, Leonard, & Carter, 1998). To promote occupational functioning of people with hand impairments, it is far better to have intervention and goals reflect personally meaningful ADLs than grip or pinch strength measures.

Manual Muscle Testing

Manual muscle testing is particularly useful for monitoring progress following peripheral nerve lesions (see Chapter 5). Facilities usually have their preferred method of grading, which may be numerical or descriptive (Shultis-Kiernan, 1992).

Sensibility

Inspect the patient's hand for dryness, moistness, and calluses (see Chapter 7). Blisters may be an alert to injurious

hand use due to sensory loss. “Wear marks” illustrate where and how the hand is used and which parts of the hand avoid use, indicating sensory impairment (Callahan, 2002).

Hand therapy does not yet have one tool that evaluates the hand's functional sensibility (Moberg, 1991). The *Semmes-Weinstein Monofilament Test* and the *Two-Point Discrimination (2PD)* test are most commonly used in hand therapy. The *Semmes-Weinstein Monofilament Test* assesses pressure threshold, and the *2PD* assesses density of receptors. The *Moberg Pickup Test* (see Chapter 7) is a functional test appropriate for use on patients with median or median and ulnar nerve lesions.

Dexterity and Hand Function

No one evaluation covers all features of hand function (Jarus & Poremba, 1993). Standard terminology regarding hand function is lacking, and there is limited evidence that the assessment of hand function indicates the patient's actual performance in ADL (Desrosiers et al., 1993; Lynch & Bridle, 1989). Thus, hand function tests should not substitute for assessments of ADL or other areas of occupation. Hand function tests, however, can be helpful measures of improvement of performance skills.

For dexterity tests to be reliable, therapists must administer them using the standard procedures from the original articles or test manuals, and they must decide whether a specific test is valid for the intended use (Mathiowetz & Bass Haugen, 1995; Rider & Linden, 1988). The tests described in this section all require further validation study.

Minnesota Rate of Manipulation Test

The *Minnesota Rate of Manipulation Test* (1969) addresses manual or gross motor dexterity. It assesses the speed and accuracy of repetitive reaching, picking up, manipulating, and placing disks the size of double checkers. It has a 3-foot-long frame with four horizontal rows of openings in which the 60 disks are placed. Five subtests comprise the test: placing, turning, displacing, one-hand turning and placing, and two-hand turning and placing. The patient performs the test while standing. Each subtest starts with a practice trial and is tested three to five times. The score is the total time for the subtest trials. This test has been standardized with adaptations for use with patients who are visually impaired (Mathiowetz & Bass Haugen, 1995).

Test-retest reliability ranges from 0.87 to 0.95 for two-trial administration. Percentile tables are available, with norms based on young adults ($n = 11,000$) and on older unemployed adults ($n = 3,000$). Procedures for Practice 42-2 presents recommendations for interpretation of a particular patient's score using normative data from a percentile table.

PROCEDURES FOR PRACTICE 42-2

Interpretation of a Score Using Normative Data From a Percentile Table (Mathiowetz & Bass Haugen, 1995)

- Administer the test according to standard procedures.
- Compare the patient’s score with the most appropriate percentile table (e.g., worker category, sex, age).
- A patient scoring at the 20th percentile performed better than 20% and worse than 80% of the normative sample.
- A score at 2.3 percentile or higher is usually interpreted to be normal or within normal limits.
- A score falling between 2.3 and 0.1 percentile is interpreted to be a mild deficit.
- A score below 0.1 percentile is interpreted to be a moderate to severe deficit.

Interpretation of a Score Using Normative Data From a Mean and Standard Deviation Table (Mathiowetz et al., 1985a)

- Administer the test according to the standard procedures.
- Compare the right-hand score with the right-hand normative data appropriate to the age and sex of the patient.

For example, if a 23-year-old man transported 66 blocks within 1 minute with his right hand, his score of 66 would be compared with the mean of 88.2 and the standard deviation (SD) of 8.8 (Table 42-1). Using the formula below, it is found that he scored 2.5 SD below the mean relative to his age group and gender.

- Use this formula to determine the SD above or below the mean for a specific patient’s score:^a

$$\text{Client's score} - \text{mean} \div \text{SD} = \text{SD} \pm \text{mean}$$

Example:

$$66 - 88.2 = -22.2$$

$$-22.2 \div 8.8 = -2.5 \text{ SD}^a$$

^aIn tests such as the *Box and Block Test*, for which a high score indicates a better performance, a negative score means below the mean. In tests such as the *Nine-Hole Peg Test*, for which a high score indicates a poor performance, a negative score means above the mean (better than average performance). Thus the therapist can document objectively that the patient’s right-hand performance on the *Box and Block Test* of manual dexterity was 2.5 SD below the mean. To determine the statistical meaning of the patient’s score, the therapist must assume that the *Box and Block Test* scores are normally distributed. In a standard normal distribution table, 97.7% of the sample scores are greater than 2 SD below the mean; 2.2% are between 2 and 3 SD below the mean; and 0.1% are more than 3 SD below the mean. By convention, a score that falls 2 SD below the mean or higher is usually interpreted to be normal or within normal limits. A score falling between 2 and 3 SD below the mean is interpreted to show a mild deficit. A score more than 3 SD below the mean is interpreted to show moderate to severe deficit. Thus the example patient would be considered to have a mild deficit in manual dexterity relative to the normative data.

Table 42-1. Average Performance of 628 Normal Subjects on the Box and Block Test^a

Age (Years)	Males		Females		Age (Years)	Males		Females	
	Mean	SD	Mean	SD		Mean	SD	Mean	SD
20–24					50–54				
Right hand	88.2	8.8	88.0	8.3	Right hand	79.0	9.7	77.7	10.7
Left hand	86.4	8.5	83.4	7.9	Left hand	77.0	9.2	74.3	9.9

Left hand	75.8	7.8	78.3	7.6	Left hand	61.3	8.4	63.6	7.4

^aValues are number of cubes transferred in 1 minute. Mathiowetz et al., 1985a.

Figure 42-2 *Box and Block Test* of manual dexterity.

Box and Block Test

The *Box and Block Test* measures gross manual dexterity. It was developed to test people with severe problems affecting coordination (Fig. 42-2). This test must be constructed according to specific dimensions and published specifications (Mathiowetz et al., 1985a). The subject transfers 1-inch blocks from one side of the box to the other. The score

is the number of blocks transferred in 1 minute for each hand. Procedures for Practice 42-3 presents procedures for administration of the test (Mathiowetz et al., 1985a).

Test-retest reliability of the *Box and Block Test*, established at a 6-month interval, was high ($r = 0.94$ for left hands and $r = 0.98$ for right hands) (Cromwell, 1976). Inter-rater reliability reflected strong correlations ($r = 1.00$ for right hand and $r = 0.999$ for left hand) (Mathiowetz et al., 1985a). Concurrent validity ($r = 0.91$) was established with the placing subtest of the *Minnesota Rate of Manipulation Test* (Cromwell, 1976).

The *Box and Block Test* is preferred to the *Minnesota Rate of Manipulation Test* because the normative data for the *Box and Block Test* have a broader range, the patient is allowed to sit while being tested, and it is time limited (Mathiowetz & Bass Haugen, 1995) (Procedures for Practice 42-3).

Purdue Pegboard Test

The *Purdue Pegboard Test* of finger dexterity (Tiffin, 1968) assesses picking up, manipulating, and placing little pegs into holes with speed and accuracy. It tests finger or fine motor dexterity (Mathiowetz et al., 1986). It has a wooden board with two rows of tiny holes plus reservoirs for holding pins, collars, and washers. The four subtests are per-

PROCEDURES FOR PRACTICE 42-3

Administration Procedures for the *Box and Block Test* (Mathiowetz et al., 1985a)

- Place the test box lengthwise along the edge of a standard-height table (Fig. 42-2).
- The 150 cubes are in the compartment of the test box to the dominant side of the patient.
- Sit facing the patient to monitor the blocks being transported.
- Give these instructions: “I want to see how quickly you can pick up one block at a time with your right [left] hand [the therapist points to the dominant hand]. Carry the block to the other side of the box and drop it. Make sure your fingertips cross the partition. Watch me while I show you how.”
- Transport three cubes over the partition in the same direction the patient is to move them.

After the demonstration, say, “If you pick up two blocks at a time, they will count as one. If you drop one on the floor or table after you have carried it across, it will still be counted, so do not waste time picking it up. If you toss the blocks without your fingertips crossing the partition, they will not be counted. Before you start, you will have a chance to practice for 15 seconds. Do you have any questions? Place your hands on the sides of the box. When it is time to start, I will say ‘Ready’ and then ‘Go.’”

- Start the stopwatch at the word *go*. After 15 seconds, say “*Stop*.”
- If the patient makes mistakes during the practice period, correct them before beginning the actual testing.
- On completion of the practice period, return the transported cubes to the compartment.
- Mix the cubes to ensure random distribution, and then say, “*This will be the actual test. The instructions are the same. Work as quickly as you can. Ready; go. [After 1 minute:] Stop*.”
- Count the blocks transported across the partition. This is the patient’s score for the dominant hand.
- If the patient transports two or more blocks at the same time, subtract the number of extra blocks from the total.
- After counting, return the blocks to the original compartment and mix randomly.
- Turn the test around so that the blocks are on the non-dominant side.
- Administer the test to the non-dominant hand using the same procedures as for the dominant hand, including the 15-second practice.

formed with the subject seated. To begin, there is a brief practice. The subtests for preferred, non-preferred, and both hands require the patient to place the pins in the holes as quickly as possible, with the score being the number of pins placed in 30 seconds. The subtest for assembly requires the patient to insert a pin and then put a washer, collar, and another washer on the pin, with the score being the number of pieces assembled in 1 minute (Mathiowetz & Bass Haugen, 1995). The *Purdue Pegboard Test* manual provides normative data using percentile tables for adults and different categories of jobs and for children 5–15 years of age by age and sex.

One-trial administration of the *Purdue Pegboard Test* produced test–retest reliability of 0.60 to 0.79. Three-trial administration test–retest reliability ranged from 0.82 to 0.91 (Mathiowetz et al., 1986). Administering three trials for the four subtests took more time (20 minutes instead of 10) but provided better reliability. Gallus (1999) reported high test–retest reliability ($r = 0.85\text{--}0.96$) and no practice effects based on individuals with multiple sclerosis. A limitation of the *Purdue Pegboard Test* is that it was developed to select industrial employees. The validity of its use in identifying a need for occupational therapy should be evaluated (Mathiowetz, 1993).

Nine-Hole Peg Test

The *Nine-Hole Peg Test* measures finger dexterity among patients with physical disabilities. This test is sold commercially, or it can be constructed according to published details (Mathiowetz et al., 1985a). Test administration is brief, involving the time it takes to place nine pegs in holes in a 5-inch square board and then remove them. The *Nine-Hole Peg Test* had high inter-rater reliability ($r = 0.97$ for right hand and $r = 0.99$ for left hand). Test–retest reliability was moderate: ($r = 0.69$ for right hand and $r = 0.43$ for left hand) (Mathiowetz et al., 1985b). Concerns exist about the transferability of these norms to data collected with commercial versions of the test that use different materials (Davis et al., 1997).

The *Purdue Pegboard Test* is preferred to the *Nine-Hole Peg Test* in the measurement of finger dexterity. Of the two, the *Purdue Pegboard Test* has better test–retest reliability; it is time limited; it is for both unilateral and bilateral assessment; and its normative data reflect a broader age range (Mathiowetz & Bass Haugen, 1995).

Jebsen Test of Hand Function

The *Jebsen Test of Hand Function* assesses hand function in terms of simulated ADL (Jebsen et al., 1969). It can be administered quickly (Jarus & Poremba, 1993). The test's seven timed subtests consisting of writing a sentence, simulated page turning, picking up small common objects, stacking checkers, simulated eating, moving empty cans, and moving heavy cans. Construction specifications and

standard procedures are documented (Jebsen et al., 1969). As with all standardized tests, it is important to follow the standard procedures (Jarus & Poremba, 1993). For example, substituting plastic checkers for wooden checkers resulted in significantly lower performance (Rider & Linden, 1988) and thus invalidated the use of norms established for the wooden checkers. In addition, reliability statistics do not apply to the adapted test (Fess, 1993).

Test–retest reliability of the *Jebsen Hand Function Test* ranged from 0.60 to 0.99, based on 26 patients whose hand impairments had leveled off. No significant practice effect was demonstrated between two sessions with these patients (Jebsen et al., 1969). Although the researchers reported data on reliability of the *Jebsen Hand Function Test*, their data represented patient groups, not normal subjects (Mathiowetz et al., 1985b). Stern confirmed the test–retest reliability with 20 normal subjects, but she also found a significant practice effect for writing and simulated feeding subtests between the first and third sessions (Stern, 1992).

The *Jebsen Hand Function Test* does discriminate between subjects with and without different physical disabilities (Jebsen et al., 1969; Spaulding et al., 1988). A moderate correlation ($r = 0.64$) between the *Jebsen Hand Function Test* and the *Klein–Bell ADL Scale* suggests that the Jebsen test may have some usefulness in predicting functional ability, but it would not be an appropriate substitute for an ADL evaluation (Lynch & Bridle, 1989). Norms for adults aged 20–94 years ($n = 300$) are published (Jebsen et al., 1969).

The *Jebsen Hand Function Test* has several limitations. One is that it does not really address the proximal upper extremity (Desrosiers et al., 1993). In addition, it measures speed, not quality, of hand function (Jarus & Poremba, 1993; Spaulding et al., 1988). In addition, some of its subtests are not representative of ordinary daily activity. Mathiowetz (1993) questioned its content validity when he found that the page turning and feeding subtests do not actually duplicate those tasks in daily life. He also questioned why writing is evaluated as a timed test and why the non-dominant hand is tested in handwriting.

TEMPA

TEMPA is an acronym from the French for *Upper Extremity Performance Test for the Elderly* (Desrosiers et al., 1993). It consists of nine tasks, five bilateral and four unilateral, reflecting daily activity. Each task is measured by the three subscores of speed, functional rating, and task analysis. The nine tasks are pick up and move a jar, open a jar and take a spoonful of coffee, pour water from a pitcher into a glass, unlock a lock, take the top off a pillbox, write on an envelope and affix a postage stamp, put a scarf around one's neck, shuffle and deal cards, use coins, and pick up and move small objects. Instructions are in the manual. The test takes about 15–20 minutes for an unimpaired elderly subject and about 30–40 minutes for an impaired elderly

subject (Desrosiers et al., 1993). Advantages of the *TEMPA* are clinical utility, especially with hand patients over 60 years of age; provision of both quantitative and qualitative data; simulation of ADL; test applicability; test availability; and acceptability to patients (Rudman & Hannah, 1998). A possible disadvantage of this test is its cost of approximately \$500. Questions have surfaced concerning the quality control in production of the test (Humiston, 2000).

TEMPA norms were established on adults 60 years of age or older ($n = 360$) by 10-year age groups and by gender. Inter-rater reliability of the *TEMPA* ranged from 0.96 to 1.00. Test-retest reliability ranged from 0.77 to 1.00. Concurrent validity with the *Action Research Arm* test was 0.90 to 0.95, and with the *Box and Block Test*, it was 0.73 to 0.78 (Desrosiers et al., 1994). Some support for construct validity was demonstrated by correlating the *TEMPA* with basic personal care ($r = 0.68$) (Desrosiers et al., 1993).

CLINICAL REASONING AND INTERVENTION

Questions to Ask

Close communication with the patient's physician is always advisable. Choosing which questions to ask depends on the diagnosis and structures involved. General categories of questions may include the physician's expectations for functional recovery; tendon status, such as fraying or vascular compromise; whether the patient is medically cleared for AROM only or AROM and/or PROM; and whether the patient is medically cleared for low-load, long-duration dynamic splinting.

ADL and Occupational Role Implications

The functional use of the upper extremity and the patient's ability to perform in the areas of occupation are what really matter. Hand therapists must be careful not to become so focused on the technical aspects of the patient's injury that they overlook the patient's function, personal goals, and life needs. In some circumstances, it may actually be better for patients to accept a stiff finger and get on with life using compensatory techniques than to interrupt the flow of their lives for therapy (Merritt, 1998). This may be true if gains are exceedingly slow, if function is not dramatically compromised, or if there are other priorities, such as ill family members, for example.

Goal Setting

Express hand therapy goals or projected outcomes in terms that reflect the patient's occupational functioning.

Ultimately, the number of degrees achieved in ROM is less important than whether the patient can open a door, get dressed, or return to work. One way to integrate concrete and functional outcomes is to measure the movement needed to accomplish an appropriate patient-specific functional task and incorporate that measurement into the stated goal. For example, if a patient wants to be able to splash water on his or her face but lacks forearm supination to do so, have the patient perform the activity with the opposite upper extremity. Measure the supination needed to perform the task. In this instance, the goal could be stated as "sufficient forearm supination (60°) for ability to wash the face" (C. Skotak, personal communication, 1999).

Quality of Movement

Poor quality of movement (called dys-coordinate cocontraction) may result from cocontraction of antagonist muscles. The cause may be habit, fear of pain, guarding, or excessive effort. Poor quality of movement looks awkward and unpleasant. It is important to identify dys-coordinate cocontraction early and to work on retraining a smooth, comfortable, effective quality of motion. Pain-free activity or pain-free occupation is the best way to promote good quality of motion. **Oscillations** are rhythmic therapeutic movements that may be helpful, but they must be pain free. Imagery, such as pretending to move the extremity through water or gelatin, may also help (Cooper, Liskin, & Moorhead, 1999). Biofeedback may aid in muscle reeducation as well.

What Structures Are Restricted, and Does PROM Exceed AROM?

Hand therapists strive to be structure specific in identifying and treating upper extremity limitations. It is not adequate to identify a general problem, such as decreased ROM. Rather, it is important to understand and treat the specific structures causing the restriction. Limited PROM may be due to pericapsular structures, such as adhered or shortened ligaments, or actual joint limitations, such as mechanical block or adhesions. PROM that exceeds AROM may be due to disruption of the musculotendinous unit, adhesions restricting excursion of the tendon (Fess, 1993), or weakness. When PROM exceeds AROM, promote active movement and function of the restricted structures with differential tendon gliding exercises, blocking exercises, place-and-hold exercises, and functional splints (discussed later). When PROM equals AROM, discern whether the restriction is joint or musculotendinous or both (see section on joint versus musculotendinous tightness), and promote both passive and active flexibility.

Joint Versus Musculotendinous Tightness

With joint tightness, the PROM of the particular joint *does not change* with repositioning of the joints proximal and/or distal to it. With musculotendinous tightness, the PROM of the particular joint *does vary* with repositioning of joints crossed by that multiarticulate structure (Colditz, 2002b). Treat joint tightness with dynamic splinting, static progressive splinting, or serial casting, followed by AROM. Treat musculotendinous tightness the same as extrinsic tightness (discussed later).

Lag Versus Contracture

A lag is a limitation of active motion in a joint that has passive motion available. A joint contracture is a passive limitation of the joint. A patient with a PIP **extensor lag** cannot actively extend the PIP joint even though passive extension is available. A patient with a PIP joint flexion contracture lacks passive extension of that joint.

Treat lags by facilitating motion of the restricted structure with scar management, blocking exercises in mechanically advantageous positions, place-and-hold exercises, static splinting to promote normal length of the involved structure, and functional splints. Treat contractures the same as for joint tightness (discussed later).

An advantageous position to test or treat extensor lag at the PIP level is to maintain MP flexion while trying to extend actively at the PIP. An advantageous position to test or treat extensor lag at the DIP level is to maintain MP and PIP flexion while trying to extend actively at the DIP. This is contraindicated if the diagnosis is acute mallet finger (see section on extensor tendon injury).

Intrinsic Versus Extrinsic Tightness

Compare the PROM of digital PIP and DIP flexion with the MP joint flexed and again with the MP joint extended. With extrinsic tightness, there is less PIP and DIP passive flexion with the MP joint flexed. With intrinsic tightness, there is less PIP and DIP passive flexion with the MP joint extended (Colditz, 2002b).

Treat intrinsic tightness with functional splinting with MPs hyperextended and IPs free. In other words, promote IP flexion with MPs hyperextended. Treat extrinsic extensor tightness with MPs flexed and IPs free, and promote composite digital flexion. Use blocking exercises with an advantageous proximal position (discussed later). Try dynamic or static progressive splinting.

Tightness of Extrinsic Extensors or Extrinsic Flexors

With extrinsic extensor tightness, there is less passive composite digital flexion available with the wrist in flexion than with the wrist in extension. In contrast, with extrinsic flexor tightness, there is less passive composite digital extension available with the wrist in extension than with

the wrist in flexion (Colditz, 2002b). Treat extrinsic flexor or extensor tightness with place-and-hold exercises, static splinting comfortably at end range (especially useful at night), dynamic or static progressive splinting during the day, and functional splinting.

BASIC INTERVENTIONS

Edema Control

Elevation, active exercise, contrast baths, and compression have been the mainstays of edema control. Treatment of upper extremity edema has also historically included retrograde massage, string wrapping, compressive garments, and modalities such as an intermittent pressure pump. Compression garments should not be too tight.

Research has challenged hand therapists recently to re-examine the anatomical and physiological bases of our treatment of edema. This inquiry has resulted in a new approach to the treatment of upper extremity edema, called manual edema mobilization (Artzberger, 2002), a technique for stimulating the lymphatic system to remove the excess large plasma proteins that cause sustained edema leading to fibrotic tissue and stiffness. This hands-on technique, which must be learned in workshops that last 2 days or longer, can lead to dramatic and effective results. The approach used in manual edema mobilization is very different from and, in some ways, opposite to traditional retrograde massage techniques. Furthermore, manual edema mobilization raises questions about whether retrograde massage is sometimes more damaging than helpful. Manual edema mobilization is a wonderful example of the groundbreaking changes in hand therapy, based on scholarly questioning and research, that keep the profession interesting.

Scar Management

Compression (e.g., Isotoner gloves, Tubigrip, or Coban wrap) and desensitization are traditionally used to promote scar softening and maturation. Silicone gel applied over the scar (Baum & Busuito, 1998) helps promote scar maturation, presumably through neutral warmth. Other inserted materials such as padding, otoform, or elastomer can also be used. Application of micropore tape over incision scars has been suggested more recently.

Although friction massage has typically been advocated for scar softening, legitimate questions have been raised as to whether this more aggressive technique may in fact cause inflammation, resulting in deposition of even more scar tissue. Manual edema mobilization may be a more effective alternative. Research is needed in this area.

Figure 42-3 Differential flexor tendon gliding exercises. The five positions: **A.** Straight. **B.** Hook. **C.** Fist. **D.** Tabletop. **E.** Straight fist. (Adapted with permission from Rozmaryn, L. M., Dovel, S., Rothman, E. R., Gorman, K., Olvey, K. M., & Bartko, J. J. [1998]. Nerve and tendon gliding exercises and the conservative management of carpal tunnel syndrome. *Journal of Hand Therapy*, 11, 171–179.)

Differential Digital Tendon Gliding Exercises

Tendon gliding exercises maximize total gliding and differential gliding of digital flexor tendons at the wrist (Fig. 42-3) (Rozmaryn et al., 1998; Pettengill & van Strien, 2002). Since tendon gliding exercises promote digital and joint motions, they are a mainstay of most home exercise programs.

Blocking Exercises

Various blocking tools and splints are available commercially or can be made easily with scraps of splinting materials (Fig. 42-4) (Skirven & Trope, 1994). Digital cylinders blocking the IPs help to isolate and exercise MP flexion and extension. A blocking splint with the MPs extended promotes intrinsic stretch as well as IP flexion. A blocking splint with the MPs flexed promotes extrinsic extensor stretch and recovery of composite fisting. A PIP cylindrical block encourages DIP isolated flexion and flexor digitorum profundus (FDP) excursion at the DIP. A DIP

Figure 42-4 Blocking splints. MP splint blocks MP motion, promoting PIP and DIP motion. Digital splint blocks PIP motion, promoting MP and/or DIP motion.

cap facilitates PIP flexion and flexor tendon excursion at the PIP.

Instruct patients who do blocking exercises to exercise comfortably into the end range to remodel the tissue. Teach them to do the exercises frequently and slowly, holding at the comfortable end range for 3–5 seconds (Schneider & Feldscher, 2002).

Place-and-Hold Exercises

Place-and-hold exercises are effective for achieving increased ROM when PROM exceeds AROM. To perform them, use comfortable PROM to position the hand (e.g., composite fisting). Then release the assisting hand while the patient tries to sustain the position in a pain-free way (Collins, 1993; Pettengill & van Strien, 2002). Place-and-hold exercises can be effective in combination with blocking exercises.

End Feel and Splinting

If there is a **soft end feel** (a favorable spongy quality at end range indicative of potential to remodel), it is reasonable to try low-load, long-duration dynamic splinting for a medically cleared patient. Dynamic splint forces must be prolonged and gentle for tissue to remodel. Forceful splinting is contraindicated because it causes pain and injury, hence inflammation and scarring (Brand, 2002; Fess, 2002b). Follow dynamic splint use with activity that challenges and incorporates the limited motion. For a firmer or **hard end feel** (an unyielding quality at end range), try increasing the time in the splint and decreasing the force. If there is a hard end feel, dynamic splinting may not be effective, and serial casting or static progressive splinting may be more useful.

Splints

Functional splints can be used in ordinary daily activity to promote mobility of restricted structures. For example, if

Figure 42-5 Offset buddy straps. Inter-digital strap accommodates different phalangeal lengths of adjacent digits. Used to allow one digit to assist the next in achieving motion and for protection.

the index finger PIP joint lacks flexion and the MP joint moves normally, try a hand-based index finger MP blocking splint, used off and on through the day. When the splint is in use, the patient achieves PIP flexion exercise while performing normal grasping activities.

Buddy straps allow one digit to assist a neighboring digit to achieve greater motion. The offset buddy strap (Fig. 42-5) accommodates different phalangeal lengths of adjacent digits (Jensen & Rayan, 1996). Buddy straps are also useful to retrain keyboard users who habitually maintain the small finger MP in hyperextension or repetitively hyperabduct the small finger when keyboarding.

A dorsal MP flexion blocking splint promotes composite flexion incorporating MP flexion and is particularly helpful when there is extrinsic extensor tightness. If the patient has difficulty incorporating MP flexion into composite fisting and, instead, extends the MPs while flexing the IPs, a dorsal hood maintaining MP flexion promotes recovery of composite fist incorporating MP flexion. (See Chapters 16 and 17 for further splinting guidelines.)

COMMON DIAGNOSES

Hand therapists 15 years ago treated more hand trauma than cumulative trauma, and surgical cases constituted most of the caseload. Nowadays, many hand therapists see a substantially greater number of patients with a soft tissue diagnosis, such as tendinitis or cumulative trauma disorders.

Stiff Hand

Any upper extremity injury can result in the serious and sometimes irreversible problem of a stiff hand. Even an

injury in the proximal upper extremity can cause serious stiffening of the digits. The stiff hand is what hand therapists try to prevent. Edema is the main culprit in the series of events leading to a stiff hand. Edema is a natural response to trauma, occurring in the inflammatory phase. The challenge for hand therapy is to strike a balance between rest and movement. Too much rest may increase the edema. Too much movement may increase the inflammation. The right amount of rest in an appropriate position reduces inflammation and promotes healing. Proximal motion plus well-tolerated hand and wrist exercise and functional use, particularly while elevated, help to reduce edema and restore motion.

Encourage the patient to achieve gentle full arcs of available motion with functional use or exercise instead of performing quick or incomplete arcs of motion that are less effective. Make exercises relevant to occupational functioning or at least goal oriented whenever possible (e.g., grasping and releasing items). If the patient's hand is painful or more swollen after use or exercise, it is imperative to decrease temporarily the amount of exercise being performed (Colditz, 2002b).

Avoid aggressive PROM. It is okay to coax tissues to lengthen within their available comfortable range, but always respect the feeling of tissue resistance, and do not exceed it. Gentle passive motion, if indicated, should be accompanied by joint traction to promote gliding of the joint surfaces. Sustained holding of a position is much more effective than fast jerky stretches, which frequently add to the inflammation (Colditz, 2002b).

During the acute inflammatory stage, static splinting is usually most appropriate. After the inflammation has subsided and while the joint displays a soft end feel, dynamic splinting is productive. Inflamed tissue is not as flexible as uninflamed tissue (Brand, 2002). Watch closely for signs of inflammation and return to static splinting as indicated. Later, if there is a hard end feel, serial static or static progressive splinting will most likely be needed. Many patients with hand impairments complain of morning stiffness. Night splinting, which can be very helpful for this problem, also corrects tissue tightness that limits daytime use of the hand (Colditz, 2002b).

Tendinitis/Tendinosis

The pain associated with tendinitis/tendinosis can be severe and can seriously impact performance in all areas of occupation. Symptoms include pain with AROM, with resistance, and with passive stretch of the involved structures. Tendons are made up of connective tissues that are not well vascularized. Tendinitis has been treated historically as if it is an inflammatory phenomenon. Recent histological evidence has shown that the pathology of tendinitis includes alterations in tissue with disorganized and degenerated collagen and atypical vascular granulation

tissue. These findings are described as angiofibroblastic hyperplasia or angiofibroblastic tendinosis. It is now believed by authorities that the patients who are diagnosed with tendinitis actually have tendinosis. Since the pathology is not primarily inflammatory, treatment approaches now emphasize interventions that restore nourishment to collagen (Ashe, McCauley, & Khan, 2004; Nirschl, 1992). The question of use of modalities with this diagnosis remains intriguing. Most authorities report that modalities are effective in reducing pain, normalizing the vascular status of the involved tissue, and quieting inflammation if it exists.

Debate is ongoing over the cause of musculoskeletal problems; whether such problems are work related remains controversial (Terrono & Millender, 1996). Tendons are vulnerable because they are relatively avascular. Cell damage may become chronic (Pitner, 1990). Biomechanical deficits include muscular weakness, inflexibility, and scar tissue. Early treatment of an acute traumatic case typically has a better prognosis than after the injury has become chronic.

Evaluation

An overaggressive evaluation that provokes pain can set the treatment timetable back significantly and undermine the trust of and rapport with the patient. Start the evaluation with a cervical screening to look for proximal causes of distal symptoms. Compare both extremities. Assess for pain that may be local or diffuse, swelling, sensory changes, and loss of function. Tendinitis typically is accompanied by pain with AROM, with resistance, and with passive stretch of the involved structures. Compare subjective and objective findings, but remember that symptoms are often elusive and may occur dynamically or intermittently. Patients who seem angry or hostile may understandably be depressed over their loss of function.

It is essential to identify the activity causing the pain. Occupational therapists possess unique skills for ergonomic-related analysis of occupational performance and activity modification. It is best to observe the actual activity. If this is not possible, simulate the activity. Ergonomic risk factors for tendinitis include forceful, rapid, repetitive movements. A movement is considered repetitive if it is performed more than once every 30 seconds or for more than half the total work time. Additional risk factors include a history of soft-tissue problems, pressure and shear forces, stress and muscle tension, and hypermobility (Idler, 1997; Keller, Corbett, & Nichols, 1998).

Intervention

Treat the acute phase with ice, compression, elevation of the involved structures, and rest if needed to manage pain. Anti-inflammatory physical agent modalities may be useful at this time (see Chapter 20), but remember that this

diagnosis is no longer thought to be primarily inflammatory. Splinting is individualized to the patient's and physician's preferences. Splinting may be most beneficial and least problematic at night. Although some physicians advocate immobilization for weeks (Idler, 1997), there are also clinical compromises associated with disuse from immobilization (Bulthaupt, Cipriani, & Thomas, 1999; Skirven & Trope, 1994). Soft supports may be very helpful. In weighing the advantages and disadvantages of splint use, consult closely with the referring physician, try to avoid pain, and monitor the clinical responses. Active pain-free motion is the best way to begin revascularizing the involved tissues.

After the inflammation subsides, upgrade intervention to restore normal function through gradual mobilization balanced with rest. Most importantly, pain must be avoided. Instruct in tendon gliding exercises in a pain-free range appropriate to the particular structures involved. Progress from isometric exercises with gentle contractions of involved structures to isotonic exercises (Johnson, 1993). Gradually introduce low-load, high-repetition strengthening in short arcs of motion. Then increase the arc of motion and modify proximal positions to be more challenging if appropriate for work simulation. Instruct in gentle flexibility exercises in a pain-free range. It is often difficult for patients to learn to perform slow and pain-free passive stretch. Aerobic exercises and proximal conditioning are essential (Pitner, 1990).

Prevent reinjury through education (Furth, Holm, & James, 1994). Simulation and biofeedback (see Chapter 20) can promote biomechanically efficient upper extremity use. Teach the patient to avoid reaching and gripping with an extended elbow or a flexed or deviated wrist. First, solve the easily recognizable issues, such as obviously poor posture or trunk twisting with reaching and lifting. Instruct in pacing to avoid fatigue that leads to re-inflammation. Unsupported upper extremity use is taxing, as are non-symmetrical upper extremity use, non-frontal trunk or upper extremity alignment, and unilateral upper extremity work. Many people with distal symptoms recover well by focusing intervention on posture, conditioning, and proximal strengthening. Using hand-held tools with ergonomic design can be helpful (Johnson, 1993). Even a small ergonomic adjustment, such as learning to lift bilaterally with proper body mechanics or making use of a telephone headset instead of laterally flexing the neck and elevating the shoulder to hold the receiver, can often lead to dramatic improvement.

Lateral Epicondylitis, or Tennis Elbow

Lateral epicondylitis involves the extrinsic extensors at their origin. The extensor carpi radialis brevis is most commonly involved. Pain is at the lateral epicondyle and extensor wad (the proximal portion of the extensor muscles) (Wuori et al., 1998). This diagnosis is differentiated

clinically from radial tunnel syndrome, in which tenderness occurs more distally over the radial tuberosity. Test for radial tunnel syndrome with the middle finger test (positive if there is pain secondary to resisting the middle finger proximal phalanx while the patient maintains elbow extension, neutral wrist, and MP extension) or by percussing distally to proximally over the superficial radial nerve. This percussion test is positive if it elicits paresthesias (Skirven & Trope, 1994; Terrono & Millender, 1996).

Exercises should include proximal conditioning and scapular stabilizing. Use built-up handles. If using a splint, support the wrist in extension, especially at night. Splinted wrist position recommendations range from neutral to about 30°. Also try a **counterforce strap**, which is a strap placed over the extensor wad to prevent full muscle contraction and to reduce the load on the tendon during the day with activity (Skirven & Trope, 1994; Wuori et al., 1998). *Avoid applying the counterforce strap too tightly, as this can cause radial tunnel syndrome.*

Medial Epicondylitis, or Golfer's Elbow

Medial epicondylitis involves the extrinsic flexors at their origin (Johnson, 1993). The flexor carpi radialis (FCR) is most commonly involved. Pain is at the medial epicondyle and flexor wad (the proximal portion of the flexor muscles) and worsens with resisted flexion and pronation. Exercise should promote proximal conditioning. Avoid activity that requires force at end ranges. Provide built-up handles. If using a splint, maintain the wrist in neutral, and try a counterforce strap over the flexor wad.

De Quervain's Disease

De Quervain's disease is tendinitis involving the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons at the first dorsal compartment. It is the most common upper extremity tenosynovitis. Finkelstein's test is positive if there is exquisite pain with passive wrist ulnar deviation while flexing the thumb (Fig. 42-6) (Mooney,

1998). This diagnosis occurs frequently among golfers, knitters, racquet sports players, mail sorters, and filing clerks (Verdon, 1996). Thumb posture in sustained hyperabduction at the computer space bar may also be provoking (Pascarelli & Kella, 1993). Differential diagnosis is for carpometacarpal (CMC) arthritis, scaphoid fracture, intersection syndrome, and FCR tendinitis (Stern, 1990).

Teach patients to avoid wrist deviation, especially in conjunction with pinching. Provide built-up handles. If splinting, use a forearm-based thumb spica, leaving the IP free. Watch for irritation from the radial splint edge along the first dorsal compartment (Skirven & Trope, 1994).

Intersection Syndrome

Intersection syndrome presents as pain, swelling, and crepitus of the APL and EPB muscle bellies approximately 4 cm proximal to the wrist, where they intersect with the wrist extensor tendons (extensor carpi radialis brevis and extensor carpi radialis longus). This diagnosis is associated with repetitive wrist motion and occurs in weight lifters, rowers, and canoers (Servi, 1997). Differential diagnosis is for de Quervain's disease (Stern, 1990), and both diagnoses can occur concomitantly. Teach patients to avoid painful or resisted wrist extension and forceful grip. Splinting is the same as for de Quervain's disease.

Extensor Pollicis Longus Tendinitis

Also called drummer boy palsy, tendinitis of the extensor pollicis longus (EPL) reveals pain and swelling at Lister's tubercle (a dorsal prominence at the distal radius around which the EPL passes). It is less common than other forms of tendinitis, but if left untreated, it can lead to tendon rupture. EPL tendinitis is associated with activities requiring repetitive use of the thumb and wrist, as seen in drummers. Rupture of the EPL may occur in persons with rheumatoid arthritis or Colles' fracture (Verdon, 1996).

Figure 42-6 Finkelstein's test for de Quervain's disease. (Adapted with permission from American Society for Surgery of the Hand. [1990]. *The hand: Examination and diagnosis* [3rd ed.]. New York: Churchill Livingstone.)

Help patients to identify and eliminate provocative activities. Enlarge the girth of utensils. The splinting choice is a forearm-based thumb spica that includes the IP.

Extensor Carpi Ulnaris Tendinitis

Tenosynovitis of the extensor carpi ulnaris (ECU) occurs fairly frequently. It causes pain and swelling distal to the ulnar head and is associated with repetitive ulnar deviation motions. Subluxation of the ECU tendon elicits a painful snap with forearm supination and wrist ulnar deviation. Differential diagnosis includes instability of the distal radioulnar joint (Stern, 1990) and ulnocarpal abutment or tears of the triangular fibrocartilage complex.

Teach patients to avoid ulnar deviation with activities. Splinting consists of a forearm-based ulnar gutter or a wrist cock-up splint.

Flexor Carpi Radialis Tendinitis

With tendinitis of the FCR, pain is over the FCR tendon just proximal to the wrist flexor creases. Differential diagnosis is for a volar ganglion (Stern, 1990) or arthritis of the scaphotrapeziotrapezoid joint. Splinting consists of a wrist cock-up in neutral or a position of comfort.

Flexor Carpi Ulnaris Tendinitis

Flexor carpi ulnaris (FCU) tendinitis is more common than FCR tendinitis. It causes pain along the volar-ulnar side of the wrist. Inflammation occurs where the FCU inserts at the pisiform. Differential diagnosis is pisiform fracture and pisotriquetral arthritis (Verdon, 1996) or triangular fibrocartilage complex injury. Teach patients to avoid wrist flexion with ulnar deviation. Splinting consists of a forearm-based ulnar gutter. For comfort, pad the ulnar head if it is prominent, so the splint does not rub or irritate it.

Flexor Tenosynovitis, or Trigger Finger

Trigger finger is also called stenosing tenosynovitis of the digital flexor. The usual cause is stenosis at the A-1 pulley, which is part of the fibro-osseous tunnel that prevents bow-stringing of the digital flexors (Culp & Taras, 2002). Tenderness is over the A-1 pulley of the digital flexor (Fig. 42-7) along with pain with resisted grip and painful catching or locking of the finger in composite flexion (Lee, Nasser-Sharif, & Zelouf, 2002).

The origin of this impairment can be inflammatory or not. It has been strongly associated with diabetes and rheumatoid arthritis (Lee, Nasser-Sharif, & Zelouf, 2002). Medical management often consists of a mixture of steroid and local anesthetic injected into the flexor sheath. The injection may be repeated a few times. Therapy consists of splinting the MP in neutral to prevent composite digital flexion (preventing triggering),

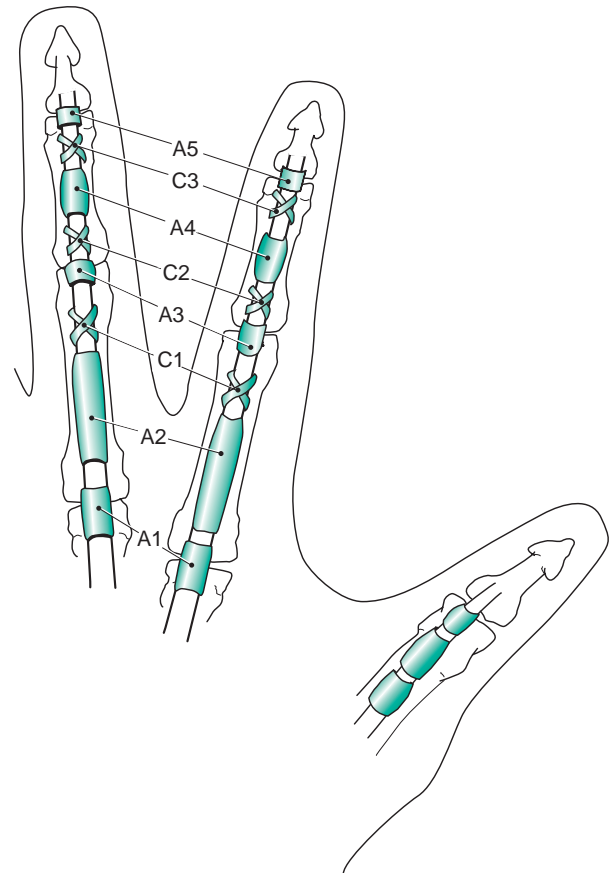

Figure 42-7 Pulley system. (Adapted with permission from Reiner, M. [1991]. *The illustrated hand*. St. Paul: Minnesota Hand Rehabilitation.)

while promoting tendon gliding, and place-and-hold fisting that avoids triggering. Built-up handles, padded gloves, and pacing strategies are helpful. Instruct the patient to avoid triggering, as this re-inflames the tissue. See the classic article by Evans, Hunter, and Burkhalter (1988). If symptoms persist, the surgeon may surgically release the A-1 pulley.

Nerve Injury

When injury or disease occurs to a neural structure in the upper extremity, there is a high likelihood that multiple areas of neural pathology will develop. This phenomenon is known as the double or multiple crush syndrome (Posner, 1998). Remembering this concept lessens the possibility of missing relevant clinical findings.

The various mechanisms of nerve injury include acute or chronic compression, stretch ischemia, electrical shock, radiation, injection, and laceration (Smith, 2002). Compression and laceration, impairments that are commonly seen by hand therapists, are described next.

Nerve Compression

Median Nerve Compression at the Wrist, or Carpal Tunnel Syndrome

Carpal tunnel syndrome is the most common upper extremity nerve entrapment (Concannon et al., 1997). It results from compression of the median nerve at the wrist. The carpal bones form the floor of the carpal tunnel. The transverse carpal ligament, also called the flexor retinaculum, forms the roof of the tunnel (Szabo, 1998) and acts as a pulley for the flexor tendons during gripping (Netscher et al., 1998).

Inside the carpal canal are nine flexor tendons (four FDP, four flexor digitorum superficialis [FDS], and the flexor pollicis longus) and the median nerve, which is most superficial (Fig. 42-8). Swelling or thickening of the tendons can lead to pressure on the nerve, resulting in sensory symptoms in the distribution of the median nerve (Hayes et al., 2002).

Carpal tunnel syndrome occurs with greatest frequency among women 40–60 years of age and is frequently bilateral (Lam & Thurston, 1998). Typical complaints include hand numbness, particularly at night or when driving a car, along with pain and paresthesias in the distribution of the median nerve (thumb through radial ring finger pads), and clumsiness or weakness. Associated diagnoses include rheumatoid arthritis, Colles' fracture, diabetes, deconditioning (Mooney, 1998), obesity (Lam & Thurston, 1998), and thyroid disease (Szabo, 1998). Transient carpal tunnel syndrome is fairly common in pregnancy (Stolp-Smith, Pascoe, & Ogburn, 1998). Carpal tunnel syndrome may be associated with repetitive use (Keir, Bach, & Rempel, 1998) or flexor tenosynovitis (Donaldson et al., 1998) caused by increased friction

between the tendons and nerve (Mooney, 1998). For these people, focus intervention on resolving the tendinitis.

Evaluation

Perform a cervical screening, and evaluate posture, ROM, grip and pinch, and manual muscle testing looking for independent excursion of FDP and FDS. Also do Tinel's, Phalen's, *Semmes-Weinstein Monofilament*, and two-point discrimination tests (Sailer, 1996). Tapping at the volar wrist elicits Tinel's sign, which is a sensation of tingling or electric shock if the median nerve is compromised. Phalen's test provokes sensory symptoms in the median nerve distribution if positive, created by maintaining the wrist in flexion for 60 seconds (Tubiana, Thomine, & Mackin, 1996). Phalen's test should be done with extended elbows to avoid confusing these findings with a positive elbow flexion test (see section on cubital tunnel syndrome). Advanced cases of carpal tunnel syndrome reveal thenar atrophy of the abductor pollicis brevis, which can be functionally debilitating (Aulicino, 2002; Concannon et al., 1997).

Intervention

Conservative medical management may include steroid injection (Terrono & Millender, 1996). Conservative therapy for carpal tunnel syndrome includes night splinting with the wrist in neutral because this position minimizes pressure in the carpal tunnel; exercises for median nerve gliding at the wrist (Fig. 42-9); differential flexor tendon gliding exercises (Fig. 42-3); aerobic exercise; proximal conditioning; ergonomic modification; and postural training (Donaldson et al., 1998; Rozmaryn et al., 1998). Teach patients to avoid extremes of forearm

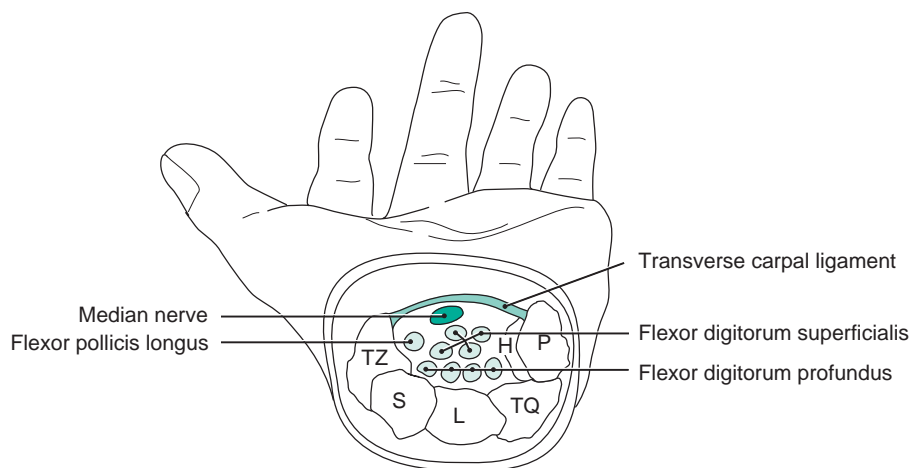

Figure 42-8 Carpal tunnel cross-section. TZ, trapezium; S, scaphoid; L, lunate; TQ, triquetrum; P, pisiform; H, hook of Hamate. (Adapted with permission from Reiner, M. [1991]. *The illustrated hand*. St. Paul: Minnesota Hand Rehabilitation.)

Figure 42-9 Median nerve gliding exercises at the wrist. Positions: **A.** Neutral wrist with finger and thumb flexion. **B.** Fingers and thumb extended. **C.** Wrist and fingers extended with thumb in neutral; **D.** Thumb extended. **E.** Forearm supinated. **F.** Thumb gently stretched into extension. (Adapted with permission from Rozmaryn, L. M., Dovel, S., Rothman, E. R., Gorman, K., Olvey, K. M., & Bartko, J. J. [1998]. Nerve and tendon gliding exercises and the conservative management of carpal tunnel syndrome. *Journal of Hand Therapy*, 11, 171–179.)

rotation or of wrist motions and to avoid sustained pinch or forceful grip. Provide padded gloves and built-up handles (Sailer, 1996). Thick padded steering wheel covers are helpful.

Surgical intervention consists of decompression of the carpal tunnel by division of the transverse carpal ligament (Hayes et al., 2002). Carpal tunnel release is one of the 10 most frequent surgeries performed in the United States (Rozmaryn et al., 1998). Post-operative therapy, when necessary, consists of edema control, scar management, desensitization as needed, nerve and tendon gliding exercises (Skirven & Trope, 1994), and eventual strengthening. Many therapists postpone strengthening exercises until at least 6 weeks following carpal tunnel release to avoid inflammation. Patients with new and mild symptoms tend to recover best (Aulisa et al., 1998).

Ulnar Nerve Compression at the Elbow, or Cubital Tunnel Syndrome

Cubital tunnel syndrome is the second most common upper extremity nerve entrapment and is the most commonly compressed site of the ulnar nerve, at its location between the medial epicondyle and the olecranon (Posner, 1998). Typical complaints include proximal and medial forearm pain that is aching or sharp; decreased sensation of the dorsal and palmar surfaces of the small finger and the ulnar half of the ring finger; and weakness of interossei, adductor pollicis, flexor carpi ulnaris, and flexor digitorum profundus of the ring and small fingers. Clawing may be more evident if the FDP is not involved because the long flexors are unopposed. Wartenberg's sign, the inability to adduct the small finger, and Froment's sign, in which effort at lateral pinch elicits thumb IP flexion due to weakness of the adductor pollicis, may be seen. Grip and pinch strength are decreased, and patients complain of dropping things (Khoo, Carmichael, & Spinner, 1996). Symptoms are worse when the elbow is flexed repeatedly or is kept in flexion

because this position dramatically reduces the volume of the cubital tunnel (Bozentka, 1998). Understandably, symptoms may increase at night if the person sleeps with the elbow flexed (Blackmore, 2002).

Cubital tunnel syndrome may result from trauma, such as a blow to the elbow or fracture or dislocation of the supracondylar or medial epicondylar area, or it may be due to chronic mild pressure on the elbow. Associated diagnoses include osteoarthritis, rheumatoid arthritis, diabetes, and Hansen's disease (Osterman & Davis, 1996).

Evaluation

Tapping over the cubital tunnel elicits a positive Tinel's sign. However, Tinel's sign may also be positive in 20% of normal people (Khoo, Carmichael, & Spinner, 1996). The elbow flexion test is positive if passively flexing the elbow and holding it flexed for 60 seconds produces sensory symptoms (Tetro & Pichora, 1996). Keep the wrist neutral while performing the elbow flexion test so as not to confound the findings with Phalen's test. Look for digital clawing and for muscle atrophy in the first web space, hypothenar eminence, and medial forearm. Perform grip and pinch testing and manual muscle testing as appropriate, and test sensation (Osterman & Davis, 1996).

Intervention

Conservative therapy for cubital tunnel syndrome includes edema control; splinting or padding the elbow; and positioning guidelines to avoid leaning on the elbow, to avoid elbow flexed postures, and to avoid elbow-intensive activity (Khoo, Carmichael, & Spinner, 1996). Elbow splinting helps prevent sleeping with the elbow flexed. Types of splints include elbow pads or soft splints, pillows, and anterior or posterior thermoplastic splints. The splinted elbow position for sleeping is usually about 30° of flexion. Additional therapy includes proximal conditioning, postural and ergonomic training, and ulnar nerve gliding exercises (Fig. 42-10).

(Adapted with permission from Byron, P. M. [1995]. Upper extremity nerve gliding programs used at the Philadelphia Hand Center. In J. M. Hunter, E. J. Mackin, & A. D. Callahan [Eds.], *Rehabilitation of the hand: Surgery and therapy* [4th ed., p. 954]. St. Louis: Mosby.)

Radial Nerve Compression, or Posterior Interosseous Nerve Syndrome

Posterior interosseous nerve syndrome is purely motor. It presents two clinical pictures. In one, paralysis affects all muscles innervated by the posterior interosseous nerve, with inability to extend the MP joints of thumb, index, long, ring, or small fingers. Wrist extension occurs only radially because of paralysis of extensor digitorum and ECU. In the other presentation of this syndrome, the person cannot extend the MP joint of one or more digits. Paralysis may spread to other digits if it is not treated on a timely basis (Spinner, 1995).

A common site of entrapment of the posterior interosseous nerve is at the supinator muscle, where it pierces the two heads of this muscle. Other causes include soft tissue tumors, rheumatoid arthritis with synovial proliferation, and radial head fractures or dislocations (Spinner, 1995). Therapy focuses on maintaining PROM and splinting to prevent deformity and promote function.

Nerve Laceration

Nerve lacerations are categorized as complete or partial. Stretching and contusion injuries can occur along with the laceration. Nerve reconstruction is termed primary if within 48 hours, early secondary if within 6 weeks, and late secondary after 3 months. The advantages associated with primary repair are that nerve stump retraction is limited and electrical stimulation can be used to identify distal fascicles (Smith, 2002).

A **neuroma**, a disorganized mass of nerve fibers, can follow nerve injury. Significant nerve pain is elicited by

tapping over the neuroma, with hypersensitivity limiting functional use of the hand. Desensitization techniques are helpful, along with padding over the painful area to promote functional use (Smith, 2002).

Following nerve injury, therapy promotes functional performance in the areas of occupation with ADL training and adaptive equipment and assists in prevention of deformity with splinting and appropriate PROM. Hand therapy provides valuable education to patients about their diagnosis and general recovery sequence and teaches protective guidelines to compensate for sensory loss. Hand therapy monitors changes in sensory and motor function and helps prevent joint contractures and imbalance by reevaluating ROM, sensation, and muscle status. Splint modifications are based on clinical changes over time.

Low Median Nerve Lesion

Median nerve laceration at the wrist results in low median nerve palsy, with denervation of the opponens pollicis (OP) and abductor pollicis brevis of the thumb and of the lumbricals to the index and long fingers. Clawing of the index and long fingers does not usually occur because the interossei remain ulnarly innervated. Loss of sensation of the radial side of the hand is present. With the absence of thumb abduction and opposition, the thumb rests in adduction, where it may become contracted (Fig. 42-11). Fabricate a hand-based thumb abduction splint to maintain balance, to substitute for lost thumb opposition, and to prevent overstretching of denervated muscles (Colditz, 2002a).

Median nerve laceration creates serious functional loss of manipulation and sensibility of the thumb, index, and

Figure 42-11 Thenar wasting (atrophy of thumb) due to median nerve problem. (From Snell, R. S. [2003]. *Clinical anatomy* [7th ed.]. Baltimore: Lippincott Williams & Wilkins.)

long fingers. Motor recovery usually occurs before sensory recovery. Be sure to teach compensatory strategies to avoid reinjury while sensibility is impaired (Colditz, 2002a). Instruct the patient to perform PROM to maintain joint mobility. Fabricate splints to sustain thumb abduction and digital MP flexion with IP extension to promote functional hand use and to counteract the deforming forces of the injury.

High Median Nerve Lesion

Injury near or at the elbow is called a high median nerve injury. Along with the motor loss identified earlier, there is denervation of FDP to index and long fingers, FDS to all digits, pronator teres, and pronator quadratus. The median nerve is considered the most important sensory nerve, and its loss severely compromises hand function. In therapy, prepare patients for probable tendon transfers by preventing deformity with splinting and by maintaining PROM of pronation, of digital MPs in flexion, of digital IPs in extension, and of thumb CMC abduction (Colditz, 2002a). Visual cues, adaptive devices, and modified handles may help compensate for the functional loss.

Low Ulnar Nerve Lesion

Laceration of the ulnar nerve at the wrist level is called a low ulnar lesion. This injury results in loss of most of the hand intrinsics. Denervation of the adductor digiti minimi, flexor digiti minimi, and opponens digiti minimi results in flattening of the hand with loss of the ulnar transverse metacarpal arch; denervation of thumb adductor pollicis (AP) and deep head of flexor pollicis brevis results in loss of thumb adduction and MP support; denervation of dorsal and volar interossei results in loss of digital abduction or

Figure 42-12 Clawing of digits seen with ulnar nerve problems. (From Snell, R. S. [2003]. *Clinical anatomy* [7th ed.]. Baltimore: Lippincott Williams & Wilkins.)

adduction; and denervation of lumbricals to the ring and small fingers results in extrinsic imbalance. The ring and small fingers present a **claw deformity**, a position of MP hyperextension and PIP flexion associated with muscle imbalance in ulnar-innervated structures (Fig. 42-12). Fine manipulation skills are compromised (Colditz, 2002a). Sensory loss involves the ulnar digits.

Splinting for ulnar nerve palsy aims to prevent overstretching of the denervated ring and small finger intrinsics. An MP blocking splint that maintains slight MP flexion and prevents MP extension is recommended (Colditz, 2002a) (see Chapter 16). Teach patients to compensate for sensory loss and to maintain passive range of the MPs in flexion and the IPs in extension. It is very important to prevent PIP flexion contractures. Built-up handles in conjunction with the MP blocking splint may be helpful.

High Ulnar Nerve Lesion

A high ulnar nerve lesion is often identified with trauma at or proximal to the elbow. There is involvement of the muscles listed earlier and denervation of FDP of ring and small fingers and of FCU. Ring and small finger clawing is less apparent with the high lesion but becomes noticeable as the FDP are reinnervated and are unopposed by the still-absent intrinsics. Splinting and treatment are the same as for a low ulnar nerve lesion. If the FDP is absent, teach the patient to maintain full PROM of the IPs of the ring and small fingers to prevent contractures (Colditz, 2002a).

Low Radial Nerve Lesion

Low radial nerve injury of the deep motor branch is called posterior interosseous palsy. Presentations vary (see section on radial nerve compression), but brachioradialis and

extensor carpi radialis longus function is usually present. Efforts to extend the wrist yield strong radial deviation. MP extension is affected. Sensation on the dorsal radial hand is affected. Therapy is similar to that described for radial nerve compression, with emphasis on maintaining PROM for wrist, thumb, and digital extension and splinting to promote tenodesis for functional pinch, grip, and release.

High Radial Nerve Lesion

A high radial nerve injury is seen commonly with humeral fractures because this nerve spirals around the humerus. Wrist and digital extensors are absent (Fig. 42-13). Sensory loss occurs on the dorsal-radial hand, which interferes less with function than does sensory loss on the palmar hand. Triceps function remains, but the supinator and all wrist and finger extensors lose function. Tenodesis is lost (Colditz, 2002a).

Splinting restores tenodesis and may be useful for many months during the wait for reinnervation, which occurs at approximately 1 inch per month. Various static and dynamic splints are available; the dynamic splints are most useful functionally. Many patients make good use of both types of splints. Compliance tends to be good because of the functional value of these splints. It is important to maintain joint suppleness while awaiting reinnervation or reconstructive surgery (Colditz, 2002a).

Fractures

Distal Radius Fracture

Distal radius fractures are among the most common upper extremity fractures (Laseter, 2002). Hand therapists frequently treat patients with this diagnosis. Distal radius fractures should not be confused with fractures of the carpal bones. The main complication associated with distal radius fracture is traumatic arthritis due to poor articular congruency (Leibovic, 1999). Decreased wrist

Figure 42-13 Wrist drop due to radial nerve problem. (From Snell, R. S. [2003]. *Clinical anatomy* [7th ed.]. Baltimore: Lippincott Williams & Wilkins.)

ROM, decreased grip strength, alteration of the carpal alignment, and instability may ensue. Other complications include tendon rupture, compression of the median or ulnar nerve, and CRPS (Laseter, 2002).

Therapy During Immobilization

Appropriate early therapy intervention can make a huge difference in the patient's overall functional recovery. If digits are allowed to become swollen and stiff, the long-term functional results can be devastating. These fractures are common among older people with osteoporosis and balance problems. Temporary loss of independence following fracture can trigger an irreversible downward spiral in their occupational functioning.

Typical medical management of Colles' fracture is cast immobilization, usually above elbow with the elbow in 90° of flexion to prevent forearm rotation during the first 3 weeks. When the patient is put in a short arm cast and the elbow is freed, begin elbow AROM for flexion and extension, but avoid resisted elbow motion so as not to stress the fracture healing. Do not perform elbow PROM without medical clearance, and be very gentle. Biceps tightness commonly follows elbow immobilization.

Certain fractures require an external fixator and/or internal fixation. Some physicians delay the referral of patients to therapy, but postponing the initiation of therapy can result in significant problems with edema and decreased ROM. It is a good idea to communicate with referring physicians and encourage routine early therapy referral for this diagnosis.

While the patient is in an external fixator, provide pin site care as the physician prescribes using sterile technique and universal precautions (Bryan & Kohnke, 1997). Teach the patient digital ROM and tendon gliding exercises, and instruct in precautions related to cast wearing. It is critical to monitor for cast tightness because this can cause CRPS. Call the physician if the cast is too tight. Discourage the use of slings because they promote unnecessary proximal stiffness, guarded posture, and disuse (Collins, 1993).

Insidious onset of shoulder restrictions is problematic and best avoided. Physicians most assuredly appreciate therapists' input regarding early signs of this problem. To prevent a frozen shoulder, proximal ROM is a high treatment priority (Skirven & Trope, 1994). Instruct in shoulder flexion, abduction, internal rotation, and external rotation (Collins, 1993). Perform as thorough a physical assessment as tolerated and as cast constraints permit. This may have to be done in phases. Early identification of guarding, excessive pain, or autonomic signs can alert the team to the possibility of CRPS.

Following distal radius fracture, the recovery of function depends on restoration of motion and strength and on maximizing the length-tension relationship of the digital flexors and extensors (Collins, 1993). Edema can

contribute to decreased ROM at uncasted areas. Patients are often surprised that uninjured and uncasted areas can stiffen.

The goals of early therapy during immobilization are to normalize edema and to achieve as nearly normal AROM of uncasted areas as possible (Collins, 1993). During this period, intrinsic tightness, extrinsic tightness, and digital joint tightness may occur (Skirven & Trope, 1994). The chance of tendon adherence is increased following open reduction and its accompanying incisional scar. Various blocking splints may be used with functional activity and exercise to resolve joint or musculotendinous tightness (Fig. 42-4). Differential tendon gliding exercises are extremely important. Frequent exercise throughout the day is better than a few long sessions. It is generally advised to perform exercises every hour or two, perhaps 5–10 repetitions each, maintaining the end position comfortably for 3–5 seconds. Incorporate exercises into occupation, including ADL, as much as possible (Bryan & Kohnke, 1997).

If extrinsic musculotendinous tightness persists, it may be appropriate to add night static progressive splinting or low-load, long-duration dynamic splinting in conjunction with exercise to normalize extrinsic length (Collins, 1993). Consult the physician before making this determination.

Therapy After Cast or Fixator Is Removed

When fracture immobilization is discontinued, physicians often recommend a custom-fabricated volar wrist splint. This is protective and can be corrective to help restore functional wrist motion (usually extension). This temporary support is particularly helpful if the patient maintains habitual wrist flexion because this “doggy paw” posture leads to development of the undesirable deformity position of MP extension, PIP flexion, and thumb adduction and extension discussed earlier (Skirven & Trope, 1994).

Following removal of the cast or external fixator, there is usually measurable limitation in ROM, with patients reporting awkwardness and decreased function (Byl, Kohlhase, & Engel, 1999). Consult the physician for medical clearance and guidelines for forearm and wrist ROM. ***Do not initiate PROM of the wrist without medical clearance because this may be injurious.*** Teach the patient to wean off the protective splint according to the physician’s guidelines, which are individualized. Edema control continues to be the highest priority until it is resolved. AROM and ADL can help correct the edema.

At any time, but especially in this early stage, overzealous therapy is harmful. Patients and families who think they should be aggressive in their home programs need education and reinforcement to avoid overdoing it. Use written material and illustrations to teach them how to observe tissue responses and monitor inflammation (Colditz, 2002b).

Temperature elevation over the joints of digits may indicate that intervention is eliciting an inflammatory reaction and should be adjusted accordingly (Fess, 1993).

It is extremely important to retrain the wrist extensors to function independently of the extensor digitorum (Laseter & Carter, 1996). Have the patient practice wrist extension with available composite digital flexion, being especially sure the MPs are flexed. Then have the patient flex the wrist with digits relaxed but extended to isolate the wrist flexors. As substitution patterns are hard to overcome, early training of biomechanically efficient movement is best. Progressive grasp-and-release activities reinforce this tenodesis training. It is also important to retrain the extensor digitorum to function independently of the intrinsics. Have the patient extend the MPs with the IPs slightly flexed to isolate the extensor digitorum.

Gradually upgrade therapy with increasingly challenging motions, combined motions, and activities aiming to restore joint suppleness and musculotendinous lengths. Dexterity activities, such as cat’s cradle, and games, such as pick-up sticks, promote spontaneous functional movements. Sorting drawers and folding small items of clothing are good home activities. Initiate graded functional strengthening with medical clearance, usually after good motion has been achieved. Again, it is easy to be too aggressive with these patients. Upgrade carefully, monitor patient and tissue responses, and adjust the intervention accordingly.

Scaphoid Fracture

Some 60% of carpal fractures affect the scaphoid (also called the navicular) bone. The mechanism of injury is usually a fall on the outstretched hand (called FOOSH). Associated ligamentous injury may also be present. Tenderness in the anatomical snuffbox, a depression at the base of the thumb between the EPL and EPB tendons, where snuff used to be placed, is a classic finding. Scaphoid fracture may be difficult to confirm radiographically initially and may not become apparent until 3 weeks following injury due to resorption at the fracture site. Once fracture is confirmed, the thumb is usually included in the cast, with the IP joint free.

Proximal scaphoid fractures may be at risk for developing avascular necrosis because of the pattern of vascular supply. Casting time may be long for this reason. Hand therapy principles are the same as for distal radius fracture (Dell & Dell, 2002).

Non-Articular Hand Fracture

Fracture occurs more often in the hand than any other area, and more than 50% of hand fractures occur at work. Motor vehicle accidents, household injuries, and recreational accidents also account for many of these injuries (Meyer & Wilson, 1995) (Fig. 42-14).

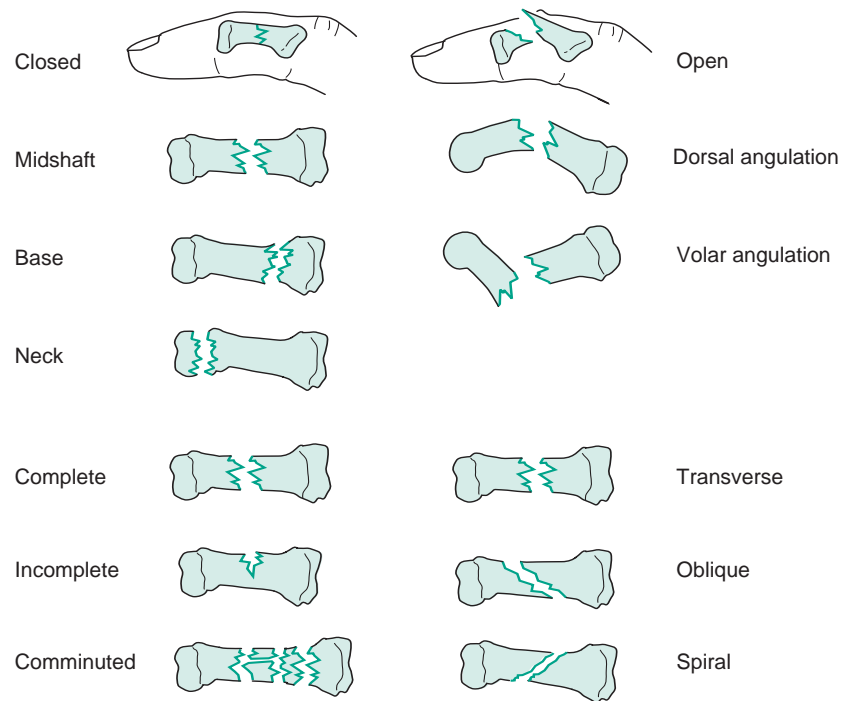

Figure 42-14 Fracture terminology. (Adapted with permission from American Society for Surgery of the Hand. [1990]. *The hand: Examination and diagnosis* [3rd ed.]. New York: Churchill Livingstone.)

Distal Phalanx Fracture

Distal phalanx digital fractures typically result from a crushing injury and occur most often in the thumb and middle finger. Tuft fractures occur at the distal tip. They are extremely painful, in part because there is often a subungual (i.e., beneath the nail) hematoma (Meyer & Wilson, 1995). Following a distal phalanx fracture, hypersensitivity, pain, and decreased ROM of the DIP joint may occur (Skirven & Trope, 1994). Monitor closely for signs of DIP extensor lag or the inability to extend the DIP joint actively despite full available passive extension (Meyer & Wilson, 1995).

Middle Phalanx Fracture

At the middle phalanx, fractures angulate according to their relation to the FDS insertion. Medical management and early positioning guidelines vary among caregivers. Following middle phalanx fractures, decreased PIP and DIP ROM are common problems. Fractures at this site may require long immobilization time for healing, with resulting stiffness. When the patient is medically cleared for therapy, isolated FDS exercises are very important. Here, too, PIP joint flexion contractures are serious complications that can occur in as little as 2 weeks of immobilization in flexion. Consult with the physician for therapy guidelines based on fracture stability and healing (Russell, 1999).

Proximal Phalanx Fracture

At the proximal phalanx, fractures tend to angulate with a palmar apex. This deforming force is due to the action of the intrinsic muscles on the proximal fragment (Purdy & Wilson, 2002). With proximal phalanx fractures, a hand-based splint in intrinsic-plus (anti-deformity) position is useful at night. A digit-based extension splint provides support and protection in the day except during exercise. Again, the physician provides therapy guidelines based on fracture stability and healing. PIP joint flexion contractures are the most likely and difficult complication. Watch for these, and catch them early. Better yet, avoid them with appropriate splinting and structure-specific exercise. PIP extensor lag and flexor tendon adherence at the fracture site are other serious problems (Purdy & Wilson, 2002).

Metacarpal Fracture

Unless there is associated trauma, metacarpal fractures at the base are frequently stable. Metacarpal fractures at the shaft may be transverse, oblique, or spiral. Metacarpal fractures at the neck are common, occurring most often in the small finger. They may result in muscle imbalance between the intrinsics and extrinsics (Purdy & Wilson, 2002).

With metacarpal fractures, dorsal hand edema is a frequent complication that can contribute to MP joint dorsal capsular tightness. If there is associated soft tissue injury,

intrinsic contracture or extensor digitorum adherence may occur (Skirven & Trope, 1994). Appropriate early therapy and preventive edema control are important (Purdy & Wilson, 2002).

Unstable fractures require fixation to achieve stability and allow early ROM. **Kirschner wires**, a common form of fixation used for hand fractures, may be used alone or in conjunction with additional fixation. Other forms of internal fixation include tension band wires, lag screws, plates, and mini external fixators (Leibovic, 1999). Functional recovery relates to anatomical restoration. To maximize functional outcomes, the ideal situation allows for early motion. Preventing stiffness of uninvolved digits is a high priority that can itself be challenging. Prolonged immobilization is associated with edema and pain. Persistent edema results in joint and tendon scar and adhesions; atrophy occurs, as well as osteoporosis (Meyer & Wilson, 1995).

Collateral Ligament Injury

PIP Joint Sprain

PIP joint sprains often result from sports involving balls. Their severity, which may be underappreciated, is described as grade I through grade III. In grade I, the ligament remains intact, but there is diffuse individual fiber disruption. In grade II, there is complete disruption of one of the joint capsule's major retaining ligaments. In grade III, there is complete disruption of one collateral ligament in addition to injury to dorsal and/or volar capsular structures. Pain, decreased ROM, and risk of flexion contracture are the most common problems associated with grade I and II injuries. Joint instability may occur with grade III injuries (Campbell & Wilson, 2002).

Therapy focuses on edema control, joint protection, and ROM. Buddy straps are helpful to protect or to promote movement. They may be offset to improve fit (Fig. 42-5) (Jensen & Rayan, 1996). Splinting is both protective and corrective. A dorsal extension blocking splint is often ordered early on for volar plate injuries associated with dorsal PIP joint dislocation (Fig. 42-15) (Lairmore & Engber, 1998). Persistent thickening about the joint commonly occurs, interfering with recovery of ROM.

Skier's Thumb

Disruption of the ulnar collateral ligament of the thumb MP joint occurs with acute radial deviation. This diagnosis, which may entail avulsion of bone fragment at the ligamentous insertion, is often seen among people who fall while skiing (Lairmore & Engber, 1998). Injury to the radial collateral ligament of the thumb MP occurs only one tenth as often (Campbell & Wilson, 2002). Following surgical repair, the wrist and thumb are casted. When therapy begins, IP ROM is the priority because full MP

Figure 42-15 Dorsal PIP extension–blocking splint. Protective digit-based splint maintains slight PIP flexion. Used to prevent full extension to protect volar plate injury.

flexion may not be achieved, especially among older patients. Avoid resistive exercise until medically cleared. Then begin with lateral pinch but avoid tip pinch until further medical clearance, which may not be for 12 weeks, as tip pinch is strenuous on the injured structures. Use a hand-based spica splint for protection. Scar hypersensitivity due to the underlying radial sensory nerve is common.

Flexor Tendon Injury

Surgical repair of flexor tendon injury is a complex undertaking performed by specialists in the field. Like the surgery, hand therapy for these patients is a complicated and specialized area. Therapy can be time consuming, and it entails substantial education of the patient, with subtle but significant changes in splinting and exercise at every session to promote function while protecting fragile repaired structures. Multiple structures are often involved, and there are many precautions and contraindications that vary according to the details of the patient's surgery and the surgeon's specifications and preferences. It is essential to maintain close communication with the patient's surgeon. A therapist experienced in the treatment of these patients should closely supervise their care.

Five anatomical zones describe flexor tendon injury to the index, long, ring, and small digits (Fig. 42-16). Zone I is from the insertion of the FDS to the insertion of the FDP. Zone II is the area where the FDS and FDP both lie within the flexor sheath, from the A-1 pulley to the FDS insertion. This region has memorably been dubbed “no man's land” to reflect the technical challenge and historically poor prognosis for repair in this area (Wang & Gupta, 1996). Zone III describes the area from the distal edge of the carpal tunnel to the A-1 pulley of the flexor

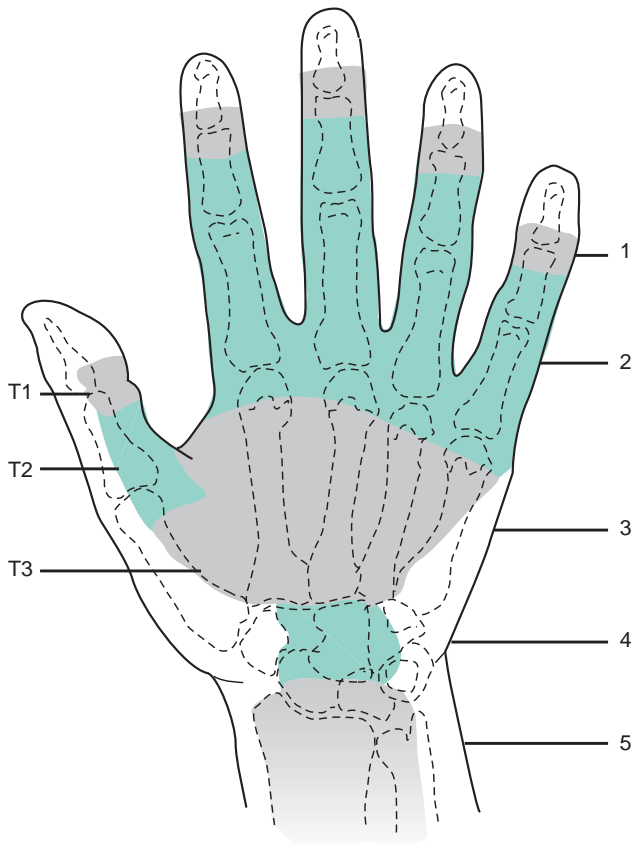

Figure 42-16 Flexor tendon zones. (Adapted with permission from Kleinert, H. H., Schepel, S., & Gill, T. [1981]. Flexor tendon injuries. *Surgical Clinics of North America*, 61, 267–286. Stewart, K. M., & van Strien, G. [1995]. Postoperative management of flexor tendon injuries. In J. M. Hunter, E. J. Mackin, & A. D. Callahan [Eds.], *Rehabilitation of the hand: Surgery and therapy* [4th ed., pp. 433–462]. St. Louis: Mosby.)

sheath, including the lumbrical muscles. Zone IV is where the flexor tendons lie under the transverse carpal ligament in the carpal tunnel. Injuries in this zone may include the median and ulnar nerves. Zone V is the area from the forearm flexor musculotendinous junction to the border of the transverse carpal ligament (Culp & Taras, 2002).

Physicians usually indicate specific postoperative positioning guidelines to protect repaired structures following flexor tendon repair. The goals are twofold and contradictory: to minimize adhesion formation and to prevent gap or attenuation of the repaired tendon (Silva et al., 1998). These dual goals highlight the complexity of therapy associated with this diagnosis. Various protocols exist for controlled mobilization, using a dorsal splint with the wrist in about 30° of flexion, MP joints in about 70° of flexion, and IP joints ideally in full extension (Wang & Gupta, 1996). The involved IP joints may have to be in some flexion if a digital nerve has been repaired. The Duran protocol entails passive digital flexion and extension within the protective

Figure 42-17 Modified Kleinert splint. Dorsal splint maintains the wrist in 30° of flexion, MPs in 70° of flexion, and IPs in extension. Rubber band attachments provide passive digital flexion.

splint to achieve 3–5 mm of differential digital tendon excursion. With this protocol, gentle active motion begins with medical clearance about 4 or 5 weeks after surgery (Culp & Taras, 2002).

The passive flexion–active extension protocol, also called the Kleinert protocol, uses rubber band attachments to the fingernails to provide passive digital flexion within the protective dorsal splint (Fig. 42-17). The patient performs gentle active digital extension and the rubber band provides passive digital flexion within the confines of the protective splint. Exercises are gradually increased to 10 repetitions comfortably every waking hour. At night, the digits may be strapped carefully and comfortably to the dorsal hood of the splint to counteract the tendency to develop PIP or DIP flexion contractures (Wang & Gupta, 1996).

The Chow protocol uses a combination of the Duran and Kleinert techniques. With advances in suture techniques, some caregivers are advocating early active motion protocols (Winters et al., 1998).

When the physician gives medical clearance to discontinue the dorsal protective splint, begin a graded program to promote functional movement. Edema control and scar management remain high clinical priorities. Assess closely and determine tissue-specific limitations that guide the therapy program. Tendon gliding exercises and place-and-hold exercises are typical early techniques. Corrective splinting is useful, along with ADL, graded activity, and upgraded exercise as appropriate.

Staged Flexor Tendon Reconstruction

Staged flexor tendon reconstruction is a complex two-part procedure. It is highly advisable to have an experienced hand therapist supervise the treatment. Staged

Figure 42-18 Extensor tendon zones. (Adapted with permission from Kleinert, H. H., Schepel, S., & Gill, T. [1981]. Flexor tendon injuries. *Surgical Clinics of North America*, 61, 267–286; Evans, R. B. [1995]. An update on extensor tendon management. In J. M. Hunter, E. J. Mackin, & A. D. Callahan [Eds.], *Rehabilitation of the hand: Surgery and therapy* [4th ed., pp. 565–606]. St. Louis: Mosby.)

flexor tendon surgery is chosen when there is significant scarring of the tendon yet potential for eventual function. It may be used in cases of flexor tendon rupture or when primary repair is not possible, such as with a complex injury involving bone and multiple tissues. In the first stage, a tendon implant replaces the scarred tendon; capsular contractures are released; and pulleys are reconstructed. The implant, which may be active or passive,

stimulates formation of a new biological sheath. In the second stage, after about 3 months, a tendon graft replaces the implant (Hunter & Mackin, 2002).

Extensor Tendon Injury

Therapy of extensor tendon injuries is complicated and requires supervision by experienced hand therapists. Various protocols are available for immobilization, controlled passive motion, or active short arc of motion following extensor tendon repair (Evans, 2002).

Seven zones describe the digital extensors for the index, long, ring, and small fingers, and five zones describe the thumb extensors (Fig. 42-18). Injury in zones I and II leads to a mallet deformity (Evans, 2002), which follows disruption of the terminal extensor tendon and manifests itself as DIP extensor lag (Fig. 42-19). Depending on the nature of the problem, in non-operative cases, therapy may include continuous splinting of the DIP in extension for 6–8 weeks as determined by the physician while the tendon heals. It is essential to maintain normal PIP ROM during immobilization at the DIP. When initiating ROM of the DIP after the terminal tendon has healed, watch closely for recurrence of DIP extensor lag and resume splinting as needed to recover DIP extension (Evans, 2002). Some physicians recommend continuation of night splinting when DIP AROM is begun.

Extensor injuries in zones III and IV lead to a boutonniere deformity, an imbalanced digital position of PIP flexion and DIP hyperextension (Fig. 42-20). The deformity is due to volar displacement of the lateral bands secondary to involvement of the central slip (Evans, 2002). In non-operative cases, splint the PIP in full extension for 6 weeks, and promote DIP active and passive flexion to prevent stiffness of the oblique retinacular ligament. In operative cases, follow the physician's guidelines, which may vary in timing and technique of mobilization and splinting. When the patient is medically cleared to begin PIP active exercises, watch closely for PIP extensor lag, and modify therapy and splinting accordingly (Crosby & Wehbe, 1996).

Figure 42-20 Boutonniere deformity. (Adapted with permission from American Society for Surgery of the Hand. [1990]. *The hand: Examination and diagnosis* [3rd ed.]. New York: Churchill Livingstone.)

Injury in zones V and VI may be treated by immobilization or by controlled early motion (Evans, 2002). Specific positioning and motion guidelines vary from surgeon to surgeon and are modified according to each patient's tissue responses. Multiple complex splints may be needed to achieve a program that balances rest and motion appropriately.

Injury in zone VII is likely to result in restrictions due to development of adhesions (Evans, 2002). Communicate closely with the surgeon for specific positioning and motion guidelines.

Tenolysis

Tenolysis is a surgical procedure to release tendon adhesions that restrict movement. Physicians do not usually perform this procedure until injured tissues have matured and PROM is maximized, as demonstrated by a plateau in progress during therapy. Therapy following tenolysis may begin as early as a few hours after surgery. The first few days following surgery are considered crucial. The physician's referral should include information on the integrity of the tendon and expected ROM goals based on intraoperative findings (Schneider & Feldscher, 2002). First priorities are edema control and ROM; observe and respect these fragile tissues' tolerances.

Complex Regional Pain Syndrome

Any upper extremity injury, whether as minor as a paper cut or as major as a complex crush injury, has the potential to result in devastating reflex sympathetic dystrophy (RSD), renamed **complex regional pain syndrome (CRPS)** by the International Association for the Study of Pain (IASP). The IASP has suggested transitional use of RSD in parentheses after the new terminology because it would be unrealistic to expect immediate abandonment of this familiar term (Stanton-Hicks et al., 1995). In this chapter, CRPS is understood to be synonymous with RSD.

CRPS type I follows a noxious event. Pain that is not limited to the territory of a single peripheral nerve occurs spontaneously and is disproportionate to the inciting noxious event. Edema is present, with abnormality of skin color or abnormal sudomotor activity in the painful area since the onset. The diagnosis of CRPS is excluded by other existing conditions that may cause the pain and dysfunction (Stanton-Hicks et al., 1995).

CRPS type II is the same as type I except that it develops after a nerve injury, whereas type I does not involve a nerve injury. CRPS type III refers to a group not otherwise specified and includes patients who do not fulfill the criteria for types I or II (Stanton-Hicks et al., 1995).

Pain that is disproportionate to the injury is the hallmark of CRPS. Constant attention to the patient's pain level and autonomic responses can lead to early medical management, if not prevention, of this challenging problem. The earlier this problem is diagnosed, the more successfully it may resolve (Walsh & Muntzer, 2002).

Over the years, many terms have been used to describe CRPS, including causalgia, Sudeck's atrophy, and shoulder-hand syndrome. Although clinical presentation is variable, traditional hand therapy literature identifies five clinical types as minor causalgia, minor traumatic dystrophy, shoulder-hand syndrome, major traumatic dystrophy, and major causalgia (Koman, Smith, & Smith, 2002).

Historically, the four cardinal symptoms and signs of CRPS have been identified as pain, swelling, stiffness, and discoloration. Secondary symptoms and signs include osseous demineralization, sudomotor changes (sweating), temperature changes, trophic changes, vasomotor instability, palmar fasciitis (thickening of palmar fascia), and pilomotor activity (goose pimples or hair standing on end).

Literature refers to people with CRPS as hypersympathetic reactors, who experience cold hands and feet, fainting, sweaty palms, heart palpitations, hyperventilation, and vasoconstriction. Authorities have unfairly labeled these people as hysterical personality types, but no good evidence supports a predispositional personality profile

for this diagnosis. A lot of methodologically bad evidence, however, unfortunately stigmatizes those with the diagnosis and biases caregivers (Lynch, 1992).

Elegant animal studies have shown that self-protection through immobilization, intended to avoid pain, is itself a risk factor for the diagnosis of CRPS. People with CRPS must learn to use the extremity in ways that are pain free and biomechanically efficient. Normalizing sensory input also helps interrupt the vicious cycle of pain and stiffness (Byl & Melnick, 1997).

Therapy for CRPS

The most important therapy guideline is no PROM or painful intervention. The first thing is to control the pain. This includes management through medications, sympathetic blocks such as stellate ganglion blocks, and modalities such as transcutaneous electrical nerve stimulation (TENS) as appropriate. Close communication with medical experts specializing in pain management is ideal.

Provide vasomotor challenge through stress loading (described later), temperature biofeedback, and posture changes during activity. Hardy and Hardy (1997) recommend resetting the sensory thresholds through contrast, vibration, and desensitization (see Chapter 27). Water aerobics and functional activities are excellent ways to provide active movement incorporating reciprocal motion. Use stress loading routinely with patients who are at risk for CRPS. Stress loading is proposed to change sympathetic efferent activity. Although the physiological mechanisms of stress loading are not known (Carlson & Watson, 1988), it is popular among hand therapists for treating active CRPS, not the sequelae.

The two components of stress loading are “scrubbing the floor” (performed literally on all fours if possible), in brief sessions, 3 times per day initially, and carrying a weighted briefcase, done with the extremity in extension. The weight should be light and tolerable. Be sure it is not too heavy. Scrubbing and carrying achieve compressive loading and distraction of the upper extremity. If actual scrubbing cannot be tolerated, substitute comfortable weight-bearing exercises.

The frequency and duration of scrub and carry are upgraded as tolerated. If wrist ROM limitations or injury precautions do not allow the patient to assume the scrub position, positions may be adapted to accomplish comfortable weight bearing (see Chapter 24). Also instruct the patient to perform frequent pain-free proximal AROM bilaterally.

Avoid PROM or other therapy until the pain and swelling begin to subside, and then monitor responses closely. Incorporate traditional hand therapy, including splinting and other non-aggravating modalities, with edema control, joint ROM, differential tendon gliding, restoration of musculotendinous lengths, strengthening, desensitization, physical agents including transcutaneous

electrical nerve stimulation and ultrasound as appropriate, and functional activity within tolerance. Manual edema mobilization is effective with this diagnosis.

Perhaps with CRPS more than other diagnoses, patient-directed therapy is essential. It is better to perform gentle, pain-free active exercises frequently for short periods than fewer and longer sessions. Light massage and active exercise help to interrupt the pain cycle. Make the exercise program bilateral and include reciprocal upper extremity motions (Byl & Melnick, 1997). Allow the progress to be as slow as necessary to prevent worsening of symptoms. This diagnosis can be overwhelming and discouraging. Provide the patient with appropriate encouragement and reassurances that progress can be made over time.

CRPS typifies the difficult clinical problems that hand therapists are trying to avert or avoid. Intervention programs that are progressing well can be suddenly and unexpectedly derailed by this disorder. For this reason, it is advisable to approach all hand therapy patients supportively and with a very careful eye, regardless of their diagnosis. Early identification of CRPS is a key to resolving it.

Osteoarthritis

Idiopathic osteoarthritis (OA) is the most common type of OA. In the upper extremity, it often affects the DIP and PIP joints. Osteophytes at the DIP are called Heberden’s nodes, and osteophytes at the PIP are called Bouchard’s nodes. For painful DIP nodes, small cylindrical splints or light Coban wrap may promote function while decreasing pain (Melvin, 1989).

Hand therapy for osteoarthritis focuses on alleviating symptoms through education in principles of joint protection, protective and supportive splinting, and provision of adaptive devices for ADL. For osteoarthritis of the thumb CMC, a hand-based thumb spica splint (Fig. 42-21) is often extremely helpful (Swigart et al., 1999). Some

Figure 42-21 Hand-based thumb spica splint. Used to provide pain relief and promote functional pinch.

therapists prefer to use a forearm-based spica splint, particularly when there is pantrapezial involvement rather than just CMC joint involvement (Melvin, 2002, 1989).

Thumb CMC arthroplasty is a common post-operative diagnosis seen by hand therapists. Surgical techniques and timelines for therapy vary among physicians. Patients are often sent to therapy a few weeks after surgery for fabrication of a static forearm-based thumb spica splint with the IP free. The physician indicates appropriate guidelines for AROM according to the particular surgical procedures performed. Post-operative therapy goals are to promote pain-free stability and function. ADL modification and joint protection remain a priority.

Rheumatoid Arthritis

Unlike osteoarthritis, rheumatoid arthritis (RA) is a systemic disease that primarily affects the synovium. Its debilitation and crippling effects can be severely disabling. Rheumatoid arthritis presents as inflammation of synovial membranes of joints and of tendon sheaths, with redness, swelling, pain, and heat in the areas of involvement (Melvin, 1989).

Digital involvement at the DIP is less common than at the PIP. If DIP involvement does occur, a mallet finger may result. Involvement at the PIP may result in swan-neck or boutonniere deformities. (See section on extensor tendons for clinical management of mallet and boutonniere deformities.) A swan-neck deformity presents as MP flexion, PIP hyperextension, and DIP flexion (Fig. 42-22). Fabricate a digital dorsal splint in slight PIP flexion to minimize deforming forces and enhance FDS function. At the level of the MP joints, deformity usually manifests as MP ulnar drift and palmar subluxation (Melvin, 1989). Thumb deformities include boutonniere (primary thumb MP involvement) and swan-neck (primary CMC involvement) deformities. The thumb may also demonstrate stiff, unstable, and painful joints at the levels of the IP, MP, or CMC. Rheumatoid arthritis often affects the wrist. This is significant because the wrist is anatomically critical to proper hand function. Wrist involvement is compounded

by concomitant hand deformity. Synovitis at the wrist can lead to flexor or extensor tendon ruptures (Melvin, 1989).

In evaluating patients with rheumatoid arthritis, observe deformities and abnormal posture, any atrophy, and skin condition. Identify crepitus of joint or tendon, palpable nodules, tendon integrity, and joint stability. Ask about morning stiffness, fatigue, and pain. The appearance of the deformity (cosmesis) is also relevant (Biese, 2002).

The goals of upper extremity splinting for rheumatoid arthritis include reducing inflammation, supporting weak tissues, and minimizing deforming forces. Splinting also provides functional assistance. Splinting is used especially in the acute stage, when inflamed structures are at risk for further damage. Forearm-based resting splints may support the wrist and entire hand, the wrist and MPs, or only the wrist.

Determine splint design according to the pathomechanics of the disease. Involved MP joints are at risk for volar subluxation. Therefore, splint the wrist in neutral or slight extension, the MP joints in available extension, and the PIP joints in slight flexion (Biese, 2002). Radial deviation of the wrist encourages ulnar drift of the digits at the MP joints because of the zigzag deformity. A splint to correct MP ulnar drift often improves the biomechanics of hand use. Talk with the patient to identify individual preferences and needs in terms of ADL and joint protection. Adapt the straps and practice with patients to be sure they can open and close them. For some people who require bilateral splints, it may be easier to use one at a time on alternate nights.

CONCLUSION

Wilson (1998) states, “The hand is not merely a metaphor or an icon for humanness, but often the real-life focal point—the lever or the launching pad—of a successful and genuinely fulfilling life” (Wilson, 1998, p. 14). Occupational therapy can be the launching pad for people with hand impairments to reestablish fulfilling lives.

CASE

EXAMPLE

P. L.: Hand Impairments

Occupational Therapy Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information</p> <p>P.L. is a 49-year-old athletic computer software manager with dominant right hand. She is single and lives alone. P.L. fell on an outstretched hand while on vacation out of state, sustaining a comminuted displaced right distal radius fracture. She was initially treated with closed reduction and a long-arm cast. Ten days later, after returning home, she underwent open reduction internal fixation of the right distal radius with percutaneous pins, synthetic bone graft material, and application of an external fixator. Family members came to stay with her to assist with self-care and ADL needs. At the time of her injury, she was looking forward to a kayaking vacation.</p>	<p>Understand the patient's diagnosis or condition</p> <p>Know the person</p>	<p>"P.L. sustained a significant injury to her dominant upper extremity (UE) requiring fixation and bone grafting. The amount of immobilization time required for healing (6 weeks) could potentially lead to significant stiffness of multiple structures."</p> <p>"P.L. is an independent and active woman who hopes to go on a kayaking trip in a few months. She is not used to depending on others for self-care or other assistance. She likes living alone, driving her sports car, and going on business trips, and right now these aspects of her life are disrupted."</p>
<p>Reason for Referral to Occupational Therapy</p> <p>P.L. was referred to outpatient hand therapy the day after surgery to maximize her functional abilities while her dominant hand was immobilized and to promote wound and fracture healing, edema control, and mobility of non-immobilized structures.</p>	<p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>"P.L.'s family is with her initially to help her function while relying on her non-dominant UE for use. Although she prefers living alone, it is good that she has some help initially. Her desire to perform her occupational roles will help her recover more quickly."</p>
<p>Assessment Process and Results</p> <p>P.L. had severe pain (9/10), significant edema, and increased autonomic signs including vasomotor instability and guarded positioning of the right UE. She had extremely limited ROM of the digits of her right hand and was also hesitant to actively move her shoulder or elbow.</p>	<p>Consider evaluation approach and methods</p> <p>Interpret observations</p>	<p>"I do not want to impose pain with my evaluation, so I will measure only AROM in a gentle fashion. I will provide encouragement and explain how autonomic responses can be normalized with pain-free motion, elevation, and edema control."</p> <p>"P.L. is at risk for CRPS and for significant stiffness of joints and tendons. Managing the edema is a high priority in order to normalize all tissue responses."</p>
<p>Occupational Therapy Problem List</p> <ul style="list-style-type: none"> • Disruption of independent living and job performance • Interruption of frequent job-related travel • Inability to sleep or to perform self-care or home activities due to pain, edema, and decreased ROM • Risk of developing CRPS with degradation of functional and clinical status as evidenced by increased autonomic signs 	<p>Synthesize results</p>	<p>"P.L. has multiple severe problems that could lead to permanent stiffness and loss of function. Despite this, she is a highly motivated successful professional and she is eager to recover."</p>

Occupational Therapy Goal List

1. Normalize autonomic signs and ameliorate pain interfering with function and sleep
2. Promote spontaneous pain-free use of the right upper extremity in daily activity
3. Achieve independent self-care and homemaking and resume job-related travel and engagement in athletic activity

Develop intervention hypotheses

“I believe that a gradual and gentle upgrade of exercises to promote healing and recover flexibility will be far more effective than overstressing her delicate healing tissues.”

Select an intervention approach

“Occupational therapy will focus on promoting healing and restoring normal joint motions and musculotendinous lengths in order to recover UE function.”

Consider what will occur in therapy, how often, and for how long

“P.L. will need upgrades to her home program weekly. Splints will need to be revised, as well as exercises and instructions/practice in using her right UE for self-care and non-resistive home tasks.”

Intervention

P.L. began a home program of education about the expected clinical course and recovery; pin site care; edema control; and shoulder, elbow, and digital ROM in pain-free ranges. Emphasis was on shoulder active exercise and upper extremity elevation. A week after surgery, P.L.’s autonomic signs were resolving. Her digits remained edematous, and AROM was still limited throughout the upper extremity except for her shoulder, which was functional.

Assess the patient’s comprehension

“I can tell that P.L. understands her instructions because she demonstrates her activities well. She is exploring what new abilities she has with her right hand and is trying to use it as much as possible in a pain-free way. She demonstrates accurate placement of her splints and describes effective choices in using them. Her follow-through at home is exactly as I hoped it would be. And she understands when to rest her hand so that she does not develop new signs of swelling or pain.”

Understand what she is doing

Compare actual to expected performance

At 2 weeks after surgery, digital AROM and PROM were slowly improving but still limited (Fig. 42-23, A & B). P.L.’s home program was upgraded to include edema control, functional grip and release activities, blocking exercises with thermoplastic supports, place-and-hold exercises, night composite digital extension static splinting, and day dynamic digital composite extension splinting. Differential digital flexor tendon gliding was restricted by adherence at the volar distal forearm incisional site, which was still healing. She had extrinsic extensor tightness, extrinsic flexor tightness, and intrinsic tightness. Fortunately, P.L. was not developing PIP flexion contractures. She had been relying on her non-dominant left hand for handwriting and all self-care. She returned to work soon after surgery and was once again traveling frequently on business.

At 3 weeks after surgery, when incisional sites were healed, manual edema mobilization began, and all functional activities, splints, and exercises were upgraded in a pain-free fashion. Silicone gel was applied to incision sites at night for scar management. P.L. continued to make slow but measurable progress. Her physician reported good radiographic alignment.

At 6 weeks after surgery, P.L.’s fixator was removed. Her physician reported good reduction and stability of the distal radioulnar joint. She was severely limited in forearm pronation and supination and in wrist AROM and PROM. She was instructed in pain-free forearm and wrist AROM. A thermoplastic volar wrist splint was fabricated for support and to correct limited wrist extension. P.L. began to resume use of her right upper extremity for handwriting intermittently and for home activities as tolerated. Although she was very compliant with her home program, her progress was slow. She had become quite adept at using her left hand for dexterity tasks.

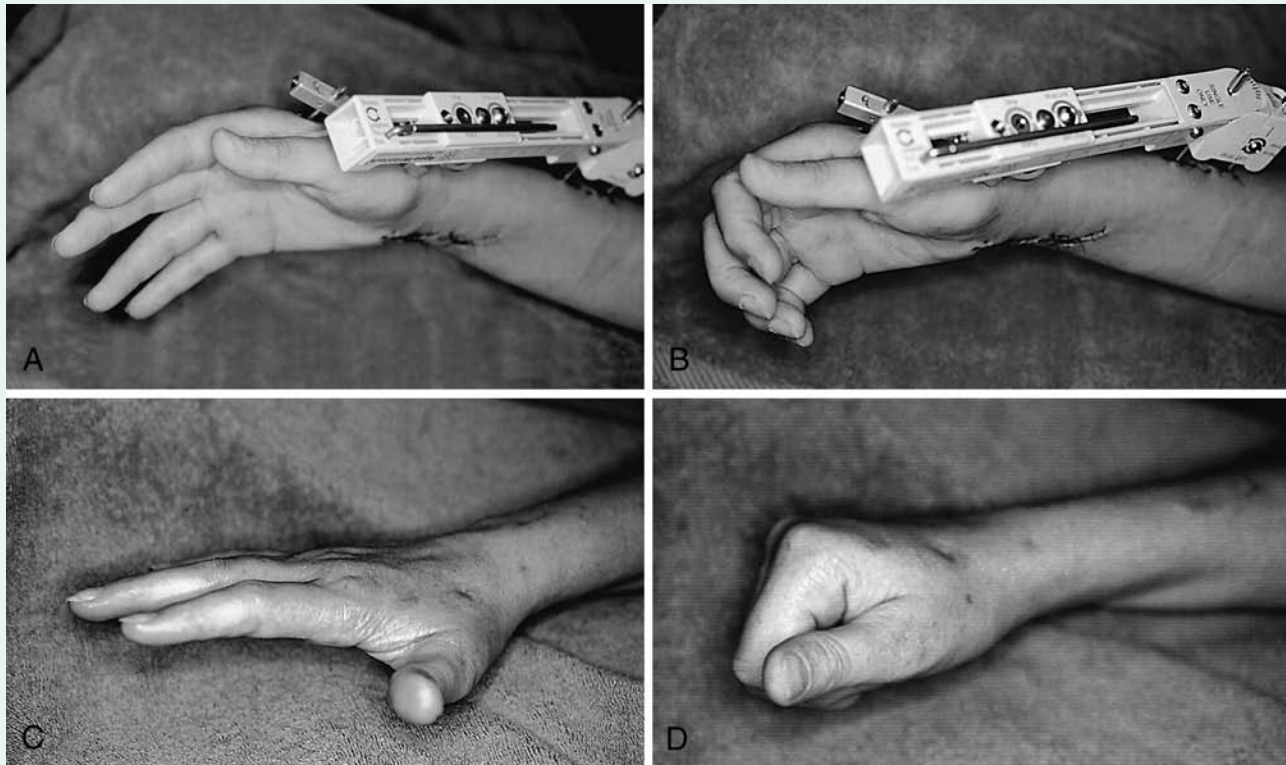

Figure 42-23 At 2 weeks post surgery, P.L.’s active digital extension (A) and flexion (B); at 10 weeks post surgery, P.L.’s active digital extension (C) and flexion (D).

Intervention (cont’d)

At 10 weeks after surgery, P.L. began to demonstrate dramatic gains in suppleness (Fig 42-23, C & D). She was significantly improved in digital edema and in all ROM. Elbow extension was normal. Forearm supination and pronation were better, with AROM being equal to PROM. Isolated wrist extension was improved. Digital composite fisting and FDP and FDS differential tendon gliding were nearly normal, and tightness of the extrinsic flexors was almost fully resolved. P.L. was using her right hand for all handwriting and grooming and for driving her sports car. She was eager to begin simulating kayaking, as she had kept her plans for a kayaking vacation. P.L. said that her dynamic splints and night static composite extension splints were helpful to her, so these were modified and upgraded. Strengthening exercises were gradually and cautiously upgraded as well.

Next Steps

Discharge from occupational therapy with home activities and splints

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“P.L. was able to go on her kayaking trip and enjoyed it. She still exercises and knows that it is important not to overdo it. She has learned how to keep her tissues flexible and has gained good strength as well.”

CLINICAL REASONING IN HAND THERAPY PRACTICE

Effects of CRPS on Functional Use of the Involved Extremity

Initially, P.L. demonstrated a guarded upper extremity position associated with autonomic signs. How might upper extremity posturing influence pain, edema, and ROM? What should the home program emphasize to promote autonomic normalization?

Effects of Edema on Upper Extremity Pain, ROM, and Function

Persistent edema of P.L.'s hand worsened her pain, stiffness, and function. What treatment techniques are helpful in resolving upper extremity edema?

Effects of Substitution Patterns on Wrist and Hand Function

P.L. could not isolate her wrist extensors from her extensor digitorum function. This interfered with recovery of normal grasp and release patterns. What clinical problems contribute to the inability to isolate wrist extensors? What functional exercises would help retrain isolated wrist extension with simultaneous grip (i.e., normal tenodesis patterns)? What choice of splint or splints might help recover these motions?

Evidence Table 42-1 Best Evidence for Occupational Therapy Practice Regarding Treatment of Hand Impairments

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Exercise to improve elbow extension	Active elbow flexion and extension with elbow extension prolonged with and without resistance.	10 subjects with elbow motion deficits of at least 30° after injury (mean age = 52 years, 6 women and 4 men, 9 right-hand dominant, 7 subjects with injury to dominant side) and 10 controls with unrestricted elbow range of motion and no history of elbow injury (mean age = 31 years, 9 women and 1 man, 9 right-hand dominant).	Two 9-second trials of alternating elbow flexion and extension on verbal command; also passive elbow extension with forearm unweighted and with a 3-lb cuff weight.	Non-randomized, two-group design. IIC2b And non-randomized, one-group, two-condition design. IIIC2b	No. Adding weight to a forearm in an effort to gain elbow extension resulted in increased activity of elbow flexors and may be contraindicated for those patients whose stiff elbow has the active component of muscle contraction in addition to the passive restrictions such as capsular tightness.	During active elbow flexion and extension, all elbow flexor muscles of stiff elbow group showed statistically significantly greater ($p < 0.05$) EMG activity compared with the control group. During prolonged extension, there was a significant ($p < 0.05$) increase of activity of the 3 flexor muscles of the stiff elbow group when weight was added. Effect sizes could not be calculated from the data provided.	Page, Backus, & Lenhoff, 2003

(continued)

Evidence Table 42-1 (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Corrective splinting for flexion contracture	Dynamic (Capener) finger extension splints were compared to belly gutter static splints to improve flexion contracture, hand strength, and hand function.	24 patients with rheumatoid arthritis and digital PIP/DIP flexion contractures randomized to group. Group 1: dynamic splints. Group 2: static splints. 22 women and 2 men; mean age = 37.08 years; all right-hand dominant; all had diagnosis of rheumatoid arthritis with finger flexion contractures <45°.	Group 1 used dynamic splint 4 times a day for variable duration with minimum of 6 hours daily for 6 weeks. Group 2 used static splint at rest for at least 6 hours daily for 6 weeks.	Matched pairs experimental design. IC1a	Yes. All subjects improved significantly. Severity of flexion contractures decreased, while strength and hand function increased. Both types of splints were effective.	Significant improvement in extension ROM of both groups ($t_{23} = 13.84, p < 0.0005, r = .94$); grip strength ($t_{23} = -3.61, p = 0.001, r = 0.60$); pinch strength ($t_{23} = 3.45, p = 0.002, r = 0.58$); hand function (Jebsen) ($t_{23} = 5.21, p < 0.0005, r = 0.73$). There was no significant difference in these outcome variables between types of splints.	Li-Tsang, Hung, & Mak, 2002

SUMMARY REVIEW QUESTIONS

1. Why should painful treatment be avoided? What signs are indicative of overaggressive intervention?
2. Name the phases of tissue healing and approximate timelines.
3. Define joint versus musculotendinous tightness, intrinsic versus extrinsic tightness, and tightness of extrinsic extensors versus extrinsic flexors.
4. Describe the anti-deformity position of the wrist and hand and explain why it is used.
5. What function is lost with a low radial nerve injury? What kind of splinting is appropriate, and why?
6. What distribution of sensation is usually impaired with carpal tunnel syndrome? What musculature might be atrophied in an advanced case? What night splint position is best for carpal tunnel syndrome, and why?
7. Describe complex regional pain syndrome and discuss intervention priorities for this diagnosis.
8. What symptoms are associated with a trigger finger?
9. Name four self-care or home activities that are safe and therapeutic for a person in a short arm cast with a healing distal radius fracture.

ACKNOWLEDGMENT

Heartfelt thanks to John L. Evarts, BS, for the photography and for his valuable ideas, contribution to content, and ongoing technical and emotional support. I also thank Cecelia M. Skotak, OTR, CHT; Virgil Mathiowetz, PhD, OTR; Michelle Pressman, MS, OTR; and Kevin Renfree, MD, for their input to a previous version of this chapter. I also acknowledge Michelle Pressman Abrams, MS, OTR, for her assistance in applying Occupational Therapy Practice Framework (OTPF) terminology to this revision.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Define key terms and concepts central to spinal cord injury and its care.
2. Value the physical, psychosocial, and occupational challenges associated with spinal cord injury.
3. Describe the tests and procedures appropriate for occupational therapy assessment.
4. List the roles and priorities of the occupational therapist in each of the treatment phases.
5. Recognize functional expectations of patients with various levels of injury.

CHAPTER 43

Spinal Cord Injury

Michal S. Atkins

Glossary

Dermatome—“The area of the skin innervated by the sensory axons within each segmental nerve (root)” (ASIA, 2000, p. 5).

Complete injury—“Absence of sensory and motor function in the lowest sacral segment” (ASIA, 2000 p. 7).

Incomplete injury—“Partial preservation of sensory and /or motor function below the neurological level and including the lowest sacral segment” (ASIA, 2000 p. 7).

Paraplegia—Loss or impairment in motor and/or sensory function in the thoracic, lumbar, or sacral segments of the

cord resulting in impairment in the trunk, legs, and pelvic organs and sparing of the arms (ASIA, 2000).

Tenodesis grasp—Passive opening of the fingers when the wrist is flexed and closing of the fingers when the wrist is extended (Wilson et al., 1984).

Tetraplegia—Loss or impairment in motor and/or sensory function in the cervical segments of the spinal cord resulting in functional impairment in the arms, trunk, legs, and pelvic organs (ASIA, 2000).

A spinal cord injury (SCI) is a devastating event that disrupts every facet of life. Diminished physical capacities, inability to get around and carry out daily routines, and feelings of confusion and despair are coupled with loss of gainful employment and questions about the ability to return home. The occupational therapist may share this burden. With such devastating losses, where does the therapist begin? How do we help patients rebuild a sense of efficacy and self-esteem? How do we set priorities for our treatment interventions?

This chapter provides beginning answers to these questions. It outlines occupational therapy evaluations, goal setting, and treatments used with persons with SCI and introduces epidemiological data, definitions, and classifications of injuries. Next, it discusses the course after injury, followed by occupational therapy evaluations and interventions. A case study of a person who was recently injured is presented. Research data, resources, and suggested readings are listed to assist the therapist in exploring SCI beyond the material outlined in this chapter.

EPIDEMIOLOGY

Spinal cord injury is relatively rare, afflicting approximately 11,000 people a year in the United States. The numbers of people with SCI alive today in the United States is estimated to be in the range of 225,000 to 288,000 (National Spinal Cord Injury Statistical Center [NSCISC], 2005). Most SCIs occur in young males. A ratio of four injured males per female persists over the past decades. The average age at injury is 37.8 years, and 52.6% of injuries occurred between the ages of 16 to 30 years (NSCISC, 2006).

The National Spinal Cord Injury Statistical Center (NSCISC), a federally funded organization established in

1973, collects SCI epidemiological data in the United States. The causes of SCI as tracked by NSCISC since 2000 are as follows: approximately 47%, motor vehicle accidents; 23%, falls or hit by object; 14%, violence; and 10%, sports injuries. Other causes, such as non-traumatic SCI, account for the remaining 7% (NSCISC, 2006). Non-traumatic SCI is caused by spinal stenosis, tumors, ischemia, infection, and myelitis (McKinley, Seel, & Hardman, 1999). In large metropolitan areas in the United States, violence, specifically gun violence, accounts for a greater percentage of SCIs (Nobunaga, Go, & Karunas, 1999). In other countries, violence accounts for only a small fraction of injuries.

In the United States, ethnic distribution of injured persons includes 62.9% whites, 22% African Americans, 12.6% Hispanics, and 2.5% from all other ethnic groups (NSCISC, 2006). This distribution shows greater representation of minority groups than the ethnic distribution of the U.S. population. NSCISC also notes a trend in the rise of injuries to minority groups (Jackson et al., 2004; NSCISC, 2005).

Most persons with SCI (59.3%) have completed high school, and 59.6% were employed at onset. Generally, the level of education of injured individuals is somewhat lower and the unemployment rate higher than in the general population. Considering the young age of onset, it is not surprising that most persons are single when the injury occurred (Stover et al., 1995).

The clinical implications of the SCI epidemiological data have great relevance to the work of occupational therapists. Therapists must appreciate that the patients' ethnic, gender, socioeconomic, and educational backgrounds may differ from their own (see Chapters 10 and 11). Additionally, given the typical age and sex of patients with SCI, sexual, bowel, and bladder management issues must be addressed with great sensitivity, and therapists must become comfortable with their role in these matters (Trieschmann, 1988).

COURSE AFTER SPINAL CORD INJURY

Spinal cord injury causes a disruption in the motor and sensory pathways at the site of the lesion (Fig. 43-1). Since the nerve roots are segmental, a thorough evaluation of motor and sensory function can identify the level of lesion (Fig. 43-2). For example, if the spinal cord is completely severed at the level of the sixth cervical nerve root, motor and sensory information below that level no longer can travel to and from the brain. This results in paralysis of

muscular activity and absence of sensation below the level of injury (Hollar, 1995).

Immediately after the injury, a period of spinal shock occurs, characterized by areflexia at and below the level of injury. Spinal shock may last hours, days, or weeks. As soon as spinal shock subsides, reflexes below the level of injury return and become hyperactive. At the level of injury, areflexia may remain as the reflex arc is interrupted.

Neurological Classification of SCI

To understand the typical course of recovery from SCI, occupational therapists must be familiar with commonly used terms that describe SCI impairment and know how levels of impairment relate to prognosis.

Definitions

Tetraplegia results in functional impairment in the arms, trunk, legs, and pelvic organs. The term tetraplegia, which has replaced quadriplegia, is defined as an impairment in motor and/or sensory function in the cervical segments of the spinal cord (American Spinal Injury Association [ASIA], 2000). It is caused by damage to neural elements within the vertebral canal, and the term is not used to describe injuries to peripheral nerves. **Paraplegia** refers to motor and sensory impairment at the thoracic, lumbar, or sacral segments of the cord. Likewise, it refers only to damage to the neural elements inside the vertebral canal. Paraplegia results in sparing of arm function and, depending on the level of the lesion, impairment in the trunk, legs, and pelvic organs. The terms paraparesis and quadriparesis, which were used in the past to describe incomplete injuries, should no longer be used (ASIA, 2000).

The neurological level is diagnosed by the physician according to the motor and sensory level. The motor level is determined by testing 10 key muscles on each side of the body, and the sensory level is determined by testing sensation of 28 key points on each side of the body (Fig. 43-2). The **neurological level** is the lowest level at which key muscles grade 3 or above out of 5 on manual muscle testing (MMT), and sensation is intact for this level's **dermatome**. Also, the level above must have normal strength and sensation. For example, a person is diagnosed as having C6 tetraplegia when radial wrist extensors test 3 out of 5 and sensation is intact for the C6 dermatome. Furthermore, all motor and sensory status above the C6 level is intact. Skeletal level refers to the level of greatest vertebral damage (ASIA, 2000).

Functional level, a term used by occupational and physical therapists, refers to the lowest segment at which strength of key muscles is graded 3+ or above out of 5 on MMT and sensation is intact. Key muscles are those that significantly change functional outcomes (Occupational

Therapy Department, 1990). The ASIA muscle list for the physician’s motor examination (Fig. 43-2) includes only some of the muscles considered important to determine a functional level.

Two other terms commonly used with people with spinal injuries are complete and incomplete injuries (Definition 43-1). **Complete injury** consists of absence of sensory or motor function in the lowest sacral segments (S4-S5) (ASIA, 2000). The term **incomplete injury** should be used only when there is partial preservation of sensory and/or motor function below the neurological level and including the sacral segment (ASIA, 2000). The physician tests innervation at the lowest sacral segment, including anal sensation and sphincter contraction.

The term **zone of partial preservation** is used for patients with complete injuries who have partial innervation in dermatomes below the neurological level (ASIA, 2000). A patient may have a C5 neurological level complete injury, although radial wrist extensors innervated by C6 are functional (zone of partial preservation). Finally, some specific cord lesions cause a common pattern of clinical findings (see Definition 43-1).

Prognosis

Not surprisingly, recovery is very much on the minds of patients, families, and staff. Neural recovery during rehabilitation is common and can result in significant improvement in function. In patients with complete injuries, muscles in the zone of partial preservation strengthen, which may result in significant functional change. This is true especially if a key muscle, such as extensor carpi radialis, strengthens enough to enable the person to extend the wrist and hold objects. Patients with incomplete injury have a better prognosis, and their recovery is less predictable in its pattern and outcome than patients with complete injury (Waters & Yoshida, 1996).

Immediately after the injury, all reflexes cease to function. When spinal shock resolves, patients have an excellent chance to regain motor and sensory function. As time after injury increases, however, the recovery rate declines. Most motor and sensory return in both complete and incomplete injuries occurs in the first 6 months post onset; the rate of recovery is minimal after a year (Waters & Yoshida, 1996; Kirshblum et al., 2004).

DEFINITION 43-1

function

ASIA Scale and Clinical Syndromes

ASIA Impairment Scale

The following scale is used in grading the degree of impairment:

- A = Complete—No sensory or motor function is preserved in the sacral segments S4-S5.
- B = Incomplete—Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5.
- C = Incomplete—Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3.
- D = Incomplete—Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade greater than or equal to 3.
- E = Normal—Motor and sensory functions are normal.

Note: To receive a grade of C or D, a person must have sensory or motor function in the sacral segments S4-S5. In addition, the individual must have either (1) voluntary anal sphincter contraction or (2) sparing of motor function more than three levels below the motor level.

Clinical Syndromes

- Central Cord Syndrome—Incomplete injury most common to the cervical region in which the center part of the cord is damaged. This lesion results in greater weakness in the upper limbs than in the lower limbs, with sacral sparing (ASIA, 2000).
- Brown-Sequard Syndrome—Half of the cord is damaged, causing ipsilateral proprioceptive and motor loss and contralateral loss of pain and temperature sensation (ASIA, 2000).
- Anterior Cord Syndrome—Lesion with variable motor and sensory loss and preservation of proprioception (ASIA, 2000).
- Conus Medullaris Syndrome—Lesions to the sacral cord and lumbar nerve roots within the spinal canal; commonly results in areflexic bladder, bowel, and lower limbs (ASIA, 2000).
- Cauda Equina Syndrome—Lower motor neuron injury to the lumbosacral nerve roots within the spinal canal; results in areflexic bladder, bowel, and lower limbs (ASIA, 2000).

As patients and significant others hope for complete recovery, it is important that the therapist maintain hope while planning a realistic course of treatment. Research data can assist the clinician in predicting recovery and outcomes. One such source is the booklet *Recovery Following Spinal Cord Injury: A Clinician's Handbook* (Waters et al., 1995), although the therapist should be cautious about sharing this information with patients when they are most vulnerable.

Long-term survival of people with SCI has improved dramatically over the past 50 years. However, their life expectancy remains somewhat less than for the able-bodied population (NSCISC, 2006).

Impairments and Their Therapeutic Implications

Paralysis is the most common result of SCI. This injury is accompanied by a variety of frequent complications. The therapist must be aware of these impairments to provide a safe therapeutic environment and educate patients in understanding how to live a safe and healthy life.

Respiration

Many patients with SCI have compromised breathing. This is true especially for individuals with cervical injuries. Respiratory complications, specifically pneumonia, have been identified as the leading cause of death in the first year of life after SCI. In lesions above C4, damage to the phrenic nerve results in partial or complete paralysis of the diaphragm. These patients require ventilatory support (Fig. 43-3). Lower cervical and thoracic spine injuries can result in paralysis of other breathing muscles, such as the intercostals, abdominals, or latissimus dorsi (Kendall, McCreary, & Provance, 1993). Thus, patients with such injuries also have impaired respiration.

Use of proper techniques and infection control standards are important for respiratory care. Under the direction of the physician, the physical and respiratory therapists and the health care team work to achieve adequate bronchial hygiene and to facilitate good breathing at rest and during activities. Good communication with the team allows the occupational therapist to support breathing goals.

Autonomic Dysreflexia

Autonomic dysreflexia, a sudden dangerous increase in blood pressure, is a possibly life-threatening complication associated with lesions at the T6 level or above (Safety Note 43-1). It is brought on by an unopposed sympathetic

Figure 43-3 A person with C2 complete tetraplegia, ventilator dependent, using a mouthstick.

SAFETY NOTE 43-1

Safety Concerns for Patients with SCI

Autonomic Dysreflexia

Individuals with injuries at the T6 level or above may develop dangerously high blood pressure in response to a noxious stimulus. This condition is brought about by unopposed hyperactivity of the autonomic nervous system. If not promptly treated, autonomic dysreflexia may result in a stroke or sudden death. An increase of 20 mm Hg or more in systolic blood pressure is a sign that must be attended to. A pounding headache is the most common symptom. Other signs and symptoms include heavy sweating, flushed skin, goose bumps, blurry vision, a stuffy nose, anxiety, difficulty breathing, and chest tightness (Consortium for Spinal Cord Medicine, 1997a).

Take the following steps:

1. Ask the person to stop any ongoing activity, as it may further increase blood pressure.
2. Check blood pressure. If high:
3. Have the person sit up with head elevated to avoid excessive blood pressure to the brain.
4. Loosen clothing, abdominal binder, and any other constrictive devices.
5. Check the urinary catheter for kinks or folds and straighten any.
6. Continue to monitor blood pressure and seek medical assistance, which may include bladder irrigation, manual fecal evacuation, and medications.

Orthostatic or Postural Hypotension

In contrast to autonomic dysreflexia, in orthostatic hypotension, blood pressure drops to dangerously low levels in response to assuming an upright position. If it is not treated immediately, the person may lose consciousness. Symptoms of orthostatic hypotension include light-headedness, pallor, and visual changes. To resolve the problem:

1. Check blood pressure.
2. If the person is in bed, lower the head of the bed.
3. If the person is in a wheelchair, lift his or her legs and observe for signs of relief. If symptoms persist, recline the wheelchair to place the head at or below the level of the heart.
4. If symptoms persist, put the patient to bed.
5. Continue to monitor blood pressure and seek medical assistance. Do not leave the patient unattended until a nurse or a physician is present.

Principles for treatment of autonomic dysreflexia are derived from Consortium for Spinal Cord Medicine (1997a) and Zejdlik (1991). Principles for treatment of postural hypotension are derived from Zejdlik (1991).

response to noxious stimuli. Some of the more common causes of autonomic dysreflexia are distended bladder, urinary tract or other infection, bladder or kidney stones, fecal impaction, pressure ulcers, ingrown toenails, invasive procedures such as urinary catheterization or enema, and pain. The main symptoms are hypertension and a pounding headache (Consortium for Spinal Cord Medicine, 1997a).

Orthostatic Hypotension, or Postural Hypotension

Orthostatic hypotension is a sudden drop in blood pressure occurring when a person assumes an upright position (Safety Note 43-1). Most common in patients with lesions at the T6 level and above, it is caused by impaired autonomic regulation. A decrease occurs in the returning blood supply to the heart, commonly because of blood pooling in the lower extremities. Orthostatic hypotension is aggravated by a prolonged stay in bed. When the patient attempts to sit up, the blood rushes down to the legs. The patient may complain of light headedness or dizziness and may faint on moving from reclined to upright. The therapist must use caution when sitting the patient up by having the patient move slowly and in stages and letting the blood pressure adjust to the change. Elevating the head of

the bed, using a tilt table, or using a reclining wheelchair can accomplish this. To control this problem further, patients benefit from wearing abdominal binders and elastic stockings (Zejdlik, 1991).

Pressure Ulcers and Pressure Relief

Pressure ulcers are a common problem for people with SCI. Most patients do not have the sensory feedback that periodically cues them to shift position in their bed or wheelchair. The constant pressure caused by maintaining a static position without shifting weight can lead to skin breakdown. All patients must be placed on a weight-shifting pressure-relief schedule.

Although most pressure relief efforts are aimed at the buttocks, many other parts of the body are vulnerable in patients with higher lesions. All insensate areas must be inspected daily. For high tetraplegic patients, these areas may also include the spine of the scapula and the back of the head.

The pressure relief program is successful only if patients with SCI incorporate this practice in their daily routines following hospitalization (Wolfe, Potter, & Sequeira, 2004). They must become responsible for carrying out pressure relief procedures themselves or for asking assis-

tance in doing so. Educational materials, such as The Consortium for Spinal Cord Medicine Clinical Practice Guidelines, *Consumer Guides—Pressure Ulcers: What You Should Know* (2002), are helpful supplements for further reinforcing the program. No exact optimal interval of pressure relief standards is defined at this time; however, there is general agreement that, in bed, patients must change their position every 2 hours and, in a wheelchair, they must relieve pressure on their buttocks every hour for 1 minute (Buss, Halfens, & Abu-Saad, 2002).

Any client interaction must be viewed as an opportunity for a “teachable moment” (Wolfe, Potter, & Sequeira, 2004). Examples of our roles in pressure ulcer prevention include:

- Training in motor skills, such as checking the skin in bed and in the wheelchair.
- Establishing routines, such as inspecting and wiping any wetness in vulnerable areas.
- Assessing environmental and contextual factors, such as helping select high-protein, healthy foods when going to the market (Clark et al., 2006; Ryan, 2003).

Bowel and Bladder Function and Management

Bowel and bladder function is controlled in the S2-5 spinal segments. Therefore, all persons with complete lesions at and above the S2-5 levels lose their ability to void and defecate voluntarily. With the presence of intact reflex activity but with a lack of cortical voluntary control, patients void and defecate reflexively. Incomplete injuries and disruption at the S2-5 levels, as seen in conus medullaris and cauda equina, may present with a mixed sensory and/or motor picture. For example, a person may feel the urge but may lack the ability to void and defecate voluntarily. The goal of a sound bowel and bladder program is to allow the person to develop an elimination routine that supports health, reduces potential complications, and allows the freedom to engage in life roles without disruption (Consortium for Spinal Cord Injury, 1998b).

Following a thorough medical examination that includes studies of the structure and function of the digestive and urinary tracts, a physician establishes a safe elimination program. Most programs involve behavioral and pharmacological interventions (Pires, 2002). Surgery is also an option that is typically offered months or years post injury to further ease elimination and reduce problems.

Nurses are the primary trainers of bowel and bladder routines, and occupational therapists have a vital role in supporting the acquisition of these new skills and habits. A typical bowel program for a person with paraplegia includes taking oral medications to allow for optimal feces consistency and establishing a daily routine of transferring to the toilet, managing clothing, inserting a suppository, and, after waiting for some time, inserting a finger to the anus

(called digital stimulation), which causes reflexive defecation. The occupational therapist may assist in facilitating skill acquisition in a person with poor vision and/or cognitive deficits. A magnifying mirror and a lamp may be placed on the floor to help the person see and further break down the activity to better reinforce each step. Persons with low tetraplegia have added challenges in becoming independent in bowel care. They may achieve independence or assist in managing their bowel care only after much practice. To compensate for poor trunk control, individuals perform the bowel program on a commode; to compensate for finger paralysis, they require a tool called the dill stick to stimulate the anal reflex to defecate (Fig. 43-4); and to compensate for lack of sensation in the anus and/or parts of the hand, they require a mirror. For safe task performance, occupational therapists may practice commode mobility and dill stick insertion focusing on effective visual compensation. When patients become skillful at bowel evacuation practices, they decrease the risk of complications. Most individuals, after discharge, opt to carry out their bowel program in the morning every other day and can complete the procedure within 45 minutes (Kirshblum et al., 1998).

Figure 43-4 A simulation of a bowel program for a person with low-level tetraplegia (ASIA A). The person is hooking his left arm under the handle for stability. He is using a dill stick to stimulate reflexic evacuation and a mirror to compensate for his lack of sensation in the anal area.

As with the bowel program, the goal of the bladder program is to achieve a simple routine with minimal risk of complications. Recurring urinary tract infection is a frequent complication and the most frequent cause of rehospitalization after spinal cord injury (Cardenas et al., 2004). To avoid complications, patients must empty their bladder routinely.

An indwelling catheter, which is a catheter that stays in the urethra and is changed only periodically, is commonly inserted soon after the person is admitted to the acute care hospital. Although some patients stay with the indwelling catheter, an effort is made to find other ways to empty the bladder (Yarkony & Chen, 1996).

Common bladder practices include use of either intermittent catheterization or reflex voiding. Intermittent catheterization (IC) involves the manual insertion of a catheter into the bladder (Fig. 43-5) at fixed intervals of approximately 4–6 hours. Reflex voiding refers to the spontaneous micturition when the bladder is full. This voiding method requires that males use a condom catheter and a leg bag and that females use a diaper (Pires, 2002). As with the bowel program, the bladder programs of persons with tetraplegia need more intervention, and the occupational therapist must become thoroughly familiar with individual techniques. Interventions may include finding a way to keep down the pants when performing IC in the wheelchair and training with a tool that helps insert the catheter into the urethra. Urinary management is more challenging to females than to males. Women have a shorter urethra and the opening is between the folds of the labia, so it is much harder for women to insert a catheter. In addition, women often need to wear diapers because their shorter urethra is more prone to leakage, and there are currently no acceptable female external collection devices that can keep the skin dry.

Figure 43-5 Catheterization: Inserting a catheter into the bladder and waiting for urine to flow.

To best meet the person's environmental and contextual demands, the occupational therapist must think and practice beyond the hospital or clinic when helping patients rehearse and refine bowel and bladder routines. As patients rebuild new routines and habits, the therapist helps identify and imbed these new functional skills in real-life scenarios such as emptying a full leg bag at a party, changing clothes when an accident happens in a mall, and performing intermittent catheterization while attending school.

Sexual Function

The need for emotional and physical intimacy does not diminish after SCI, and questions about intimacy, sexuality, fertility, and reproduction must be answered by a team of sensitive and knowledgeable professionals. SCI affects both sexual intercourse and reproduction. Usually, male patients with complete injuries are unable to have psychogenic (voluntary) erections and ejaculations. They can, however, have reflex erections that may be controlled by stimulation, such as pulling the pubic hairs (Ducharme & Gill, 1997). Patients with complete injuries at S2-5 lose bowel, bladder, and genital reflexes and have a complete loss of erection. As with physical performance, male fertility is decreased after SCI. Advances in technology, however, provide ways for male patients to sustain an erection and improve the chances of fathering children (Ducharme & Gill, 1997).

Although sexual and reproductive functioning is less affected in women, sex, fertility, and menopause are still issues of concern. Some consequences related to these issues are dysreflexia and bladder incontinence during intercourse and complications of pregnancy and delivery (Jackson & Wadley, 1999).

For both men and women, other psychological, social, and physical issues add to the difficulty in resuming satisfying sexual roles. Problems with mobility, dependency, and societal role expectations are some of the issues the person with SCI must face. Knowledgeable members of the team must address sexual issues with patients. Individual counseling, often by a psychologist, takes place after a thorough evaluation by a physician. The following four areas are typically addressed: sexual satisfaction, sexual function, fertility, and desirability. Patients learn that, despite their injury, they can continue to be desirable and have an active sex life (Ducharme & Gill, 1997).

The occupational therapist addresses many issues that relate to sexuality. Therefore, therapists must develop the necessary expertise and comfort level to deal with this sensitive and important subject. Some examples for the therapist's involvement may be helping people groom themselves to improve their appearance and to feel more attractive, creating a cozy environment that allows for intimacy, and finding equipment to compensate for lack of hand function.

Temperature Regulation

Many people with SCI cannot regulate body temperature, which can lead to hypothermia or heat stroke (Zejdlik, 1991). Due to decreased sensation, patients may become severely sunburned or frostbitten. Education in the importance of neutral temperatures and the prevention of skin exposure to sun and severe temperatures is an important part of the occupational therapy program (Hill, 1986).

Pain

Acute and chronic pain (duration of more than half a year) is common after SCI. Approximately 65% of individuals with SCI report having chronic pain, and persons with tetraplegia report having more pain than persons with paraplegia (Siddall & Loeser, 2001). Considering the violent nature of most injuries, it is not surprising that most patients have pain at onset and that pain persists for a long time. Although many types of pain are present, they are most commonly classified as follows:

- **Mechanical pain:** Local soft tissue pain associated with the injury. Mechanical pain, common in the shoulder of the person with tetraplegia, may be caused by direct trauma, muscle imbalance, and overuse of weak muscles. It is the most common pain in people with SCI (Siddall et al., 2003).
- **Radicular pain (also called segmental root pain):** Pain that often follows the segmental distribution of the nerve.
- **Neuropathic pain (also called deafferentation or central pain):** Pain that originates in the spinal cord and is thought to be the result of misdirected neural sprouting after the injury.

For many people with SCI, pain contributes to activity limitations, lack of participation, and depression. Available treatments include prescription and non-prescription medications, physical agent modalities, medical procedures such as nerve blocks, and psychotherapy (Widerstrom-Noga & Turk, 2003). The occupational therapist's contribution to pain management includes a thorough evaluation and a myriad of interventions. Although treatment goals are often directed toward reducing impairments, our main contribution is in changing habits and roles and facilitating engagement in meaningful activities and full participation. This approach is especially valuable because most persons continue to live with some pain throughout their lives and new pains arise with aging.

Fatigue

Physiological, psychological, and environmental factors all contribute to patients' fatigue. Persistent pain, antispasmodic medications, and prolonged bed rest are

physical factors that can make the patient feel tired or sleepy. These factors are often compounded by restless nights interrupted by hospital routines, such as repositioning patients in bed and waking them for checking vital signs and administering medications. Occupational therapists must be aware of these constraints and observe and listen to the patient. They must find the optimal waking hours for activities and report nighttime sleep disturbances, any changes of behavior that medication may cause, and other factors.

Spasticity and Spasms

An injury to the spinal cord often results in an increase in transmission within the synaptic stretch reflex. This results in spasticity. Spasticity develops into clonic or tonic spasms triggered by sensory stimuli such as sudden touch, infection, or other irritation. Management of spasticity is important in maximizing a patient's functional independence. Severe spasticity may hinder function; for example, the hypertonicity of the hip and knee adductors can make donning pants difficult. The most common way to decrease spasticity is to use a muscle relaxant, such as baclofen. An intrathecal pump, motor point, or nerve blocks may be used in severe cases. Spasticity can lead to contractures, so routine positioning in bed (Fig. 43-6) and in the wheelchair and range of motion are essential; patient and family must participate in these measures for continuity of care (see Chapter 21).

Deep Vein Thrombosis

Deep vein thrombosis is the formation of a blood clot, most often in a lower extremity or the abdomen or pelvic area. A clot may develop further and dislodge from the venous wall, forming an embolus. This condition poses a threat to the patient because the embolus may travel and occlude pulmonary circulation (Consortium for Spinal Cord Medicine, 1997b). The therapist helps prevent this condition by observing any asymmetry in the lower extremities in color, size, and/or temperature. When deep vein thrombosis is identified, the patient must have complete bed rest and anti-coagulants to prevent embolus (Consortium for Spinal Cord Medicine, 1997b). This is a good time to inform the patient and family about the symptoms, prevention, and care of deep vein thrombosis.

Heterotopic Ossification

Heterotopic ossification, which is pathological bone formation in joints, has been recorded in 15–53% of SCI patients (van Kuijk, Geurts, & van Kuppevelt, 2002). It is a condition in which connective tissue calcifies around the joint. Heterotopic ossification usually appears 1–4 months after injury. The symptoms are a warm, swollen extremity, fever, and/or range-of-motion limitations.

Figure 43-6 Positioning in bed. **A.** Alternate the arm in shoulder abduction and external rotation. **B.** Side view of **A**, showing placement of foam wedge. **C.** During side-lying, keep the upper back flat on the bed to protect the weighted shoulder. (Printed with permission from Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

Most often seen in the hip and shoulder joints, heterotopic ossification can result in joint contractures. Positioning in bed and in the wheelchair (see Fig. 43-6) and daily range of motion prevent or control heterotopic ossification. As the first indication of heterotopic ossification most typically is range-of-motion limitation, the occupational therapist must use each range-of-motion session to monitor joint ranges, especially in patients with spastic muscles (Garland, 1991).

Psychosocial Adaptation

As mentioned earlier, SCI dramatically disrupts life (see Chapter 35). What coping mechanisms are enlisted to enable the individual to adjust to these dramatic life challenges? Despite inconclusive and conflicting research, many authors agree that reactions to SCI may include periods of shock, anxiety, denial, depression, internalized and externalized anger, adjustment, and acknowledgment. These coping behaviors may be enlisted in a different order, and some may be skipped (Livneh & Antonak, 1997).

Depression

Although it is not universal, many patients have varying degrees of depression, sadness, or grief (Consortium for Spinal Cord Medicine, 1998a). Logically, we associate depression with the grieving time right after the injury; depression, however, may persist long after the injury. Fuhrer et al. (1993) estimated that, after SCI, up to 25% of men and 47% of women have symptoms of depression. Depressive symptoms are also associated with lack of social and occupational involvement. Injured individuals who show more symptoms of depression participate less in worker, volunteer, and student roles. Interestingly, level of injury does not appear to be associated with depressive symptoms. Individuals with a high cervical lesion are not necessarily more commonly or intensely depressed than individuals with paraplegia (Fuhrer et al., 1993).

To understand the complexity of the psychosocial adjustment to SCI, we must also examine the reactions of the patient's family and significant others. The family and significant others may also go through these psychological reactions. Concurrently, they may have to reassess their future commitment to the injured person. A

mother, for example, may grieve and be sad while having to decide whether to take her fully dependent son home after a turbulent adolescence.

SCI, independent of its severity, is an emotionally traumatic and overwhelming event. Therefore, in every encounter with the patient, we must ask ourselves: Is the person ready to hear this information? Is this “chunk” of information too much for the person? Often, the patient may answer these questions directly, but at times, the therapist may need to collect cues from facial expressions and/or from body language if patients have arm and trunk movement (Potter et al., 2004; Wolfe, Potter, & Sequeira, 2004).

Occupational therapists and other health care professionals must also examine their emotional reactions and the influence of these emotions on the patient and therapeutic process. For example, sometimes upon interviewing a newly injured person, I become especially sad as I strongly identify with something in the patient’s life narrative (e.g., the struggles of a mother with two young children). I am reminded of my projection, as the patient may be perfectly accepting and cheerful. Furthermore, studies show that health care professionals may overestimate the degree of patients’ distress and depression. Patients’ descriptions of their own depression are often milder than perceived by the health care professional (Cushman & Dijkers, 1990).

As occupational therapists, we contribute to psychosocial adaptation after SCI by incorporating the following considerations into evaluation and treatment.

- Set aside all preconceived biases about who the patient is and how he or she should feel or behave. Instead, concentrate on learning to know patients, their unique life contexts, and their individual reactions to their trauma.
- Provide psychological support. At times when the patient is overwhelmed with sadness, it is okay just to be present and available to the person. It is okay to stop an activity, find a quiet environment, possibly outside, and listen, affirm, and educate.
- Select activities with a just-right challenge. After weeks of being dependent, patients find hope by being able to feed themselves or turn on a CD player independently.
- When providing information, don’t overwhelm the person with too much detail. Find the opportunity for a “teachable moment” for a particular “chunk” of information and be sensitive of patients’ signs to help you determine how to proceed and when to stop (Potter et al., 2004; Wolfe, Potter, & Sequeira, 2004).
- Accept patients’ emotional states without judging them (Hammell, 1995). Lack of evidence of depression or anger does not necessarily mean that individuals are coping poorly with their injury. They may be using ways of coping that are not the textbook ones.

Remember that there is no requirement to mourn to learn to accept and live with the injury (Cushman & Dijkers, 1990).

- Create opportunities for peer education and support. Peers with SCI are often very effective in reaching patients and in making them feel less isolated and more optimistic. Individuals with similar levels of injury can truly understand the pain that comes with SCI and may help the therapeutic process.

ASSESSMENT: GETTING TO KNOW THE PERSON

Prior to the assessment, the occupational therapist checks the medical chart for medical clearance to begin the evaluation. The patient often has other trauma, such as lacerations of internal organs, closed head injury, and fractures. Special care is taken to review records and communicate with the physician to ensure the safety of the patient. The initial evaluation is often difficult, as the newly injured patient may be sedated, in pain, and/or confused. Furthermore, this assessment may be interrupted by numerous medical procedures and may be restricted by medical and spinal precautions. Therefore, the occupational therapist must be flexible in choosing appropriate evaluation time, in gathering bits of information in interrupted sessions, and in choosing the right tool for the moment when the patient is available. In essence, the evaluation process should not be limited to set scheduled intervals, and the therapist must view each encounter with the patient as part of an ongoing assessment. Information should be also collected from significant others and other team members. Thus, at the end of the assessment period, the therapist assembles all fragments of information into a full, initial evaluation. Treatment begins while the evaluation is in progress. This prevents further complications, such as range-of-motion limitations and edema. The therapist may also address patients’ immediate needs, for example making them more comfortable in bed, which further establishes rapport and trust.

Often various members of the interdisciplinary team repeat parts of the evaluation. A positive trend toward an interdisciplinary team evaluation in which a few members of the team evaluate the patient together brings organized information gathering to the process that is not redundant. Assessment in occupational therapy after SCI includes all levels of occupational functioning.

Occupational Profile

The goals of the initial evaluation include beginning to establish rapport and trust, teaching patients about their potential, and learning about who they are and what is

important to them. From the first encounter, the therapist also begins to educate the patient and to plan discharge. This is true especially today, when hospital stays have been cut to a bare minimum. In the acute phase and shortly after the injury, patients may be quite limited in their knowledge of the nature of their injury, prognosis for recovery, and potential for function. It is important not to overwhelm the patient with more than can be absorbed at that moment. The therapist must always leave room for hope without deceiving the patient.

To gather deeper understanding of patients' roles, activities, and the meaning behind the activities, use open-ended questions. Charting a typical day's schedule prior to injury allows for creative questioning and enables the therapist to sketch a person's habits, routines, and other activities.

The *Canadian Occupational Performance Measure (COPM)* is an excellent tool for working with the SCI population. It focuses on finding out patients' occupational goals and their priorities (Donnelly et al., 2004) (see Chapters 4 and 10). If patients are not psychologically ready to formulate goals that are important to discharge, first goals may be directed toward their attaining more control over their immediate environment.

Evaluation of Performance Skills

Spinal stability must be established prior to any physical contact with the patient. The occupational therapist must clarify with the primary physician how much movement and load are allowed without jeopardizing spinal integrity.

The physical assessment includes upper extremity range of motion, strength, muscle tone, and sensation (see Chapters 6 and 7). The therapist also observes the patient's endurance, trunk balance, fatigability, and pain. *The Manual Muscle Test* is most widely used to measure strength. This test is useful in determining the functional level of the person. The appearance of the upper extremities can reveal signs of reflex sympathetic dystrophy, which is an upper limb disease marked by severe pain and swelling. Such findings are vital for prevention of further deformity by immediately initiating an aggressive treatment regimen.

Hand and Wrist of the Patient with Tetraplegia

Evaluation of the hands and wrists is both physical and functional. Most therapists observe hand use while the person is performing activities such as picking up coins or pieces of a game or eating. Most hand motor function tests are not specific to tetraplegia, and although they prove somewhat useful in determining abilities and capacities, many are old and require much time to administer. Some such tests are the *Sollerman Hand Function Test* (Sollerman & Ejeskar, 1995) and the *Jebsen Test of Hand Function* (Jebsen et al., 1969). New hand tests have been de-

veloped to specifically assess hand function before and after hand reconstruction surgeries. Some such tests are the *Standardized Object Test (SOT)* and the *VadenBerge Hand and Arm Function Test* (van Tuijl, Janssen-Ptten, & Seelen, 2002). New tetraplegia hand-specific functional assessments are needed. The *Tetraplegia Hand Activity Questionnaire (THAQ)* (Land et al., 2004) may prove useful but has yet to be tested. Pinch and grip strength are measured by dynamometers when hand muscles are functioning (van Tuijl, Janssen-Potten, & Seelen, 2002). To measure weak pinch and grip, more sensitive instruments than the standard dynamometer and pinch meter are used. Finally, using the client-centered approach of *The Canadian Occupational Performance Measure*, clinicians find out what is most relevant to the person. By asking the person to list functions they want and need to perform with their hands and examining their performance in these areas, the therapist can concentrate on those functional components most relevant to the person.

Evaluation of Performance in Areas of Occupation

Selection of appropriate functional evaluations is determined by level of injury and stage of recovery. Occupational therapists rely on observations and standardized and non-standardized assessments to evaluate basic and instrumental activities of daily living (ADL), leisure, school, vocational interests, and aptitudes (see Chapter 4).

Activities of Daily Living and Instrumental Activities of Daily Living

Often full ADL evaluation is postponed because of medical and spinal restrictions, and predictions regarding length of stay and functional outcomes are rendered without complete data. The *Functional Independence Measure (FIM)* (see Chapter 4) is widely used to assess function; however, some instruments are designed specifically for the patient with SCI, such as the *Quadriplegia Index of Function* (Gersham et al., 1986) and the *Modified Barthel Index* (Yarkony et al., 1987). A relatively new and promising instrument dedicated to the person with spinal cord injury in *The Catz-Itzkovich Spinal Cord Independence Measure (Catz-Itzkovich SCIM)* (Catz, Itzkovich, Ring, et al., 2001). This functional instrument measures self-care, respiration, sphincter management, and mobility (Catz, Itzkovich, Steinberg, et al., 2001).

Leisure

Persons with SCI have high unemployment rates and much free time (Schoherr et al., 2005; Yerxa & Locker, 1990). Finding past relevant and meaningful leisure activities is of great importance for improving quality of life

(see Chapters 4 and 34). Leisure assessments may include the *COPM* and interest inventories. Most SCIs occur to young men, thus, it is not surprising that sports are meaningful to many patients. Assessing the potential for engaging in sports following the injury may include activities such as an outing to a game and/or being introduced to a wheelchair sports program.

School and Vocation

A full vocational evaluation is rarely performed during acute rehabilitation because patients are focused on more immediate challenges. Many have lost the physical ability to engage in prior occupations. Vocational exploration begins with defining patients' abilities and interests. Observation of factors such as hand function and work habits contribute information for the prevocational team and department of vocational rehabilitation.

Home and Community

The home visit is an invaluable assessment tool for the person with SCI, and the earlier it is performed, the better. This visit allows the therapist to assess home accessibility and safety and to evaluate the capacity of patients and their families to problem solve (Atkins, 1989). Assessing transportation issues is important, as persons with SCI must often find new ways to get around. This evaluation may involve taking a bus for the first time or referring the patient to special disabled driving services (see Chapters 31 and 36).

SETTING GOALS: ORDERING PRIORITIES FOR MEANINGFUL AND RELEVANT ACTIVITIES

Setting treatment goals in the acute phase may seem overwhelmingly difficult for both patient and therapist. Complications seem to hinder progress, and patients are often confused, fearful, and uncertain about their impairments and abilities. Answers to the following questions help patient and therapist set priorities, establish short-term goals, and start treatment while evaluation is still in progress:

- What must be done to prevent further deformities and complications?
- What activity is important to the patient to engage in right now?

The development of short-term goals stems from the therapist's ability to perform an activity analysis. Short-term goals may address functional performance areas and tasks, underlying problems, or the component skills necessary to perform an ADL. For example, a per-

son with C4 tetraplegia who wants to use a mouthstick for word processing on the computer must first tolerate sitting upright in the wheelchair for significant periods. Increasing tolerance for sitting upright is an appropriate short-term goal for achieving the independence of mouthstick computer use.

Functional Expectations

Expected functional outcome charts predict the degree of functional independence for a particular level of injury. One such chart was published in a 1999 document, *Outcomes Following Traumatic Spinal Cord Injury: Clinical Practice Guidelines for Health Care Professionals* (Consortium for Spinal Cord Medicine, 1999). The consortium is administered and financed by the Paralyzed Veterans of America. This document is presented here in part. It includes an evidence-based expected functional outcome chart (see Appendix). Not surprisingly, when the patient and therapist agree on the task and the expected functional outcome, the outcome of those predictions are most successful. In a 2000 study, Schonherr et al. (2000) explored the relationship between the expected predictions and their outcomes. The researchers also identified the effect of patient versus rehabilitation team predictive agreement and lack of agreement on outcomes. They found that prognosis on self-care and mobility was clearer with paraplegia than with tetraplegia and that predicting mobility and function of persons with incomplete injuries was less accurate and more complex (Schonherr et al., 2000).

Age-Specific Considerations

Although every patient has unique considerations in treatment planning, this chapter highlights the unique needs of adolescents and older adults.

Adolescence and Young Adulthood

The adolescent with SCI must deal with complicating normal developmental factors coupled with new impairments and disabilities (Smith et al., 1996). Psychological adaptation to the injury may be especially difficult for adolescents, as the injury comes in the midst of development of adult self-image, identity, and independence. The therapist is challenged to maintain a delicate balance between the sometimes competing needs to support patients and families and to encourage the young person to be self-reliant. Warning the family about avoiding overindulgence can lead to more engaged and assertive participation by the patient (Smith et al., 1996). At times, when the adolescent exhibits brooding or defiant behaviors that are harmful to progress, a strict behavioral program becomes necessary to draw the adolescent into positive participation (Massagli &

RESEARCH NOTE 43-1

Abstract: Donnelly, C., Eng, J. J., Hall, J., Alford, L., Giachino, R., Norton, K. & Kerr, D. S. (2004). Client-centered assessment and the identification of meaningful treatment goals for individuals with spinal cord injury. *Spinal Cord*, 42, 302–307.

In this retrospective study, Canadian researchers examined the rehabilitation records of 41 individuals with SCI. The researchers reviewed and compared the *Canadian Occupational Performance Measure (COPM)* and individuals' *Functional Independent Measure (FIM)* scores. Their objectives included finding patients' identified goals, self-perceived performance, and satisfaction in the areas of self-care, productivity, and leisure. They also examined the relationship between subjects' *COPM* and *FIM* outcome scores. Results: The most frequent goals listed by subjects were in the areas of self-care (79%). Of those goals, the most frequently mentioned ones were functional mobility, dressing, grooming, and feeding. Goals relating to productivity were listed by 12% of participants followed by leisure (9%). The researchers found fair relationship between specific *COPM* performance and satisfaction scores and *FIM* motor change scores. These data suggest that individuals perceived positive changes in their performance (subjectively measured by the *COPM*) as their function increased (as objectively measured by the *FIM*).

Implications for Practice

Finding meaningful treatment goals for each individual is the key to a successful outcome of the rehabilitation process. It serves to engage the patient in the rehabilitation process and directs the therapist and, often, the rest of the team in choosing relevant performance areas. This is especially important with shortened length of stay, as the list of potential areas for intervention can be overwhelmingly long, yet not necessarily relevant to an individual patient.

The most frequently identified patient goals in descending order were functional mobility, dressing, grooming, and feeding. These goals reflect the wish of many patients to gain independence in managing their own body first. Many patients shift their focus to productivity, leisure, and social activities at a later time.

The *FIM* is a widely used measurement scale for documenting the severity of disability, team performance goals, and outcomes of rehabilitation. If patient-identified goals are similar to the prescribed *FIM* items as described by this study, the rehabilitation process will be both predictable and smooth. The *FIM* is limited, however, in the case of people with high tetraplegia (C1-4 ASIA A) who remain fully dependent on others and also for those patients who are interested in achieving individual goals not included in the *FIM* list. Unlike the *FIM*, the *COPM* requires patients to identify their goals and to prioritize them. This assessment is client-centered and closely reflects occupational therapy values, and thus has been gaining in popularity since its introduction in 1998. Since the *FIM* is most widely used in rehabilitation hospitals in the United States and accepted by third-party payers in charting interventions and lengths of stay, it becomes our challenge to honor and advocate for patient goals even when they are not part of the *FIM* list.

Jaffe, 1990). Along with establishing independence, primary goals for the adolescent must include the following:

- Reentering the student role—Goals may include meeting with school personnel and visiting the school with the patient (Massagli & Jaffe, 1990).
- Sexual roles—Adolescents must be assured that individuals with SCI can remain sexually active (Massagli & Jaffe, 1990).
- Driver role—Initial evaluation and referral may be carried out in the acute rehabilitation phase and may be continued in the transition and adaptation phases. Driving, if possible, may provide the adolescent with a valuable sense of empowerment, independence, and increased motivation.
- At times, it is hard to remember that adolescents are minors and that all fundamental decisions must be made with parental participation and consent. The parents must be supported and must be part of the team, helping the patient make appropriate choices.

Parents must also participate in educational sessions to ensure consistency in treatment, for example, with pressure relief.

The Older Adult

Having SCI and being elderly may be considered a dual diagnosis. The physiological process of aging can make rehabilitation from SCI particularly difficult, and older patients tend to have more medical complications (Scivoletto et al., 2003). Most geriatric SCIs are attributed to falls that result in lesions at the cervical level (DeVivo & Stover, 1995). The central cord syndrome is common among the elderly SCI population.

The geriatric patient may require downgrading of expected functional outcomes, given physical and/or cognitive limitations. Some important factors are decreases in muscle strength, endurance, energy, and physical fitness (McColl et al., 2003); joint degeneration; bone decalcification; skin integrity; cognition; vision; and emotional

changes. Older patients may require more assistance in activities of daily living, and hence, the focus of rehabilitation may be helping them identify resources in the community and teaching them to direct their care effectively (Scivoletto et al., 2003).

Aging with Spinal Cord Injury

Long-term survival rates of patients with SCI have improved dramatically in the past few decades, and many people with SCI live for decades after injury (DeVivo, Krause, & Lammertse, 1999). Along with normal aging issues, some unique problems arise in this population. Using the upper limbs for mobility (pushing a wheelchair, transferring), overuse of weak muscles, and muscle imbalance may cause chronic shoulder pain and less often, elbow and wrist pain (Consortium for Spinal Cord Medicine, 2005; Curtis et al., 1999). Other body changes may include skin changes with increasing susceptibility to pressure ulcers, decreased bone density, susceptibility to fractures, impaired cardiovascular fitness, and renal and bowel complications. Additional problems include depression, an increase in functional dependence, and decreased mobility (Liem et al., 2004; Whiteneck et al., 1993).

The occupational therapist, using knowledge of energy conservation, joint protection, and activity analysis, must communicate with and educate the patient in restructuring activities to accommodate the new condition. An aging patient, once independent in all self-maintenance skills, may need help in the morning to conserve energy for work. A grandmother who wants to interact with her toddler grandson may have to train him to climb onto her lap rather than picking him up.

INTERVENTION

The occupational therapist treats individuals with SCI at various settings and at various times. Throughout this treatment continuum of acute care, acute rehabilitation, transition, and adaptation, most treatment principles remain the same. The focus of care changes, however, as the patient's internal processes and external environment change.

Acute Recovery: Focus on Support and Prevention

Immediately after injury, most patients are admitted into an intensive care unit, where the focus is on preservation of life and stabilizing fluids, electrolytes, and cardiopulmonary and other vital functions. The patient is immobilized in traction and waiting to hear whether

surgery is required to stabilize the spine. For prevention of pressure ulcers, the patient is put in a rotating bed (Yarkoni & Chen, 1996). In the intensive care unit, medical and surgical procedures take precedence over therapy. The therapist must be flexible, often seeing the patient for brief periods throughout the day. One or two 15-minute sessions per day are often helpful to the patient, who may be in pain, fatigue easily, and become confused or overwhelmed by this fast-paced environment of electronic devices and medical procedures. The occupational therapist's initial contact should be within 24 hours of admission. Treatment begins as the initial evaluation is in progress, allowing the therapist to begin to gain a full picture of the patient (Hammell, 1995). In addition to ongoing patient and family support and education, the goals of therapy in the acute recovery phase include:

1. Provide some environmental controls to help the patient get some control.
2. Maintain normal upper limb joint range of motion and prevent deformities (Yarkoni & Chen, 1996).

To prevent range-of-motion limitations, therapists use positioning techniques and assist with range-of-motion exercises. In bed, most persons with tetraplegia tend to lie with their arms adducted close to their body, internally rotated, and with elbows flexed (Consortium for Spinal Cord Medicine, 2005). Therefore, movement in joints particularly susceptible to contractures must be monitored daily (van Kuijk, Geurts, & van Kuppevelt, 2002). These are scapular rotation, shoulder scaption (the functional motion between abduction and flexion), shoulder external rotation, elbow extension, and forearm pronation. Hands are fitted with resting hand splints. Upper limbs are placed in either some abduction or external rotation (see Fig. 43-6, A and B). Alternating arms between these positions puts all vulnerable joints in stretch. It is important to note, however, that although the goal is to preserve range of motion, one must consider the comfort of patients and allow them a good night sleep.

Range of motion to the hand of the tetraplegic patient is performed in a special way to facilitate **tenodesis grasp**: passive opening of the fingers when the wrist is flexed and closing of the fingers when the wrist is extended (Fig. 43-7) (Wilson et al., 1984). The patient, family, and others are taught how to perform range-of-motion exercises to facilitate tenodesis. Again, range-of-motion exercises must be augmented with proper positioning in bed and in the wheelchair.

Acute Rehabilitation: Focus on Support, Education, and Meaningful Activities

In the 1970s, the mean length of stay in acute SCI rehabilitation was 144.8 days. By the late 1990s, mean length of

Figure 43-7 Ranging to facilitate tenodesis grasp. **A.** When the wrist is extended, the fingers are flexed. **B.** When the wrist is flexed, the fingers are extended.

stay had decreased to 44 days and to 39 days by 2006 (NSCISC, 2006). To make matters worse, at present, insufficient health care money is being allocated for outpatient services, and patients' needs are being only partially met (Zigler et al., 1998). Consequently, therapists are often frustrated, trying to accomplish too much in too little time. It helps to conceptualize rehabilitation as a lifelong endeavor, with acute rehabilitation being only the beginning phase. Shortened hospital stays serve as a catalyst for making tough decisions about what is most important to accomplish during inpatient stay.

During acute rehabilitation, occupational therapy continues to focus on providing education and support to patients and helping them begin to explore meaningful activities that restore a sense of efficacy and self-esteem. Treatments must always be structured with these overriding goals in mind. This chapter offers basic information. For specific detailed interventions, consult the reference list.

Educating Patients and Family

Each encounter with patients and families must be viewed as an educational opportunity. The style, quantity, and direction of each session must be carefully considered (Hammell, 1995; Wolfe, Potter, & Sequeira, 2004). While

patients are learning to put on a shoe, for example, the therapist may ask if they have checked skin integrity and, by so doing, draw attention to the importance of skin inspection. This discussion may also inform the patient about preferable shoe styles and sizes, pedal edema, and deep vein thrombosis. These “teachable moments” arise often and help imbed details in newly learned skills and routines (Wolfe, Potter, & Sequeira, 2004). Nurses, the only team members who see the patient throughout the day, are pivotal in enforcing a daily routine. The therapist must communicate with them daily to ensure a coherent and consistent program.

Education is often enhanced by learning and problem solving with a peer or in a group (Hammell, 1995; Wolfe, Potter, & Sequeira, 2004). Group learning is widely used in SCI centers, to inform and invite group dialogue on topics such as home modifications, accessibility rights, attendant management, assertiveness, travel, and driving. Experiential group activities, such as going to a restaurant, are recommended for building emotional and social alliances with peers while learning from each other's successes and failures. Educational materials and videos are available through groups such as the Paralyzed Veterans of America and the Spinal Cord Injury Association (Resource 43-1). Participation in self-initiated learning, such as surfing the Internet, empowers the patient. On the

Internet, many SCI consumer web sites offer tips, personal stories, and chat rooms, which can provide a lively forum for communication, self-expression, and information. Family education must result in competence in range of motion, positioning, pressure relief, assistance in ADL, and use of equipment. Home and weekend passes provide an excellent opportunity to develop and refine skills.

Self-Efficacy and Self-Management Skills

Patients' medical and psychological status, as well as being in a hospital environment, invite passivity and submission to hospital routines and to professional staff recommendations of care. The therapist and the rest of the health care team must encourage patients in taking an active role

in managing their care, in evaluating behaviors, and self-reflecting about failures and successes (Lorig, 2003; Radomski, 2000). In addition, our challenge as therapists is to recruit, educate, and empower our patients to be problem solvers. By so doing, we encourage active participation, generalization of information, and the transfer of learning to the discharge environment (Radomski, 1998; Wolfe, Potter, & Sequeira, 2004). When planning an outing, ask the group to prepare a list of items to be checked to ensure a safe, successful outing. Upon return to the hospital, encourage discussion of the outing to reflect on ways future outings can be improved. Practical issues like restaurant accessibility to wheelchairs and self-catheterization in public bathrooms may arise. This discussion is also a good time to reflect on performance accomplishments during the outing and to share failures and success experiences in a supportive environment.

Focusing on the Discharge Context: Objects, Locations, Activities, and People Central to the Patient

An early home visit can save many hours of therapy as the therapist obtains a visual image of the patient's discharge environment (Atkins, 1989). Engaging the patient in visualizing post-discharge activities at home helps make treatment relevant. For a bath evaluation, for example, the therapist must look for a setting that resembles the patient's home as closely as possible.

Balancing Self-Maintenance Skills and Meaningful Activities

In acute rehabilitation, most patients are relearning skills that they mastered in childhood, such as eating and dressing independently. This training is an important part of our job. For many patients, however, this training is frustrating, time consuming, tiring, and a constant reminder of their impairments and disabilities. The therapist has the difficult task of helping the patient see when relearning skills is valuable and when the skill should be accomplished by an attendant, either for now or permanently. The ultimate goal of rehabilitation is no longer viewed as the attainment of maximal functional independence. Rather, it is the attainment of optimal desired functional independence. Functional expectations charts (see Appendix 43-1 at the end of this chapter) help us understand the range of expectations for a given level of injury considering only the motor and sensory status of the patient. These charts do not answer such questions as these: Why should the patient dress for half an hour when his wife can dress him in 5 minutes? Will it still take that long after adequate training? What will the patient do when his wife is away? Such discussions encourage patients and families to explore the range and consequences of their choices. The novice therapist will find books such as *Spinal Cord Injury: A Guide to Functional Outcomes in Occupational*

Therapy (Hill, 1986) and *Physical Management for the Quadriplegic Patient* (Ford & Duckworth, 1987) especially valuable because they contain photographs that demonstrate various skills, their sequencing, and the use of assistive devices.

Choosing Equipment

Initially, when pain, spinal precautions, and orthoses, such as a body jacket, may stand in the way of accomplishing goals, assistive devices may be handy facilitators. When obstacles diminish, some equipment, such as a dressing stick, can be eliminated. Only essential equipment should be sent home with the patient, since much of it is costly and it may further complicate the person's life. Also, a universal device should be favored over multiple assistive devices (Clark, Waters, & Baumgarten, 1997).

Most persons with SCI require lifetime use of wheelchairs for their mobility. Choosing the optimal wheel chair requires great expertise and has important implications for ease of mobility, accessibility, and participation (see Chapter 18). The therapist and the patient must consider many factors in weighing the advantages and disadvantages of specific chairs (Consortium for Spinal Cord Medicine, 2005). For example, if a young adult with a functional level of C6 is returning to college following a rehabilitation stay and would like to use an attractive looking manual wheelchair to look and feel less disabled, questions about the layout of campus, the terrain, and distances between classes must first be answered prior to recommending the optimal wheelchair. The person's endurance, posture, and transportation are factors that must all be weighed in selecting either a manual wheelchair or a power wheelchair.

Patients and families should be involved also in the purchase of any other major equipment, such as commode, other bathroom equipment, or a bed.

Special Treatment Considerations Based on Level of Injury

The level of injury dictates the degree of motor, sensory, and autonomic nervous system impairments. Consequently, treatment considerations and outcomes vary greatly with each level. Most evidence-based data, as in the following discussion of the levels of SCI, describe individuals with complete injuries, as the clinical picture is similar from person to person. Outcome of incomplete injuries cannot be easily predicted or generalized because impairment varies greatly between individuals.

The Patient with High Tetraplegia: C1 to C4

Patients with complete C1-3 require an external breathing device because their diaphragm is either paralyzed or only partially innervated (C3). Most persons with C4 tetraple-

gia require assistance with ventilation during acute care, but as the diaphragm strengthens, they are able to breathe independently. The most common device for assisted breathing is the ventilator, a pneumatic electric machine that forces room air into the lungs. Expiration is passive. This device is attached via plastic tubes directly to a hole in the trachea (see Fig. 43-3).

People with complete high tetraplegia are paralyzed from the neck down. These patients require a highly specialized team to stabilize them medically and to prevent further complications, such as respiratory infections and pressure sores. The occupational therapist who works with this population must be comfortable with nursing procedures. These tasks include suctioning (removing secretions from the trachea), manually ventilating the patient with a manual resuscitator (Ambu-bag), and proficiently managing a ventilator (Nead & Hughes, 1997). The rehabilitation team must also be well coordinated, providing the patient and family with care while preparing them for discharge. Patients with high lesions have a myriad of issues to deal with in many domains of their life. It may be surprising to realize that, despite seemingly insurmountable obstacles to success, many patients with such lesions live healthy and meaningful lives (Whiteneck et al., 1989).

Some additional roles the therapist may have in treating persons with high cervical injury include teaching them to direct their own care; helping them select specialized and sophisticated equipment (see Chapter 19) for life support, mobility, and ADL; and training them in the use of mouth sticks, which are rigid long rods held in the mouth that allow the patient to perform activities such as turning pages, drawing, typing, painting, and playing board games (see Fig. 43-3) (Adler, 1989; Hammell, 1995).

The Patient with Lower Cervical Injuries: C5 to C8

As in the acute recovery phase, physical intervention includes positioning in bed and in the wheelchair (see Fig. 43-6), splinting the upper extremities, daily upper extremity range of motion, and strengthening. Strengthening, an important goal in this phase, can be performed by using weights, pulley systems, skateboards, suspension slings, mobile arm supports (discussed later), and modalities such as biofeedback and neuromuscular electrical stimulation (Sadowsky, 2001; Trombly, 1989) (see Chapters 20–22). See Procedures for Practice 43-1 for resources to inform intervention to improve hand function.

Patients with C5 Tetraplegia

Initially, the deltoids and biceps, key muscles for this level of injury, are weak, so upper limbs require support to function. The mobile arm support, also called a ball-bearing feeder, is a mechanical device attached to the wheelchair. This shoulder and elbow support carries the weight of the arm and reduces friction in motion (Wilson

PROCEDURES FOR PRACTICE 43-1

Intervention to Improve Hand Function for Persons with Tetraplegia

The following references offer practical information about helping patients improve their grasp.

Education and Training in Compensatory Hand Grips (Curtin, 1999)

- Analyses of hand grips of 30 individuals with C6, C7, or C8 tetraplegia
- Provides helpful criteria and vocabulary for understanding the function and compensatory techniques of the tetraplegic hand
- Provides analyses of pre-grip preparation and grasping techniques for which there are excellent drawings included

Regimen of Hand Splinting Principles Designed to Promote Tenodesis Hand Function (Harvey, 1996)

- Analysis of muscle adaptation explains kinesiological mechanism of hand tenodesis.
- This explanation aids the therapist in deciding on a sound splinting regimen to promote tenodesis hand function.

et al., 1984). The mobile arm support can assist the patient in driving the wheelchair, feeding, hygiene and grooming, and carrying out tabletop activities, such as writing and cooking (Atkins, Clark, & Waters, 2003). If and when the strength of the deltoids and biceps is 3+/5 or greater and endurance is good, patients can engage in activities without mobile arm supports (Zigler et al., 1998).

Patients with C5 complete tetraplegia need a way to grasp and hold objects, since their wrists and hands are paralyzed. First, the wrist must be stabilized with a splint or orthosis. Next, a device is attached to the hand to enable the person to perform activities. The universal cuff is a simple, inexpensive utensil holder that rests around the palm (Fig. 43-8). Other U- or C-shaped clamps can be attached to objects such as a telephone receiver or a shaver. Some splints, devices, and orthoses accommodate the wrist and the hand as a unit. One is the Ratchet wrist-hand orthosis, which is made of metal and manually controlled. To maximize functional gain with this orthosis, the patient must be carefully trained.

Most patients with C5 tetraplegia can master tabletop activities. They lack trunk control and muscles below the shoulder, however, so they are mostly dependent in dressing and bathing (see Appendix 34-1) (Consortium for

Figure 43-8 A person with C5 tetraplegia using a universal cuff.

Spinal Cord Medicine, 1999). With adequate emotional and financial resources, persons with C5 tetraplegia engage in meaningful, productive activities. Case in point: Mr. L. is a financial consultant who lives on his own and has part-time attendants. He lives a busy life full of business trips and leisure activities with friends. He attributes his success to much planning and good organizational skills.

Patients with C6 and C7 Tetraplegia

Patients with C6 and C7 tetraplegia may attain significantly higher levels of independence than the C5 patient. The addition of radial wrist extensors allows patients to close their fingers with a tenodesis grasp. This is a critical functional enhancement because, with it, light objects may be picked up, held, and manipulated. The wrist-driven wrist-hand orthosis, or the flexor hinge splint and tenodesis splint, is a metal device that transfers power from the extended wrist to the radial fingers, allowing a stronger pinch (Fig. 43-9) (Atkins, Clark, & Waters, 2003; Consortium for Spinal Cord Medicine, 1999).

More fully innervated proximal scapular and shoulder muscles, such as the rotator cuff, deltoids, and biceps, allow for an increase in upper limb strength and endurance. Patients can also roll in bed, and their arms can cross the midline more forcefully, with the addition of the clavicular pectoralis muscle. The ability to use the triceps, the key muscle for C7 tetraplegia, allows the patient to reach for objects above head level, such as items on a store shelf; transfer with greater ease; and push a manual wheelchair.

Figure 43-9 A person with C6 complete tetraplegia using the wrist-driven wrist-hand orthosis.

Patients with C8 Tetraplegia

Hand function is significantly improved with the addition of extrinsic finger muscles and thumb flexors. Hand dexterity and strength are limited by the absence of intrinsic finger and thumb muscles. A person with complete C8 tetraplegia grasps objects with the metacarpophalangeal joints in extension and the proximal interphalangeal and distal interphalangeal joints in flexion. This is called a claw hand or intrinsic minus hand (Formal & Smith, 1996).

Surgical Options for the Upper Extremities

Restoring hand function is the top priority of many individuals with tetraplegia (Moberg, 1978, Snoek et al., 2004). To improve hand function, persons with C5, C6, C7, or C8 injuries may have surgical options. These options do not provide for a normal hand but aim to restore pinch, grasp, and reach. Tendon transfer surgeries are recommended only after full spontaneous motor and sensory recovery has occurred and no earlier than a year after injury because most of these procedures permanently alter the musculoskeletal structures (Waters et al., 1996).

Upper limb reconstructive surgeries, although not frequently performed, are available for increasing motion and function of the upper extremities (Bryden et al., 2004). These surgeries may shorten or change the direction of pull of tendons of passive (paralyzed) muscles to provide a mechanical advantage to the thumb or fingers. Other common procedures may entail tendon transfers of functioning

muscles. Typically, a proximal functional muscle with strength of 4/5 or above is attached to a tendon of a distal paralyzed muscle. Following the surgery, the patient learns to contract a proximal muscle to move a distal joint (Waters et al., 1996). An example of a hand tendon transfer surgery is the brachioradialis to flexor pollicis longus. This surgery restores lateral pinch by attaching the tendon of a strong (4/5 muscle or above) brachioradialis to a paralyzed flexor pollicis longus. To pinch an object, the patient flexes the elbow while the forearm is in pronation. To improve the stability of the thumb, the interphalangeal joint is fused.

The pre-operative and post-operative evaluation, education, wound care, and muscle reeducation must be carried out by an experienced therapist. Additionally, consistent communication with the operating physician is vital for favorable outcomes. Overall, patients who have gone through reconstructive surgeries perceive their surgeries positively and as improving their function and appearance (Bryden et al., 2004).

A select number of centers worldwide offer a relatively new and complex procedure for achieving hand function. A hand grasp neuroprosthesis, a permanently implanted electrical stimulation system, allows the person with C5-6 injury to open and close the hand by moving the opposite shoulder. This electrical device is composed of eight electrodes implanted into various muscles; electrode leads; transmitter; and a shoulder sensor. An external controller box on the wheelchair controls the device remotely with no connecting wires. Often the neuroprosthesis surgery is either combined with or follows other hand surgeries that allow for optimal use of the device (Kilgore et al., 1997).

The Patient with Paraplegia

Most people with complete or incomplete paraplegia are independent in self-maintenance, self-enhancement, and self-advancement roles, although they require assistance with heavy housekeeping and physically demanding vocational pursuits (Consortium for Spinal Cord Medicine, 1999). Paraplegics with injuries at T10 and below may attain skills more easily and rapidly than patients with higher injuries. Good trunk control enables a person with low paraplegia to bend down and from side to side without fear of falling forward. Skills performed while upright (e.g., bowel management, lower body dressing, undressing, and bathing) require the patient with a higher injury to secure the trunk by supporting the body with one arm while performing the activity with the other to prevent falls (Zigler et al., 1998).

Typically, patients with paraplegia have fewer medical complications than those with tetraplegia, and self-maintenance skills are learned quickly. Thus, the therapist and patient may shift the focus to self-enhancement and self-advancement roles. Community outings are encouraged as soon as possible to facilitate early integration and participation (Zigler et al., 1998) (Fig. 43-10).

Figure 43-10 A person with paraplegia using a reacher to retrieve hard-to-reach items on a shopping outing.

The Ambulatory Patient: Incomplete Paraplegia and Tetraplegia

Typically when we think of spinal cord injuries, we picture a person using a wheelchair. Yet many individuals with incomplete SCI are able to walk (Fig. 43-11). Data shows that there has been an increase in incomplete injuries in the United States in recent decades (Jackson et al., 2004). This positive trend brings with it some unique challenges to the patient and occupational therapist.

For expedient and relevant treatment planning, the occupational therapist must clearly understand ambulation goals soon after admission. Early discussion with the physical therapist helps clarify goals and enables the occupational therapist to outline a treatment course that takes walking into consideration. Answers to the following questions guide treatment planning:

1. Will upper extremity aids be needed to assist in walking (e.g., a forearm trough walker)? If so, how will the patient carry objects if both hands are occupied?
2. What lower extremity braces are needed? Will the patient require assistance in donning and doffing the braces?
3. Is the goal walking short distances only? Will the patient need a wheelchair for mobility in the community?

Not surprisingly, ambulatory patients with tetraplegia pose the greatest challenge with their often weak upper extremities. In the wheelchair, equipment such as lapboards,

armrests, and mobile arm supports support weak arms and allow for function. When upper limb proximal muscles are weak, hand function becomes difficult or impossible, since the patient lacks a mechanism for bringing the hand to the mouth or face. Various devices are available, which enable the person to both lift and support the arm. A solution for supporting the arm depends on the pattern of upper extremity muscle strength (e.g., a table vs. a chair-mounted mobile arm support). Frequently, however, these devices are less than optimal.

Concomitant Brain Injury and Cognitive Deficits

Much attention is given to the visible paralysis of the injured patient, while less visible traumatic brain injury may be overlooked and unattended to (Zejdlik, 1991). If we think about the velocity of the body at the time of impact in injuries such as motor vehicle accidents and falls, it becomes apparent that head injuries are common. The percentage of patients who suffer concomitant injuries to the brain and spinal cord may be as high as 40–50% (Davidoff, Roth, & Richards, 1992). These injuries may be diffuse or focal and mild or severe (Zejdlik, 1991). Since Chapter 39 is solely devoted to traumatic brain injury, the discussion here is limited to elements that are unique to the dual diagnosis.

The occupational therapist must be vigilant for clues of brain injury in the first encounters with the patient. A period of unconsciousness and post-traumatic amnesia raises a red flag. Therapists should ask patients directly whether they have trouble remembering events or sense any changes in their thinking. Patients may lack insight, however. Often, the family is an excellent source of information as they usually know the pre-morbid cognitive

Figure 43-11 A person with ASIA D incomplete tetraplegia cooking while using an arm trough walker. The 8- to 10-pound Halo vest interferes with balance and limits vision.

status of the patient. The evaluation of the patient is made more challenging with factors such as fatigue, medication side effects, pain, depression, sleep deprivation, and sensory deprivation (Davidoff, Roth, & Richards, 1992). A formal screening can determine whether consultation with a communication specialist is indicated. It is common in many hospitals to request such consultations automatically if the patient had any period of unconsciousness or post-traumatic amnesia.

Cognitive deficits in the SCI population may not be limited to those incurred as a result of the injury. Factors such as previous head injuries, learning disabilities, and a history of alcohol and drug abuse are often present, and they affect the patient's cognitive functioning (Davidoff, Roth, & Richards, 1992). Although the effects of a mild brain injury associated with SCI may diminish over time, the prognosis for recovering from a preexisting cognitive deficit is poor (Davidoff, Roth, & Richards, 1992).

Transitions: Restoring Roles at Home and in the Community

A growing body of literature challenges the old concepts of traditional rehabilitation services in its success at helping smooth the transition from hospital to home. A quicker, more effective transition is essential as acute rehabilitation lengths of stay continue to decrease (NSCISC, 2006). Along with impairment reduction and increased physical independence, the rehabilitation team must engage in moving the person toward a life of managing disability, maintaining general health, preventing complications, and managing social, occupational, and financial environments that are often difficult and complex (Kendall, Ungerer, & Dorsett, 2003; Potter et al., 2004).

As time passes in acute rehabilitation, the health care team and occupational therapists must transition from a protective role to a “launching” role, exposing the person to the real world and promoting autonomy (Nelson, 1990). Key elements in encouraging reintegration include offering patients an increased number of activity choices, having them assess their own confidence in performing a skill, requiring them to prepare for the activity on their own (call in preparation for an outing or search the internet, for example), and when tasks are completed, having patients reflect on their successes and failures.

If therapists conclude that the rehabilitation program is too short for achieving optimal outcomes, they must be prepared to articulate and document the need for longer hospitalization. This is especially true if the short stay may jeopardize the safety of the patient. The therapist may also be called upon to find resources that allow the patient to continue to receive care and engage in occupations following discharge. Often the patient is referred to an outpatient clinic to continue treatment. Most patients continue

to gain strength during the first year after their injury and after their discharge from the acute rehabilitation facility (Waters & Yoshida, 1996). This increase in strength may allow the patient to become more independent. Outpatient programs teach patients to use new movement and offer intensive ADL training. As patients gain strength and endurance and improve their balance, they should be encouraged to reassess and reprioritize their goals. For example, a patient who once could not carry out a bowel program but who later exhibits normal strength in manual muscle testing of the triceps and latissimus dorsi can begin bowel training.

Customized orthoses, such as the wrist-driven wrist-hand orthosis, are commonly given to the patient soon before discharge because production and adjustment of orthoses require much time. Therefore, orthotic training often begins during the last days of hospitalization and continues during outpatient visits to ensure good fit and use. Outpatient evaluation and training in the use of other equipment is beneficial because the patient and family can use these devices at home immediately.

The outpatient occupational therapist should begin and/or continue working on goals and skills that move the patient toward greater community integration (e.g., driving and vocational evaluation and training). The outpatient education of family members and attendants must continue to assure continuity and progress.

With the help of the social worker, liaison nurse, or case manager, the therapist can minimize barriers to receiving therapy after discharge. A frequent barrier is lack of transportation. If patients cannot leave home, an agency such as the Visiting Nurses Association may provide occupational therapy services at home for a limited time.

Other transitional services, such as support groups and transitional living centers, must be identified. Independent living centers are federally funded programs designed to promote reintegration. They are located in most large cities in the United States and provide resources and access to financial, vocational, rehabilitative, and community-based programs (Forchheimer & Tate, 2004).

To further ease clients' transition from hospital to home, models are continuing to emerge and evolve that reflect third-party payers' growing awareness of the benefits of less costly alternatives to hospitalization, preventing complications, enhancing health and quality of life, and supporting the goal of full participation. Examples for such models include:

- Clients living for days to months in a transitional residence with family members and/or attendants. Clients and their families are encouraged to seek health care providers' help only when they cannot solve problems independently. Such residential programs are often housed either at or near the acute rehabilitation center.

- Following discharge, clients receiving the assistance of a federal or state transitional services team, which may include a case manager, an occupational therapist, a physical therapist, a vocational counselor, and others. They may assist in finding accessible housing, implementing home modifications, and finding monetary benefits.

Adaptation: Focus on Facilitation Toward Full Participation

The path from being a dependent patient to becoming a person with a sense of efficacy and self-esteem is long and individual. The occupational therapist must encourage persons with SCI to develop competencies and satisfaction in life roles (Trombly, 1995). Although some laws (e.g., Americans with Disabilities Act) aim to encourage individuals with SCI to participate fully in all societal roles, many barriers continue to hinder full participation. The unemployment rate of individuals with SCI is significantly higher than in the general population, and income is lower (Krause et al., 1999; Mead et al., 2004).

Yerxa and Locker (1990) studied the pattern of engagement in daily occupations and quality of life among people with SCI. They found that people with SCI had much more free time than their nondisabled counterparts. Other studies show that life satisfaction was not related to the level of injury but to social integration, access to the environment, and occupation (Richards et al., 1999; Schonherr et al., 2005). These

studies heighten the importance of looking beyond treating impairments and analyzing the daily activities of each individual, revealing meanings of these activities, and promoting them.

Occupational therapy literature emphasizes the role of the occupational therapist in helping individuals with SCI analyze their daily life, find solutions to simplify daily routines, and engage in experiential creative problem solving in the community (Hammell, 1995). This occupational therapy role has yet to be fully practiced because models for independent living are few, and only a few of these models employ occupational therapists. To fill this role, we must seek work in group homes and governmental agencies and rely less on traditional hospital-based employment. We must also engage in shaping public policy (Baum, 2000; Hammell, 2004).

The World Health Organization’s (WHO) development of *The International Classification of Functioning, Disability and Health* (WHO, 2001) reflects a growing global recognition of the importance of viewing people with disabilities in a more holistic way, as healthy, functional, human beings engaged in social, vocational, and avocational pursuits. This model, therefore, parallels occupational therapy values and beliefs more closely than previous disease-oriented models (Brachtesende, 2005; Hemmingsson & Jonsson, 2005).

As occupational therapists, we have the opportunity and obligation to educate consumers, the public, and policy makers to help enable people with SCI to live a full, meaningful life by facilitating full participation in their desired life roles.

CASE

EXAMPLE

Able: Spinal Cord Injury

Occupational Therapy Process

Patient Information

Able is a 19-year-old man with C6 ASIA A (complete) tetraplegia resulting from an ocean diving accident 3 months ago. Able is a sophomore at a community college. He came to the United States from Samoa to attend college on a football scholarship. Able is single and lives with fellow students

Clinical Reasoning Process

Objectives

Understand the patient’s diagnosis or condition

Examples of Therapist’s Internal Dialogue

“If Able has a functional level of C6 he may be able to achieve independence in many areas. Unfortunately, because he has an ASIA A (complete) injury, his muscle and sensory return will most likely be only in the Zone of Partial Preservation (ZPP).”

in a rented house near campus. He has a large and supportive family in Samoa. After his injury, Able’s mother, aunt, and two of his sisters came to be with him for a month. Able is fluent in English. He was hoping to stay in California and resume his studies. He did not have a discharge destination.

Following his injury, Able was sent to a trauma center, where he underwent posterior fusion surgery to stabilize C4 to C7 vertebrae and was placed in a Philadelphia collar, a rigid collar that limits neck motion. Following surgery, Able was prescribed spine restrictions in order to protect the surgical site. Precautions allowed Able to perform shoulder bilateral/symmetrical activities with minimal resistance (no greater than 3+/5) and unilateral, active only activities with no resistance.

During the post-operative hospital stay, Able was on a rotating bed to prevent pressure sores. The occupational therapist performed daily upper limb range-of-motion exercises. She established a shoulder-positioning program and fitted Able with prefabricated resting hand splints. In conversations with the patient and his family, the therapist began to explain rehabilitation. The occupational therapist documented that the family was engaged and supportive and that the patient appeared passive and quiet. Able was transferred to a rehabilitation center 3 weeks post injury.

Know the person

“Able is passive and quiet and seems quite depressed. Knowing that the best predictor of future behaviors and disposition is pre-morbid personality and behaviors, I am very hopeful that he soon will feel better, as he sees his renewed abilities. It is excellent that he has such a supportive, loving family; however, we will most likely request that they limit their visits somewhat, in order to enable Able to see that he can manage without them, to allow him to become more active in his rehabilitation, and to encourage him to begin directing his own care. Prompt identification of discharge destination and potential caregivers is crucial for goal setting. Therefore, the social worker must address these important issues as soon as possible.”

Reason for Referral to Occupational Therapy

Able was referred to occupational therapy to address limitation in self-maintenance, self-advancement, and self-enhancement roles.

Appreciate the context
Develop provisional hypotheses

“Able’s past accomplishments and tough school/sports schedule required him to be disciplined and structure his time efficiently. I think this will help him in the acute rehabilitation setting, a place that requires hard work. More importantly, his past level of engagement is an indicator that he will be able to continue a life full of participation in meaningful occupations.”

Assessment Process and Results

Occupational profile: Interviews included establishing rapport; in-depth interviews about Able’s typical day, interests, routines, habits and roles; and administering of the *Canadian Occupational Performance Measure*. Initially, because of Able’s withdrawn mood, the therapist secured Able’s permission and interviewed his family about his life and about family goals.

Consider evaluation approach and methods

“Two casual contacts were made, establishing rapport with Able and his family and meeting Able’s immediate needs. These included making Able more comfortable in bed and assessing his ability to press buttons (nurse call light, phone use, bed and TV controls).”

Findings: Able was clear about wanting to stay in California and resume his studies. His family was going to go back to Samoa in a few weeks. He and his family described his busy schedule. Football occupied most of his non-study time. For fun, he “hung out” with his roommates, some of whom where also from Samoa. Information from the social worker indicated no clear discharge destination and no knowledge of who will assist Able with his care.

Physical evaluation: Included measuring both upper extremities (BUE) passive range of motion, tone, sensation (pain, light touch, proprioception and object identification), and *Manual Muscle Test (MMT)*. Observations of reach and hand use included activities such as picking up a coin or a tissue and pushing a button.

Results of MMT:

Scapulae and shoulder muscles: 3+ or above/5 throughout.
 Elbows: 4/5 flexion; 0/5 extension.
 Forearms: 4/5 supination; 2–/5 pronation.
 Wrist: Radial wrist extensors: Right 3+/5; left 3/5; bilateral ulnar wrist extension and flexion 0/5
 Fingers and thumbs: 0/5
 Sensory level: C2-6 dermatomes intact; impaired C7 and absent below (see Fig. 43-2).
 Tone throughout both upper limbs: Within normal limits.
 Hand use: Drags objects to edge of table; picks up objects with the two hands

Summary of upper limb findings: Right hand dominant. Symmetry in strength with right arm slightly stronger than left. Shoulder strength 3+/5 and above. Deficits in reaching away from body and in pronation. Fair tenodesis action bilaterally; beginning effective hand compensatory techniques for picking up and manipulating objects.

Activities of daily living: Able was given a universal cuff in the acute hospital, and he is able to feed himself with a spoon and a fork and to brush his teeth. He needs assistance with set up for these activities (*Functional Independent Measure-5*). He is dependent with all other self-maintenance skills.

“I hope that Able’s roommates and friends will help and support him when his family is no longer here. When he will indicate that he wants his friends around, we will encourage them to visit and be involved in his therapy.”

“Able had a large repertoire of occupations prior to his injury. He has excellent potential for resuming his studies. I need to further explore his engagement with football and, as he gains skills and feels more self-confident and competent, explore with him the range of options of engaging in sports. For example, either being a spectator and/or acquainting him to wheelchair sports.”

Interpret observations

“Initial spinal precautions limit full resistive exercises to neck, scapulae, and shoulders and allow only for minimal resistance, symmetrical exercises. This will be achieved with routine activities such as washing the face. A full strengthening program can be carried out to elbows and wrists. Left wrist will also benefit from neuromuscular electrical stimulation (NMES) to radial wrist extensors.”

“Able is beginning to compensate for his finger paralysis. He has learned to drag objects to edge of table and to hold objects with two hands to compensate for weak grip. Further education and experiential training will help him with other compensatory techniques such as weaving objects through his fingers and using extreme ranges.”

Occupational Therapy Problem List

- Decreased performance skills: Moderate depression, lack of engagement with the rehabilitation team, excessive dependency on family.
- Decreased performance skills: Upper limbs’ weakness, sensory deficit, decreased endurance and control.
- Limitations in all occupational areas including ADL, IADL, education, work, leisure, and social participation.
- Decreased knowledge of spinal cord injury management, resources, and of directing own care.

Synthesize results

“The problem list is overwhelming as Able’s disability is devastating, affecting physical capacities and all his occupational roles. I have to remind myself that tackling this long list will sort itself out daily, as we reassess Able’s engagement in the program, his progress, and his evolving list of priorities.”

Occupational Therapy Goal List

Initially Able had difficulty coming up with goals, as he appeared overwhelmed with his paralysis and was not able to determine what he would be able to physically do. With the help of his therapist, the team, and his family, his short-term goals included feeding, brushing his teeth, shaving, dressing, writing, and using the phone and the computer.

After approximately 5 weeks, with renewed hope, Able expressed interest in resuming his studies.

Toward discharge, goals included visiting a transitional living center, visiting Able’s college, going to his college football game, and becoming independent in self-catheterization.

Develop intervention hypotheses

“Feeding, brushing teeth, and writing and using the computer are skills that will be easy for Able to develop. This will improve his self-confidence and feelings of competence. Able will have a harder time dressing his lower body. The reality of the amount of energy and time it takes to complete this task right now may help Able sort out his priorities as to what an attendant will do for him and what he will do himself.”

Select an intervention approach

“The occupational therapy intervention approach will focus on compensatory or adaptive approach.”

Other goals included:

- Increase upper limb strength and endurance and improve hand function (tenodesis hand).
- Learn routine spinal cord injury (SCI) precautions for skin care, pressure relief, bowel and bladder care, and autonomic nervous system functioning.
- Learn to direct own care.
- Learn SCI resources in the community.
- Choose cushion and wheelchair.

Consider what will occur in therapy, how often, and for how long

“I must remember that the interventions in acute care are only the beginning of a long process of rehabilitation toward participation. In acute rehabilitation Able will be seen for 2 to 3 hours a day, 6 days a week for 8 weeks. As a discharge destination emerges, we will help find the appropriate OT program to continue his care.”

Intervention

First 3 weeks:

- ADL training including feeding, brushing teeth, and grooming using a universal cuff.
- Evaluation for the use of right wrist-driven wrist–hand orthosis with clinic trial equipment. Ordering, checking fit, and training in orthosis use.
- Exploration and training in writing, computer skills, and telephone use.
- Hand use in routine activities, such as compensatory techniques in swiping a card, handling money, and opening pill bottles.
- Individual, short educational sessions focused on specific interventions, such as how to use the hand and how to best maximize hand function.
- Wrist strengthening program through exercises, activities, and NMES.
- Selecting and trying different wheelchairs.

Assess the patient’s comprehension

“Able’s pre-morbid self-discipline and high level of occupational engagement were, indeed, reliable predictors of his ability to engage in therapy despite his depression. In the first few weeks, he talked little, and although not fully engaged, he went along with the program as if “going through the motions” of therapy. As he gained some independence, he became more animated. He enjoyed working with the computer because he realized that going back to school would be possible. It was wonderful to get to know Able as his warm and engaging personality began to emerge when his depression lifted. He began initiating ideas, solved problems easily, and seemed interested in newly introduced equipment. He also became more outgoing and started socializing with other patients. Able’s family needed to return to Samoa 5 weeks into his rehabilitation stay. The shift from family to friends’ support happened naturally as all his acquaintances understood his need for support. This transition also helped facilitate his community reentry and thinking about football and school. Able and his friends began preparing for his attendance at the college football game. Able had to plan by calling and asking for his friends’ assistance before and during the game.

Weeks 4 through 6:

- Spinal precautions were lifted, allowing Able to move his neck and shoulders freely and engage in a full strengthening program. Able was referred to a progressive resistive exercise physical therapy group.
- Training in upper body dressing and beginning of lower body dressing.
- Expanded on student role activities such as using a tape recorder and handling books and papers.
- Education: Individual and group. Group experiential training in topics such as taking public transportation, assertiveness training, and directing care. Individual: Daily self range-of-motion exercises.
- Training in hand use with and without the orthosis through activities with peers (for example, board games).
- At 5 weeks, Able identified a new goal of wanting to attend his team’s football game at his school.
- Ordering of cushion and permanent wheelchair.

“Because Able decided to stay in California with no family around, team meetings involved finding alternatives for further care because all felt that Able would not be ready to live alone post discharge. Able liked the idea of an interim discharge to a transitional living facility. This would enable him to acquire more skills and to attain greater self-efficacy prior to returning to school and to independent living.”

Weeks 7 through 8:

- Able trained in doing intermittent self-catheterization with a wrist-wrist-driven hand–orthosis.
- Able, his friend and the occupational therapist planned and attended the team’s football game.
- Able and his therapist contacted his college, met with the Disabled Student Counselor and toured the college to assess its accessibility.

Understand what he is doing

Compare actual to expected performance

Know the person

Prior to his discharge Able traveled with the social worker and occupational therapist and toured the discharge Transitional Living Center.

Appreciate the context

Next Steps

Post discharge, Able was accepted to a Transitional Living Center (TLC). This facility offered continued rehabilitation services at reduced intensity and cost. Able continued to receive occupational therapy, for the purpose of resuming his studies and for facilitating training of an attendant. After approximately 1 year, Able rented an apartment with a flat mate he met at the TLC and resumed college.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Able wanted to maintain contact with his rehabilitation team. It was wonderful to chat with him over the phone and hear about his progress. He missed his family but had close supportive friends. Despite his severe disability, Able resumed a meaningful life, fully participating in social and vocational pursuits.”

“I hope that he will continue to be vigilant with his preventative care, taking meticulous care of his skin, bladder, and bowel in order to maintain his good health.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE 43-1

Effects of Depression and Lack of Involvement on Rehabilitation

In interviews and observations in acute care and acute rehabilitation, Able's therapists noted that the patient appeared depressed and uninvolved in his care. What could the therapist do to facilitate greater involvement and participation by the patient? What bodily and environmental factors might exaggerate these problems? What bodily and environmental factors might improve these problems?

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE 43-2

Bladder Management for a Person with C6 Tetraplegia

Near the time of his discharge from the rehabilitation center, Able expressed interest in taking care of his bladder. Will he be able to carry it out independently? What steps will you take in training him in his bladder care?

Evidence Table 43-1 Best Evidence for Interventions Used in Occupational Therapy after Spinal Cord Injury

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Intervention to improve upper extremity strength and tenodesis grasp	Comparison of 4 treatment groups: conventional, electrical stimulation, biofeedback, and combined electrical stimulation and biofeedback.	Persons with tetraplegia who were receiving inpatient rehabilitation services.	Intervention 1 time per day, 5 days per week for 5–6 weeks.	IC3a (random assignment; small treatment groups [10–13 per group]; attrition; no controls who did not receive treatment)	No treatment group was superior to the others. Analysis of data pooled from all groups shows statistically significant pre–post treatment differences.	N/A	Kohlmeyer et al., 1996
Self-care skills training	Occupational therapy and physical therapy provided during inpatient rehabilitation.	Persons with tetraplegia from traumatic or non-traumatic spinal cord injury who were receiving inpatient rehabilitation (55 individuals at admission; 45 at discharge).	Not specified.	IIIB3c (1 group, pre–post only, attrition of subjects)	Yes. Statistically significant improvement in self-care and motor skills (based on <i>Functional Independence Measure</i> scores).	Paired t score = 10.3; $p < 0.0005$; $r = 0.84$.	Lysack et al., 2001

Appendix 43-1 Expected Functional Outcomes*

USING EXPECTED FUNCTIONAL OUTCOMES CHARTS

Outcome-based practice guidelines can provide estimates of the effect of rehabilitation on functional status or activity restrictions. In the Expected Functional Outcomes charts that follow, the Consortium for Spinal Cord Medicine has put forth its best description, based on outcome studies and expert consensus, of outcomes of people with motor complete spinal cord injury (SCI) 1 year after injury. These outcome guidelines are presented with the full recognition that outcomes are not fully under the influence or control of health care providers. Differences in patient characteristics; the course of medical events; psychological, social, and environmental supports; and cognitive abilities have strong influences on outcomes.

These outcome-based guidelines can be used to establish goals, provide information for quality improvement, and compare performance across facilities with similar populations. When used appropriately, outcome-based practice guidelines provide a benchmark for comparing programs and services while improving both the processes and outcomes of care that have an enduring impact on long-term functioning in the community. Disability outcome measures are generally focused on the degree to which a person can independently complete an important function or activity of daily living (ADL). This definition of disability is consistent with the World Health Organization (WHO) model of disablement in which disability is measured at the level of the person interacting with the environment during daily routines. In the completion of daily tasks, adaptive equipment becomes a crucial adjunct to the independence of the person with SCI.

The following charts present expectations of functional performance of SCI at 1 year post injury for each of eight levels of injury (C1-3, C4, C5, C6, C7-8, T1-9, T10-L1, and L2-S5). The outcomes reflect a level of independence that can be expected of a person with motor complete SCI, given optimal circumstances.

The categories presented reflect expected functional outcomes in the areas of mobility, activities of daily living, instrumental activities of daily living, and communication skills. The guidelines are based on consensus of clinical experts, available literature on functional outcomes, and data compiled from the Uniform Data

System (UDS) and the National Spinal Cord Injury Statistical Center (NSCISC). Within the functional outcomes for people with SCI listed in the tables that follow, the panel has identified a series of essential daily functions and activities, expected levels of functioning, and the equipment and attendant care likely to be needed to support the predicted level of independence at 1 year post injury. These outcome areas include:

- **Respiratory, bowel, and bladder function.** The neurological effects of spinal injury may result in deficits in the ability of the individual to perform basic bodily functions. Respiratory function includes ability to breathe with or without mechanical assistance and to adequately clear secretions. Bowel and bladder function includes the ability to manage elimination, maintain perineal hygiene, and adjust clothing before and after elimination. Adapted or facilitated methods of managing these bodily functions may be required to attain expected functional outcomes.
- **Bed mobility, bed/wheelchair transfers, wheelchair propulsion, and positioning/pressure relief.** The neurological effects of SCI may result in deficits in the ability of the individual to perform the activities required for mobility, locomotion, and safety. Adapted or facilitated methods of managing these activities may be required to attain expected functional outcomes.
- **Standing and ambulation.** Spinal cord injury may result in deficits in the ability to stand for exercise or psychological benefit or to ambulate for functional activities. Adapted or facilitated methods of management may be required to attain expected functional outcomes in standing and ambulation.
- **Eating, grooming, dressing, and bathing.** The neurological effects of SCI may result in deficits in the ability of the individual to perform these activities of daily living. Adapted or facilitated methods of managing these activities of daily living may be required to attain expected functional outcomes.
- **Communication (keyboard use, handwriting, and telephone use).** The neurological effects of SCI may result in deficits in the ability of the individual to communicate. Adapted or facilitated methods of communication may be required to attain expected functional outcomes.
- **Transportation (driving, attendant-operated vehicle, and public transportation).** Transportation activities are critical for individuals with SCI to become maximally independent in the community.

* Reprinted with permission from the Paralyzed Veterans of America (PVA). Consortium for Spinal Cord Medicine (1999). *Outcome following traumatic spinal cord injury: Clinical practice guidelines for health care professionals*. Washington, DC: Paralyzed Veterans of America.

Adaptations may be required to facilitate the individual in meeting the expected functional outcomes.

- **Homemaking (meal planning and preparation and home management).** Adapted or facilitated methods of managing homemaking skills may be required to attain expected functional outcomes. Individuals with complete SCI at any level will require some level of assistance with homemaking activities. The hours of assistance with homemaking activities are presented in the tables.
- **Assistance required.** The Expected Functional Outcomes charts include the number of hours that may be required from a caregiver to assist with personal care and homemaking activities in the house. Personal care includes hands-on delivery of all aspects of self-care and mobility, as well as safety interventions. Homemaking assistance is also included in the recommendation for hours of assistance and includes activities previously presented. The number of hours presented in both the panel recommendations and the self-reported *Craig Handicap Assessment and Reporting Technique (CHART)* (Whiteneck et al., 1992) data is representative of skilled and unskilled and paid and unpaid hours of assistance. The 24-hour-a-day requirement noted for the C1-3 and C4 levels includes the expected need for unpaid attendant care to provide safety monitoring.

Adequate assistance is required to ensure that the individual with SCI can achieve the outcomes set forth in the Expected Functional Outcomes charts. The hours of assistance recommended by the panel do not reflect changes in assistance required over time as reported by long-term survivors of SCI (Gerhart et al., 1993), and they also do not take into account the wide range of individual variables mentioned throughout this document that may affect the number of hours assistance is required. The *Functional Independence Measure (FIM)* estimates are widely variable in several categories. One does not know whether the representative individuals with SCI in the individual categories attained the expected functional outcomes for their specific level of injury or whether there were mitigating circumstances such as age, obesity, or concomitant injuries that would account for variability in assistance reported. An individualized assessment of needs is required in all cases.

- **Equipment requirements.** Minimum recommendations for durable medical equipment and adaptive devices are identified in each of the functional categories. Most commonly used equipment is listed, with the understanding that variations exist among SCI rehabilitation programs and that use of such equipment may be necessary to achieve the

identified functional outcomes. Additional equipment and devices that are not critical for the majority of individuals at a specific level of injury may be required for some individuals. The equipment descriptions are generic to provide for variances in program philosophy and financial resources. Rapid changes and advances in equipment and technology will be made and therefore must be considered.

Health care professionals should keep in mind that the recommendations set forth in Appendix 43-1 are not intended to be prescriptive, but rather to serve as a guideline. The importance of individual functional assessment of people with SCI prior to making equipment recommendations cannot be overemphasized. All durable medical equipment and adaptive devices must be thoroughly assessed and tested to determine medical necessity to prevent medical complications (e.g., postural deviations, skin breakdown, or pain) and to foster optimal functional performance. Environmental control units and telephone modifications may be needed for safety and maximal independence, and each person must be individually evaluated for the need for this equipment. Disposable medical product recommendations are not included in this document.

- **FIM.** Evidence for the specific levels of independence provided in Appendix 43-1 relies both on expert consensus and data from the *FIM* in large-scale, prospective, and longitudinal research conducted by NSCISC. *FIM* is the most widely used disability measure in rehabilitation medicine, although it may not incorporate all of the characteristics of disability in individuals recovering from SCI, it captures many basic disability areas. *FIM* consists of 13 motor and 5 cognitive items that are individually scored from 1 to 7. A score of 1 indicates complete dependence, and a score of 7 indicates complete independence. The sum of the 13 *FIM* motor score items can range from 13, indicating complete dependence for all items, to 91, indicating complete independence for all items. *FIM* is a measure usually completed by health care professionals. Different observers, including the patient, family members, and caregivers, can contribute information to the ratings. Each of these reporters may represent a different type of potential bias. It should also be noted that, although the sample sizes of *FIM* data for certain neurological level groups are quite small, the consistency of the data adds confidence to the interpretation. Other pertinent data regarding functional independence must be factored into outcome analyses, including medical information, patient factors, social participation, quality of life, and environmental factors and supports. In Appendix 43-1, *FIM* data, when available, are reported in three areas. First, the expected *FIM* outcomes are docu-

mented based on expert clinical consensus. The second number reported is the median *FIM* score, as compiled by NSCISC. The interquartile range for NSCISC *FIM* data is the third set of numbers. In total, the *FIM* data represent 1-year post-injury *FIM* assessment of 405 survivors with complete SCI. Sample size for *FIM* and Assistance Data is provided for each level of injury. Different outcome expectations should clearly apply to different patient subgroups and populations. Some populations are likely to be significantly older than the referenced one. Functional

abilities may be limited by advancing age (Penrod, Hedge, & Ditunno, 1990; Yarkony et al., 1988).

- **Home modifications.** To provide the best opportunity for individuals with SCI to achieve the identified functional outcomes, a safe and architecturally accessible environment is necessary. An accessible environment must take into consideration, but not be limited to, entrance and egress, mobility in the home, and adequate setup to perform personal care and homemaking tasks.

Appendix 43-1. Expected Functional Outcomes Level C1-3

Functionally relevant muscles innervated: Sternocleidomastoid; cervical paraspinal; neck accessories

Movement possible: Neck flexion, extension, rotation

Patterns of weakness: Total paralysis of trunk, upper extremities, lower extremities; dependent on ventilator

SUMMARY REVIEW QUESTIONS

1. List three key epidemiological factors of the SCI population and describe how these factors influence evaluation and treatment.
2. List three precautions the therapist must consider in planning for an outing with a patient with C5 injury.
3. What is a tenodesis grasp? Why is it important, and how can the occupational therapist facilitate it?
4. List five parts of the initial occupational therapy evaluation of a patient with SCI.
5. Describe a typical feeding setup for person with C5 tetraplegia.
6. What are the functional expectations for the patient with a C7 injury?
7. You read in the medical chart that a patient lost consciousness at the time of injury. How do you modify your evaluation? Describe how concomitant brain injury may alter your treatment goals and interventions.
8. What are the roles of the occupational therapist in the transition phase?

ACKNOWLEDGMENT

I thank the patients and staff at Rancho Los Amigos National Rehabilitation Center, who have inspired and taught me so much over the years. I also thank my husband, Richard Atkins, for his assistance in editing this chapter. Last, I thank the photographer, the late Paul Weinreich.

CHAPTER 44

Rheumatoid Arthritis, Osteoarthritis, and Fibromyalgia

Y. Lynn Yasuda

CHAPTER OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe key features of rheumatoid arthritis, osteoarthritis, and fibromyalgia.
2. Identify clinical sequelae that interfere with meeting occupational functioning goals.
3. Select assessments to optimize occupational functioning for patients with rheumatoid arthritis, osteoarthritis, and fibromyalgia.
4. Describe interventions to enable patients to meet their occupational functioning goals.
5. Identify preventive interventions to enable prolonged continuance of desired occupational goals.

Glossary

Allodynia—Pain in response to a normally non-painful stimulus.

Crepitus—Grating, crunching, or cracking sound or sensation during joint or tendon motion.

Daily activity log—Recording of experiences or impressions by patients as they occur.

Energy conservation—Breaking up physically active periods with rest periods, resulting in increased amount of physical activity (Cordery & Rocchi, 1998).

Hyperalgesia—Increased response to painful stimuli.

Joint protection—Methods to reduce external stress applied to impaired joints.

Lag—Difference of active ROM subtracted from passive ROM, measured in degrees.

Morning stiffness—Subjective complaint of local or general lack of easy mobility of the joints upon arising. This is a non-specific indication of inflammation in RA; duration is directly proportional to the severity of the inflammatory process. Complaints vary from none to many hours. Patients with OA may also complain of morning stiffness, but it tends to be milder and brief.

Rheumatoid nodules—Firm, usually painless lumps of variable size found in patients with RA. They can be found over areas that are subject to mechanical trauma (e.g., elbows, heels, and hands) and on finger flexor and extensor tendons.

Although more than 100 rheumatic diseases have been identified, this chapter focuses on rheumatoid arthritis (RA) and osteoarthritis (OA) because they are the most common rheumatic diseases encountered in an occupational therapy clinic. Both can be disabling, and both require intervention to allow optimal occupational functioning. Other rheumatic diseases may have some symptoms similar to RA or OA, and the principles used to manage these two diseases can be used when encountering others. Each rheumatic disease has unique manifestations, however, and occupational therapists must address these as well. This chapter also briefly discusses fibromyalgia (FM). FM is a complex syndrome that commonly has multidimensional physical and psychological characteristics. The best treatment results appear to occur when a multidisciplinary approach is used to manage the various features of the condition (Goldenberg, Burckhardt, & Crofford, 2004).

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a systemic, inflammatory disease that affects joints and can affect the major organs of the body, including eye, skin, lungs, heart, gastrointestinal system, kidneys, nervous system, or blood. Common symptoms are symmetric polyarticular pain and swelling during the inflammatory stage, **morning stiffness** (usu-

ally lasting more than 2 hours), malaise, and fatigue. Remissions and exacerbations are common with the course of disease, ranging from self-limiting disease to severe chronic disease. Estimates of prevalence range from 0.3–1% of the adult population, with RA occurring 2.5 times more often in women and commonly being seen in women aged 40 to 50 years (Gornisiewicz & Moreland, 2001; Goronzy & Weyand, 2001).

The etiology of RA remains unknown and is likely multifactorial, including genetic factors and exposure to unknown environmental factors. The joints most often involved are the wrists, PIP, MCP, elbows, metatarsophalangeal, and temporomandibular joints, although other joints can be involved as well (Gornisiewicz & Moreland, 2001).

OSTEOARTHRITIS

Osteoarthritis (OA), the etiology of which is still unknown, is currently thought to be a group of disorders in which biomedical, biochemical, and genetic factors play a role (Lozada & Altman, 2001). Commonly, a gradual loss of articular cartilage can be seen, combined with thickening of the subchondral bone, bony outgrowths at joint margins, and mild, chronic nonspecific synovial inflammation (Hochberg, 2001). Excessive biomechanical loading, which may occur after trauma to a joint or to normal cartilage or bone or both, can lead to cartilage loss. Repetitive impact

loading to specific joints, such as seen in selected vocations and avocations, can lead to joint problems. Joints most commonly involved are the knees, hips, interphalangeal joints, the first CMC joint, and the spine, although other joints can be involved. Common symptoms are joint tenderness, sometimes accompanied by crepitus, limitation of movement, pain after use that is relieved by rest, and progression of pain at rest and at night. Morning stiffness in the involved joint generally lasts less than 30 minutes (Lozada & Altman, 2001). One third of people aged 65 years and older have knee OA. Before the age of 50, men are more likely than women to have OA, but after age 50, OA is more prevalent in women. Diagnosis is based on the history, physical examination, and radiographic features of joint space narrowing, sclerosis of bone, marginal osteophytes, and bony remodeling (Hochberg, 2001).

Assessment (RA and OA)

In response to a request for services, the occupational therapist reviews the chart, observes and interviews the patient concerning occupational functioning, and may use screening tests to determine whether referral for occupational therapy is indicated. A patient who risks decline in occupational functioning because of pain, fatigue, loss of strength, endurance, or joint range of motion (ROM); change in environment, including social support; or loss of coping skills or whose function may be improved can benefit from occupational therapy (Backman, 1998; Feinberg & Trombly, 1995).

Assessment begins with obtaining an occupational profile through interviewing to find out the occupational history of the client's typical day. This occupational history interview can yield information in several areas. For example, it can give information about the balance of rest and activity, the meaning and importance of various occupations, the environmental and social supports and/or barriers to performance, and the effect of client factors on performance, adjustment to disability, and a sense of self-efficacy. It also allows the therapist to learn the patient's perspective on occupational functioning in relation to the severity of the physical impairment.

From the occupational profile, the occupational therapist obtains information about the patient's important occupations and beginning information about impairment and context issues that affect the performance of these occupations. This will facilitate occupation goal setting by the patient through an instrument such as the *Canadian Occupational Performance Measure (COPM)* to determine areas of occupational functioning that are important to the person and that are at risk or are compromised (Backman, 1998; Law et al., 1994). As initial patient-identified goals are recognized, all subsequent aspects of as-

essment are related to finding out whether more detailed occupational functioning deficits or impairment issues exist. Occupational functioning and performance context assessments may include specific ADL evaluations and environmental analyses, including social support and architectural issues, to determine the influence of the environment on the patient's ability to function (Backman, 1998). Common assessments of impairments of abilities and capacities may include but are not limited to ROM evaluation, strength testing, and evaluation of hand deformities, pain, fatigue, and psychosocial status. Sensory evaluation should be done if systemic involvement has led the patient to make complaints that indicate polyneuropathies or nerve compression.

Psychosocial Factors to Consider before Goal Setting

To identify the patient's goals, the therapist must recognize the patient's response to the impairment issues that the disease has imposed. This helps establish the treatment plan. For example, a person who recognizes that the diagnosis is accurate and who understands and accepts the consequences of the disease process may design goals that can be met immediately, such as finding appropriate adapted equipment to continue working. Another person may not accept the diagnosis and, therefore, deny that any issues are present, believe that normalcy will soon return, and feel that dependency on others is appropriate.

If patients are situationally depressed or angry at having the condition, the therapist may be entreated to try harder to reduce the impairment, or the patient may look for questionable alternative interventions. Clear and attainable objectives established with the patient at this time may be significant in helping the patient to continue to engage in meaningful occupations. Meeting treatment objectives successfully, even in small increments, is important with these patients.

Dubouloz et al. (2004) were concerned that patients with RA have difficulty using the help-seeking strategies recommended in occupational therapy, such as using social support or pacing, which often carry associated meaning perspectives (i.e., personal beliefs, values, feelings, and knowledge) that have been identified as barriers to change. It has been suggested that these barriers can be overcome through a process of transformation of meaning perspectives. Following their study to determine meaning perspectives of women with RA, they concluded that clinicians could encourage patient self-reflection during interventions to guide the discovery of meaning perspectives and meaning perspective transformation of importance to individual clients. For example, if the therapist asks what does the illness mean to her/him and the patient responds, "This illness has made me give up almost all of my social relations," then this illness meaning per-

spective provides a beginning understanding of what impact the illness has had on occupational balance. This type of discussion could eventually lead to a transformative meaning perspective, in which the patient integrates the occupational therapy intervention (for example, “this illness has led me to pace my activities, so I can once again have lunch with friends, although not as frequently”) as a result of a new recognition of a desired change in occupational balance. Dubouloz et al. (2004) suggested that further research is needed in this area to develop a model for therapists (and others) to take appropriate action.

The therapist should work with the patient to examine all activities and to determine which are most important to the individual. The patient is encouraged to decide which activities can be eliminated or performed differently. The skill of the therapist in helping patients recognize the value of assistive devices or alternative ways of performance is often needed to enable lifestyle redesign because some devices or alternative ways of performance connote a sense of disability that is not congruent with the person’s body image. Crutches, canes, and hand splints are prime examples. People, even some health care professionals, find it difficult to use these devices because they denote a negative body image despite their advantages of prolonging walking and functional hand use. Alternatives, which may include change of vocation, also may require significant counseling to enable the patient to recognize the advantages to the change. For example, if the patient’s job requires much stooping and lifting and no alternatives are available for this at work, vocational counseling to examine other job opportunities that do not stress involved joints may be indicated.

Personal Care and Instrumental ADLs

Survival skills to live independently in the community include personal care skills and instrumental activities of daily living (IADLs) skills. Patients may not always identify these skills as their most important occupational performance goals because they presume that someone will be there to do these tasks for them. It is not always possible to obtain assistance, however, and it may, in fact, be inconvenient to find help. Therefore, many patients can be helped to choose accomplishment of these tasks as part of their goals. Backman (1998) described ADL and IADL instruments for occupational therapists working with patients who have rheumatic disease. Observation of skills is important to assess how the person accomplishes tasks. Are joint protection methods used? Is the person aggravating impaired joints while doing these tasks? Are **energy conservation** techniques used? Is adapted equipment used? It is important to ask the person how often these tasks are performed and when assistance is sought. Although the patient may answer questions about per-

sonal care in an idealized manner during an interview, it is up to the therapist to aim for accuracy in obtaining the information. For example, consider the following scenario:

“Do you dress yourself?” “Yes.”

“Did you dress yourself this morning before arriving to the clinic?” “No, because we were in a hurry to get here.”

“Did you dress yourself yesterday?” “No, because it was late and we had to get to church on time.”

“Did you dress yourself in the past week?” “Yes.”

“How many days last week did you dress yourself?”
“Possibly only once or twice because I had a lot of morning stiffness and it was painful. Besides, my daughter was home to help me.”

The reader can see how pursuit of the question is important to identify problems that may need further attention.

With patients who are admitted to the hospital, all morning personal care may be observed. The therapist, however, may first encounter a patient as an outpatient. In this case, observation of all personal care activities may not be practical.

The use of a self-administered questionnaire saves time in a comprehensive evaluation. The self-administered *Evaluation of Daily Activity Questionnaire* (Nordenskiöld, Grimby, & Dahlin-Ivanoff, 1998) has been tested with women with RA in Sweden. This 102-item checklist asks the respondent to indicate degree of difficulty of various tasks. The therapist can use a scoring procedure to note changes as function improves with the use of assistive devices.

For patients who work, a number of interviews and observational tools exist that are not specific to arthritis (Backman, 1998). These instruments can be used, but the evaluator must pay special attention to joint and systemic problems unique to these diseases as this assessment is done. The person may be able to do tasks, but repetition and effort during a test may not pose the problems that are seen when translated to an 8-hour workday. Another method to look at IADL skills when evaluation time is limited is to simulate key areas that may be problematic. For example, if patients say they cannot reach and place items in cupboards above the counters in the kitchen, having the person lift an item of similar weight to a cupboard in the occupational therapy clinic may provide clues as to whether the problem lies in grip strength, shoulder ROM, pain, or weakness.

An area of ADL that is sometimes overlooked is sexual expression. This area can be problematic for the person with arthritis because of pain, discomfort, fatigue, limited ROM, and other physical limiting factors. It can be awkward for patients to bring up this topic as part of ADL. The therapist must be sensitive to patients’ cultural background in pursuing this aspect of ADL, but this topic should be brought up to allow the patient to discuss problems in this area (Majerovitz & Revenson, 1994). If the

sexual expression problems are related to psychological areas unrelated to the disease, a referral to a psychologist may be indicated. In interviewing patients for problems with sexual expression, the approach is similar to that for other aspects of ADL: ask whether the problem is inability to perform activities, impairment of an ability area, or due to contextual or environmental factors. Depending on which factors are problems, provide intervention appropriately.

Range of Motion

Observation and measurement of upper extremity active ROM from an upright position gives the examiner useful information about functional ROM that the patient has for use in occupational functioning (see Chapter 5). Pain is often a reason for limited active ROM in arthritis, but limited ROM also can be from weakness, contractures, or joint derangement. Radiographs that show osteophytes, erosions, joint narrowing, and other skeletal problems rule out strengthening for the purpose of increasing active ROM. It is important to limit measurement to those areas of concern.

Strength

Testing of muscle groups or motion in areas of involvement with the patient in an upright posture provides information about function (see Chapter 5). For example, the patient who actively flexes the shoulder to 60° and takes moderate resistance without pain is likely to be able to lift a light plate to place it on a low shelf above the counter. Testing resistance to joint motions also enables the examiner to record whether pain limits the amount of resistance taken by the joint. It is important to use principles of joint protection in applying resistance to joints at the end of active ROM, to observe the patient's face for an indication of pain, and to stop immediately. Otherwise, the patient may have more pain than usual after leaving the testing session.

Strength in the hand can be measured with grasp meters and pinch meters (see Chapter 5). The Jamar dynamometer is a common instrument that is used to measure grasp. Although the metal of the dynamometer is bothersome to some patients because of deformities and pain, it is still useful, as most objects used in everyday life are inflexible. If, however, a patient has grasp strength less than 5 pounds, the Jamar dynamometer does not provide accurate measures of differences in strength as a result of intervention. In this case, other tools, such as an adapted sphygmomanometer (Melvin, 1998) or the *Grippit* (Nordenskiöld & Grimby, 1993) show small increments of change brought about by intervention. Standard pinch meters can be used with patients, although the standard method of measurement, advocated by Mathiowetz et al. (1985), cannot always be used with patients with RA

because of significant thumb and finger deformities and, therefore, the norms would not apply. Even though the norms cannot be used for comparison, it can be useful to describe how the pinch was achieved, for example, “the thumb pad is pressed against the index finger proximal phalanx, secondary to limited thumb abduction.” Although this may be accompanied by ulnar deviation by the second MCP, this is useful for actively holding a small object. These compensatory mechanisms used by patients with severe deformity must be thoroughly evaluated, especially when surgery to improve hand function is considered. Some patients with severe RA have pinch strength greater than the available gross grasp strength.

Hand Assessment

Among the various hand assessments, Backman and Mackie (1995) and van Lankveld, Graff, and van't Pad Bosch (1999) developed instruments specifically for this population. Others that were not designed for this population can be useful for some purposes (Backman, 1998). Standardized hand assessments are useful as a baseline measure if an intervention is intended to show change in hand function or to assist in decision making for elective hand surgeries.

Endurance

In arthritis, especially RA, the ability to sustain functional motion can be limited by fatigue, weakness, or pain. Self-assessment measures of ability to sustain functional performance are useful for determining how fatigue interferes with meaningful occupations. If the patient has to rest all day because the previous day's activity caused fatigue or increased pain, activities of a prolonged, sustained nature must be curtailed to enable participation in occupations of highest choice. This is discussed further under fatigue management.

Pain

Pain can be evaluated during joint examination and/or during performance of occupations. At times, specific knowledge of pain location, severity, and time of day is useful, especially if intervention is to alter any of the parameters of pain. The *Visual Analog Scale* for pain has been found to be a simple and reliable tool to measure pain (Huskisson, 1974) (see Chapter 5).

Hand and Wrist Deformities

It is useful to record hand and wrist deformities to determine the best course of action for intervention to allow occupational performance. For each joint of the wrist and hand, the following problems should be palpated and recorded: (1) swelling, heat, and/or redness (cardinal signs of inflammation); (2) pain; (3) subluxation or dislocation;

(4) **crepitus**; (5) tendon rupture; and (6) **rheumatoid nodules**.

In OA, common hand deformities include spurs at the dorsolateral and medial margins of the DIP joints of the fingers, which generally develop slowly and are called Heberden's nodes. Heberden's nodes can cause volar and lateral deviation of the distal phalanx. Heberden's nodes are 10 times as prevalent in women as in men. A similar enlargement at the PIP joints of the fingers is called Bouchard's nodes. When the first CMC joint is involved, tenderness and pain at the base of the metacarpal and a squared appearance of the hand are present, which is evidence of subluxation at this joint (Brandt & Slemenda, 1993). Precision and power pinches are most at risk when the first CMC is significantly involved. In a review of 99 patients with hand OA, more than half had functional loss. Nearly half of the 99 had a concomitant history of OA of the knee (Altman et al., 1990). McFarlane et al. (1990) found, in following 32 patients with hand osteoarthritis from entry to a year later, that osteophytes, particularly when fast growing, produced pain. The slower the change in size, the less likely it is that the joint was seriously compromised.

The deformities that can be found in RA are complex. The following description of common deformities and how they develop will enable the therapist to apply appropriate interventions, such as hand splints, joint protection techniques, and/or patient education programs that dispel myths and increase the patient's understanding of causation of deformity.

Deformities of the Wrist

It is estimated that 95% of persons with persistent RA develop bilateral wrist joint involvement (Wilson, 1986). Three pathological processes that can produce deformity are cartilage degradation often seen early in RA, synovitis with erosion, and ligamentous laxity. Cartilage degradation may cause bony erosion and may lead to ruptured tendons, especially the extensor tendons of the ulnar fingers or the flexor pollicis longus (Shapiro, 1996). Even without erosion, synovial expansion can lead to volar subluxation of the proximal carpal row, which has been noted in 80% of RA wrists. The new positioning of all of the carpals can elicit pain. If intercarpal pressure increases during gripping motions, pain increases concomitantly, leading to a desire to reduce grip strength to reduce pain (Shapiro, 1996). Both cartilage loss and synovitis can lead to lax ligaments and further carpal derangement with wrist instability, which can lead to a radial shift of the carpus on the radius (Taliensnik, 1989). Even if the synovial destruction stops prior to significant deformity, fibrous ankylosis of some wrist joint surfaces may occur. Synovial erosion that proliferates and causes massive joint destruction, including any combination of tendon ruptures and joint derangement, can produce a floppy wrist (Shapiro, 1996).

Deformities of the Metacarpophalangeal Joints

Although ulnar drift of the MCP joints is uncommon in the early stages of RA, Wilson (1986) reports that 45% of patients whose disease has persisted longer than 5 years demonstrate this deformity. Ulnar drift is a combination of deviation of the phalanx from the metacarpal head and a lateral shift of the phalanx upon the metacarpal (Wilson, 1986) (Fig. 44-1). Wilson suggests that the following are contributors to this deformity:

1. Synovitis within the MCP joint stretching the radial collateral ligaments, which are weaker than their ulnar counterparts.
2. When the synovitis subsides, the extensor tendons migrate ulnarly, eventually ending up in the valleys between the metacarpal heads.
3. As the fingers flex, the flexors pull the digits ulnarly unopposed by the weakened radial collateral ligaments.
4. Contractures of the intrinsic muscles caused by a reflex protective muscle spasm secondary to the synovitis contribute MCP volar subluxation. This disrupts the balance of the volar plate, sagittal bands, transverse metacarpal ligament, and collateral ligament.
5. When wrist synovitis causes radial deviation of the wrist, the dynamics of the finger flexor tendons change as they cross the MCP, providing an ulnar force.

Figure 44-1 MCP ulnar deviation and subluxation. (Reprinted from the ARHP Arthritis Teaching Slide Collection. Used with permission of the American College of Rheumatology.)

6. MCP joint cartilage loss and bony erosion lead to volar subluxation, pulling the finger flexors ulnarly during flexion.
7. Flexor tenosynovitis can also lead to volar subluxation of the MCP joint.

The MCP collateral ligaments normally tighten on MCP flexion. Thus, abnormal laxity of the radial collateral ligament at the MCP joint can be evaluated by placing each of the patient's MCP joints in full passive flexion. Each digit is then pushed toward the ulna. In a normal hand, the digit has little or no movement laterally. If the radial collateral ligament is stretched, the finger can be easily displaced ulnarly.

When and if the MCP joints become fixed in flexion because of disease, the midpalmar crease may become moist and macerated from lack of exposure to air. This can be accompanied by a foul odor as it becomes difficult for the person to clean the hand; therefore, patient, therapist, and physician must be attentive in preventing this deformity.

Deformities of the Interphalangeal Joints

Swan-neck and boutonniere deformities are the most common finger deformities (Rizio & Belsky, 1996) (Figs. 44-2 and 44-3). Prolonged synovitis of the PIP joint can spread proximally under the central extensor slip, which becomes attenuated, and between the extensor and intrinsic tendons. When the central slip and lateral bands stretch, they migrate volarly, and a boutonniere deformity is produced (Rizio & Belsky, 1996; Wilson 1986). Nalebuff (1984) has described three stages of the boutonniere deformity. Stage I exhibits only a slight extensor lag, and a slight loss of DIP flexion occurs. A 40° PIP flexion deformity is considered stage II. In stage III, the PIP joint has a fixed flexion deformity.

Figure 44-2 Swan-neck deformity: PIP hyperextension with DIP flexion. (Reprinted from the ARHP Arthritis Teaching Slide Collection. Used with permission of the American College of Rheumatology.)

Figure 44-3 Boutonniere deformity: PIP flexion with DIP hyperextension. (Reprinted with permission from Feinberg, J. R. [1992]. Effect of the arthritis health professional on compliance with use of resting hand splints by patients with rheumatoid arthritis. *Arthritis Care and Research*, 5, 17–23.)

If the initiating PIP synovitis is anterolateral, it can stretch the transverse retinacular ligament, allowing the lateral band to migrate dorsally, resulting in a PIP joint hyperextension, or swan-neck deformity. Lateral bands in this position prevent the normal volar and lateral shift that allows PIP flexion. With progression of the synovitis, joint erosion and, finally, destruction occur with fibrous articular adhesions or bony ankylosis (Wilson, 1986). The swan-neck deformity can also be caused by the destructive effect of the synovitis beginning at any one of the three digital joints (Rizio & Belsky, 1996). The disturbance in function in patients with a swan-neck deformity is directly caused by the loss of flexibility of the PIP joint (Rizio & Belsky, 1996). Four types of swan-neck deformities have been described (Wilson, 1986). Type I deformity is characterized by full flexibility of the PIP joint. Patients complain of transient locking and trouble initiating PIP flexion. Type II deformity exhibits a flexible PIP when the MCP is flexed, but when the MCP is extended, there is limited PIP flexion. When there is significant loss of PIP motion, the deformity is designated type III. In type IV, there is intra-articular destruction and limited motion.

Deformities of the Thumb

Nalebuff's (1984) description of four types of common thumb deformities provides a shorthand for complex problems. Type I, or boutonniere deformity, is the most common and is characterized by MCP joint flexion and IP joint hyperextension (Fig. 44-4). This usually occurs when synovitis of the MCP joint stretches the extensor mechanism, including the dorsal capsule, extensor pollicis brevis tendon, and extensor hood. This results in MP flexion; volar subluxation of that joint may occur also. The stretching of the extensor pollicis brevis tendon allows it to displace ulnarly and volarly. Type II begins at the carpometacarpal (CMC) joint and results in MCP flexion and

Figure 44-4 Nalebuff type I thumb deformity. (Reprinted from the ARHP Arthritis Teaching Slide Collection. Used with permission of the American College of Rheumatology.)

adduction and IP hyperextension. This type is not common. Type III, or swan-neck deformity, is common; it is characterized by MCP joint hyperextension and adduction and IP joint flexion. The origin of this deformity is synovitis at the CMC joint (Stein & Terrono, 1996).

Three other types of thumb deformity have been recognized and classified (Stein & Terrono, 1996). The most common of these is type IV, gamekeeper's deformity. This is characterized by MCP adduction and lateral instability of the MCP joint and is the result of attenuation of the ulnar collateral ligament. As the proximal phalanx deviates radially at the MCP joint, the first MCP assumes an adducted position, and the web space contracts. Type V consists of MCP hyperextension and IP flexion. The first metacarpal is not always adducted, and the CMC joint is usually not involved. Initiating cause is instability or attenuation of the volar plate at the MCP joint. Type VI consists of marked skeletal collapse and loss of bone substance called arthritis mutilans; the thumb becomes quite short and typically is unstable, with skin that appears to be redundant in relation to the underlying skeleton. It is ordinarily associated with similar deformities in the other digits.

Intervention (RA and OA)

Intervention addresses the problems identified by evaluation and is guided by the manifestation of the disease, the patient's adjustment to disease progression, and the patient-identified limitations in occupational functioning. The understanding of the altered biomechanical forces on joints, the systemic aspects and progression of rheumatoid arthritis, and the patient's level of engagement in meaningful occupation drive the occupational therapy intervention. Intervention in RA varies as the disease progresses from the acute (characterized by synovial inflam-

mation and proliferation and systemic symptoms such as fever and pain) to the subacute, non-inflammatory phase and then to the chronic stage, in which the disease is burned out, but deformities are created or remain. In all stages, fatigue and exacerbation of pain are avoided. The occupational functioning goals identified by patients may be impaired by any of the following:

- Limited knowledge of the disease and its progression
- Limited knowledge and skill to modify activities at home or in the community to protect joints and conserve energy
- Limited ability to manage a full day, balancing between rest and activity
- Joint limitations and deformities
- Limited strength
- Limited knowledge of use of splints
- Limited knowledge on how to adapt or modify the environment
- Limited sense of self-efficacy to redesign lifestyle

The key intervention in OA is patient education concerning unloading and protecting involved joints and strengthening the muscles around joints. Other interventions include modification of the environment, prescription of assistive devices, splinting, and lifestyle redesign.

Patient and Family Education

With RA, all interventions require teaching the patient and family about the disease, its symptoms, and how prolonged synovitis can lead to irreversible joint destruction. Physicians and nurses explain how medications work. Occupational therapists must reinforce the importance of following medication guidelines and the reasons for it. Patients must understand that joint deformities cannot be prevented if the disease progresses unchecked without anti-inflammatory or disease-modifying medications. Although not all cases can be controlled easily or well with medications, the large number of choices allows the opportunity to try a variety until the appropriate compound and dose are discovered. Those who do not respond early to the medication can feel discouraged. The occupational therapist teaches adaptation to the disease progression. Besides helping the patient and family to understand the disease, the occupational therapist must instill hope that the use of adaptation and modifications as needed throughout the course of the disease can permit continued meaningful occupational functioning.

With OA, the goal of education is to enable the patient to control long-term management of OA. Understanding how OA affects joints and understanding OA-related **joint protection** principles and their application to daily living are key areas for education.

Joint Protection and Fatigue Management

With RA, the occupational therapist uses joint protection techniques to reduce pain and deformity. The goals of joint protection are to reduce loading to vulnerable joints, develop strategies to help preserve the present integrity of joint structures, relieve joint pain during activities, and reduce local inflammation (Cordery & Rocchi, 1998). The principles of joint protection described by Cordery and recently revised by Cordery and Rocchi (Procedures for Practice 44-1) require the therapist to apply teaching–learning techniques that will lead to these behavioral changes.

Joint protection principles are appropriate to OA, although the rationale varies from that of RA, since OA is limited to selective joint involvement without systemic effect. Joint protection guidelines for OA include the following: avoid pain in activities, maintain joint ROM and increase muscle strength and fitness, reduce excessive forces on involved joints, avoid staying in one position for long periods, and balance activity and rest (Cordery & Rocchi, 1998).

Respect Pain

The pain-sensitive structures in the joint are the fibrous capsule, ligaments, fat pads, and periosteum. Pain during the inflammatory process of RA is common. Pain can also be elicited when attenuated ligaments and deranged joint spaces are aggravated through use that lengthens the ligaments further or resistive motion that compresses the

joint spaces (Shapiro, 1996). When pain is present at rest during the inflammatory process, reducing activity level to prevent increasing pain and to promote reduction of inflammation is indicated. In the chronic phase, the aggravating postures or precipitating activities are avoided, or adaptations are devised.

In OA, joint pain produced by engagement in activities is a useful symptom that may indicate stress to joints by use that exceeds the limits of comfort to the involved joint. Examples of this include prolonged kneeling and squatting, both of which can aggravate knee symptoms. Kneeling and squatting can usually be avoided by relocating items from low surfaces to higher levels and sitting on a stool to work. Equipment that can be used to avoid kneeling and squatting includes such items as long-handled dustpan and reachers. To avoid lifting heavy loads, when the spine and lower extremities are painful, usual equipment can be replaced by lighter versions made of materials such as aluminum, plastic, or nylon canvas. Examples of this are nylon canvas suitcases and briefcases. A rolling cart and luggage roller can be used. Postures that aggravate back symptoms when the spine is involved, such as prolonged leaning over a desk, can be modified by use of an upright reading rack. Leaning over a railing to pick up an infant from a crib can be avoided by adapting the railing to open to mattress level and sitting to transfer the infant to one's lap or an elevated stroller (see Chapter 32). Raising the height and firmness of chairs, toilet seats, beds, and other furniture avoids knee or hip pain during arising. Lateral supports or armrests may also be used to assist with rising from the seated position. To avoid pain when the thumb CMC is affected, the person can use jar openers, electric can openers, electric scissors, and lightweight or large-handled utensils to prevent undue stresses to this joint (Cordery & Rocchi, 1998; Stein & Terrono, 1996).

Maintain Muscle Strength and Joint ROM

Balanced strength around unstable joints can reduce further injury to the capsule, ligaments, and cartilage. Joint protection during therapeutic exercise includes ensuring that muscle pull does not accentuate deformity. Joint position and ROM are critical for optimum functioning of muscles. Limited range at one joint, such as the shoulder, requires exaggerated motions at distal joints to accomplish a task.

In the presence of acute joint inflammation with RA, when range can become limited, joint protection includes use of gentle, pain-free ROM exercise. Attempts to go beyond this range can raise intra-articular pressure and aggravate existing pain.

In OA, maintaining daily activities within the limitations of the patient's pain prevents disuse atrophy. Strengthening around an unstable joint can increase stability and reduce pain. Bony enlargement around the

PROCEDURES FOR PRACTICE 44-1

Principles of Joint Protection

- Respect pain as a signal to stop the activity.
- Maintain muscle strength and joint ROM.
- Use each joint in its most stable anatomical and functional plane.
- Avoid positions of deformity and forces in their direction.
- Use the largest, strongest joints available for the job.
- Ensure correct patterns of movement.
- Avoid staying in one position for long periods.
- Avoid starting an activity that cannot be stopped immediately if it proves to be beyond capability.
- Balance rest and activity.
- Reduce the force.

From Cordery, J., & Rocchi, M. (1998). Joint protection and fatigue management. In J. Melvin & G. Jensen (Eds.), *Rheumatologic rehabilitation series, vol. 1: Assessment and management* (pp. 279–321). Bethesda, MD: American Occupational Therapy Association. Reprinted with permission.

CMC joint of the thumb can inhibit motion. When this occurs, a bony block can prevent attempts to increase ROM and lead to further pain; therefore, attempts to increase ROM are avoided.

Use Each Joint in Its Most Stable Anatomical and/or Functional Plane

The most stable anatomical and/or functional plane is one in which muscle, not ligament, provides resistance to the motion (Cordery & Rocchi, 1998). For example, in a type I thumb deformity with flexible hyperextension of the IP joint, pinch with IP flexion against the pad of the thumb provides increased stability.

Avoid Positions of Deformity and Forces in Their Direction

Avoid external loads and internal forces that facilitate deformity when the degree of disease puts them at risk (Cordery & Rocchi, 1998). Turning resistive round door-knobs in an ulnar direction when the finger MCP joints are subluxed volarly and ulnarly is an example of force to be avoided by use of a lever door opener.

Use the Strongest Joints Available for the Job

Use of stronger, larger joints can handle greater forces. Examples of this principle include lifting objects from the floor by using the hips and knees instead of bending at the spine; pushing or pulling objects rather than carrying them; and using a belted waist pack rather than holding the purse with hook grasp (Fig. 44-5, A & B).

Ensure Correct Patterns of Movement

Incorrect patterns may be the result of pain, tenosynovitis, deformity, muscle imbalance, or habit (Cordery & Rocchi, 1998). For example, to raise the arm, the shoulder hikes (scapular elevation and upward rotation) as substitution for painful glenohumeral flexion. Using the glenohumeral joint within pain limits keeps this joint mobile. Another example is to push up when arising from a chair by using the flat surface of the palm rather than the dorsum of the fingers to prevent deforming forces toward MCP flexion.

Avoid Staying in One Position for Long Periods

This advice has been recommended for workers in general, as prolonged static postures can lead to muscle fatigue. When fatigued muscles cannot provide stability around a joint, the load transfers to the underlying joint capsule and ligaments that may already be stretched secondary to disease (Cordery & Rocchi, 1998). People with OA are prone to “gelling” or stiffness and discomfort that follow periods of inactivity. If, in addition, the activity requires static hold of involved joints over a long time, the muscles surrounding that joint tire and are less effective in sup-

Figure 44-5 How to distribute a load over a larger area and use the largest joint available for a task. **A.** Problem: Patient carries her handbag using the small joints of the hand. **B.** Solution: Patient uses a belted waist pack. (Courtesy of the Collection of Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

porting the joint (Cordery & Rocchi, 1998). Change of position or taking breaks and performing active ROM during activities that are normally prolonged, such as use of the computer, is recommended to prevent muscle fatigue and soreness and subsequent poor patterns of use. This principle is difficult to follow, as patients, like every-

one else, want to complete tasks. Performing active ROM to affected joints every 15–20 minutes may minimize stiffness and facilitate muscle function (Brandt & Slemenda, 1993).

Avoid Starting an Activity that Cannot Be Stopped Immediately if It Proves to Be Beyond the Person's Ability

This principle requires planning and is not always easy, especially for an unfamiliar task. Fatigued muscles surrounding affected joints can lead to poor patterns of use and increased pain when timely rest is impossible. This principle has been well applied in newer designs of compact walkers that have seats and trays to make them convenient to use shopping, in the community, or in the kitchen. These walkers have enabled many who engage in community activities to sit when desired, rather than searching for and perhaps not finding a sitting surface. Another example of application of this principle is having patients identify midway locations, such as a chair on the porch that is located between the car and the kitchen. The patient can sit on this chair if unable to ambulate the complete distance to the target location.

Balance Rest and Activity

People with RA generally need more rest than others. Individuals must plan balance between activity and rest to accomplish priority activities for the day and week (Furst et al., 1987). It is not uncommon to hear patients state, for example, that after finishing all the housecleaning, they stayed in bed the following day. Determining and implementing appropriate balance between rest and activity requires self-monitoring, the value of which is further described in the section on Fatigue Management.

Reduce the Force

Strong effort or resistive motions can be problematic for involved joints, leading to further destruction and/or pain. In the hand, this can be avoided by building up handles to avoid tight grasp, which can put excessive stress on problematic finger joints and increase compressive forces at the wrist (Shapiro, 1996). Other ways to reduce resistive motions are the use of assistive devices, such as lightweight cooking utensils and jar openers that use the power of the upper arm rather than involved hand and wrist joints.

Work simplification methods also reduce stress on joints. Rather than carrying objects back and forth in the kitchen repeatedly, placing them all on a rolling cart to push them across the room at one time reduces the force on small hand joints. Resistive activities that push unstable MCP joints toward the ulna should be avoided (Fig. 44-6). If, however, a patient's favored leisure activity has been a hobby such as knitting and if satisfactory substitute activities cannot be found, the therapist must assess how the

Figure 44-6 Avoidance of ulnar deviation forces: cutting an apple using a dagger grip on the knife to push the fingers radially.

patient can knit without use of undue force. Suggestions include building up the needles and using large doweling for needles, taking frequent rest breaks, searching for loose-weave patterns, and other solutions that patients may suggest.

In OA, the cartilage is too thin to protect against repetitive use of force, which produces destructive effects on cartilage. Patients' understanding of joint physiology and the role of the proprioceptors can help them to understand which daily occupations use excessive force, such as the effect of carrying heavy loads up and down stairs. This understanding lets the patient recognize the need to use alternative methods to accomplish the task; for example, in this case, to have others carry the load down the stairs or carry small amounts of load in a backpack and use the handrail to reduce the impact load to involved knee joints.

Fatigue Management

Fatigue has been described as the enduring subjective sensation of generalized tiredness or exhaustion (Belza, 1995). Contributors to fatigue are multidimensional and include physiologic, behavioral, and environmental factors (Belza, 2001). To control the effects of fatigue on everyday activities, the therapist teaches the patient to analyze daily activities to determine activities that increase pain and fatigue (Cordery & Rocchi, 1998). Gerber et al. (1987) found that rest breaks during the day can support a full day of activity. This was shown in a study of a 6-week course of energy conservation and joint protection training for patients with RA in which participants were taught to take periodic short rest periods during prolonged activ-

ities. As a result, 50% of these persons increased the amount of time they were active, compared with 11% of the control subjects (Gerber et al., 1987). In the 6-week course, the patients used worksheets to determine what may and may not be changed in their daily schedules to self-assess realistic changes. Additional activities provided in the workbook for the course continued this self-analysis to enable patients to plan their fatigue management. *Managing Your Fatigue*, a useful brochure published by the Arthritis Foundation, can accompany patient education programs on this topic.

Although fatigue that accompanies systemic disease in RA does not exist in OA, continued use of affected joints, along with other joints, can increase the discomfort level in these joints. Self-monitoring by recognizing onset of pain and discomfort with a routine daily schedule should be used to determine when activity should be stopped to rest the joints. By recording length of time in a task that is followed by moderate to severe pain and/or fatigue, patients can reduce the time in the task to decrease pain and/or fatigue. Cordery and Rocchi (1998) advocate rest

periods shorter than 30 minutes several times a day between tasks.

Maintain Joint Mobility

Patients with RA commonly have limited ROM because of inflammation, joint destruction, weakness, reflex inhibition from pain, or limited use. The cause of the limitation directs the intervention.

During acute joint inflammation, joint motion should be maintained with at least one complete ROM exercise daily. The brochure *Exercise and Your Arthritis* by the Arthritis Foundation (Resources 44-1) is an example of information that patients can follow. It is important not to overstretch inflamed tissues in RA, as tensile strength can be reduced by as much as 50%, leading to tears (Minor, 1996). Active and active assistive ROM are commonly used during this period. If the patient's effort against gravity leads to discomfort or there is lag in the joint (most notable in the shoulder), passive ROM may be used to ensure that contractures do not occur during this period. It is imperative to pay attention to

RESOURCE 44-1

Patient and Professional Education

Arthritis Foundation—www.arthritis.org

A national resource with branches in every state. Patient education brochures can be obtained free or downloaded and printed. Examples of brochures are: *Golf and Arthritis*, *Managing Your Pain*, *Managing Your Activities*, *Protect Your Joints*, *Living with Osteoarthritis*, *Living with Rheumatoid Arthritis*, and *Living with Fibromyalgia*. Local offices can be found from the national website. Local offices may sponsor community programs, such as PACE (People with Arthritis Can Exercise) and aquatic exercise classes, as well as self-help courses and education and support groups. A magazine for the lay public, *Arthritis Today*, provides education as well as resources, such as travel agencies accommodating people with disability. Professional materials may also be found at the website.

MedlinePlus—www.medlineplus.gov

This website is co-sponsored by the U.S. National Library of Medicine and the National Institutes of Health. It provides health information for the lay public on over 700 topics on conditions, disease, and wellness. Information on fibromyalgia, rheumatoid arthritis, and osteoarthritis can be found here.

Fibromyalgia Network—www.fmnetnews.com

Publishes quarterly the *Fibromyalgia Network Health Journal*, which has current information for patients. Also has free patient-education brochures and information on the website.

National Fibromyalgia Association—www.fmaware.org

Provides free patient-education brochures and publishes a lay health journal 3 times/year, *Fibromyalgia AWARE*. On the medical advisory board are well-respected health professionals who focus on treatment and/or research for this condition.

The Oregon Fibromyalgia Foundation (OFF)—www.myalgia.com

This organization was founded in 1995 by Robert Bennett, MD, and Sharon Clark, PhD, and their colleagues from a well-known fibromyalgia center at the Oregon Health & Science University. The website provides a comprehensive synopsis of the research from medical journals, useful books in publication, as well as more basic lay information on many aspects of fibromyalgia.

Supplemental Reading

Foltz-Gray, D. (2005). *Alternative treatments for arthritis*. Atlanta: Arthritis Foundation.

This paperback book provides information on alternative treatments for arthritis. Each treatment is described, along with common uses, scientific evidence, side effects and interactions, safety concerns, dose, and ways to find a practitioner.

the patient's response if outside assistance is given because stoicism and the desire to not lose range may prevent the patient from reacting to pain overtly. Gentle active ROM in the evening can reduce morning stiffness (Minor, 1996), although some have found that the best time for performing this activity is in the morning after they take anti-inflammatory medication.

When joint inflammation has subsided, increasing ROM with gentle, controlled stretching can regain all or some of the loss that occurred during the inflammatory stage. General guidelines for ROM exercises for patients with RA include the following (Coppard, Gale, & Jensen, 1998; Minor, 1996):

- Exercise daily when stiffness and pain are the least.
- Take a warm shower or apply heat and/or cold before or after exercise.
- Perform gentle ROM exercise in the evening to reduce morning stiffness and in the morning to limber up prior to arising.
- Modify exercise (decrease frequency or adapt movement) to avoid increasing joint pain either during or after the exercise. Pain following exercise is a guide to reduce the number of repetitions.
- Use self-assistive techniques, such as wand exercises, to perform gentle stretching.
- Reduce number of repetitions when the joint is actively inflamed.

Strengthening

Patients with chronic RA are at risk for the ill effects of inactivity, including muscle atrophy and decreased exercise capacity, endurance, and cardiovascular fitness, resulting in a deconditioned state (Komatireddy et al., 1997). Research suggests that exercise may not be as detrimental as previously believed.

Isometric exercise is often used prior to or in conjunction with dynamic resistive and aerobic exercise programs. Initially, isometric exercise may be indicated to improve muscle tone, static endurance, and strength and to prepare joints for more vigorous activity (Minor, 1996). Isometric contractions performed at 70% of the maximal voluntary contraction, held for 6 seconds, and repeated 5–10 times daily can increase strength significantly (Minor, 1996). Minor recommends that while performing isometric exercise: (1) maintain the contraction for no more than 6 seconds, (2) avoid maximal effort, (3) exhale during the contraction and inhale during a similar period of relaxation, and (4) avoid contracting more than two muscle groups at a time. Dynamic exercise can improve both strength and endurance (Minor, 1996). Protect unstable or inflamed joints from damage during resistance exercises and perform within pain-free range. Start with 8–10 antigravity repetitions without pain before adding

resistance. Reduce intensity, frequency, or ROM if joint swelling or pain occurs (Minor, 1996).

Splinting

In the treatment of OA, the use of a hand splint can be useful to stabilize an unstable first CMC joint in palmar abduction and thus balance forces on an unstable joint. Weiss et al. (2000) concluded that wearing a thumb CMC splint provided pain relief. Additionally, for those with early OA, which is defined as subluxation of MC base and osteophyte less than 2 mm, the amount of subluxation was reduced when wearing the splint. In the treatment of RA, hand splints have been used for a variety of purposes (Falconer, 1990). The effectiveness of splints for all of these purposes has not been extensively documented, although some studies have addressed pain reduction, grip strength, and comfort of a variety of orthoses (Kjeken, Moller, & Kvien, 1995; Stern et al., 1996; Ter Schegget & Knipping, 2000; Tjihuis et al., 1998). The following are some reasons splinting has been found useful with people with RA.

Reduce Inflammation

During the inflammatory process, joint rest by means of immobilization has been found to reduce joint inflammation, as was shown in an early study (that apparently has not been replicated more recently) when the ring size was significantly reduced in a small sample of persons with RA who were treated by immobilization versus those not immobilized (Partridge & Duthie, 1963). It is very common for resting hand splints to be prescribed during the inflammatory period. Some patients state that, when they awaken in the morning, the hand is more comfortable, having rested in a comfortable position during the night. The joints that are covered by a splint should be determined by the location of the inflammation. For example, if only the wrist is involved, a wrist splint is indicated. If the whole hand and wrist are involved, the orthosis should include all joints. The occupations of the patient may require fitting two orthoses for the inflamed hand. A night resting splint that covers all joints may be alternated with a shorter orthosis that allows the fingers to be free to perform pain-free non-resistive activities during the day.

Provide Support and Reduce Pain to Unstable Joints during Function

During the post-inflammatory stage, if unstable or subluxed joints or other joint deformities occur, the external support of an orthosis can enhance stability or prevent joint motion. Stability is provided only to joints posing problems. Feinberg and Brandt (1984) found that, when splinting relieved pain, adherence to splint wearing was good. Feinberg (1992) also found that patient education enhanced patient adherence to wearing of splints.

Prevent Undesirable Motion during Occupational Performance

A key example of this is to prevent hyperextension of the finger PIP joints (swan-neck deformity) through the use of a three-point splint that allows flexion but prevents hyperextension. Another example is to use an orthosis in the early stage of the Nalebuff type I deformity of the thumb, hyperextension of the IP joint. Although patients can be taught to remember to flex the IP joint when using a pinch motion, an orthosis that limits hyperextension can be a passive reminder to prevent further hyperextension and stretch to collateral ligaments. A practice that is controversial is immobilizing the finger PIP joint into extension when an early boutonniere deformity is seen. Some positive results have been seen in controlling the deformity for a limited time (Palchik et al., 1990).

Increase ROM or Prevent Deformity

Dynamic splinting, using an orthosis with finger extension outriggers, has been commonly used after finger MCP Silastic implant arthroplasty. This use of dynamic orthoses has been proposed for other purposes, such as to reduce contractures secondary to the disease, but little evidence supports this outcome or the use of dynamic splinting to prevent deformity.

Position Joints for Occupational Performance

An example of positioning joints for occupational performance is the use of the MCP ulnar deviation orthosis (Fig. 44-7, A & B) to permit continued use of the IP joints of the hand, when, if unsplinted, pain would be induced at the MCP joint with activity. Information regarding types of splints and use of custom versus prefabricated orthoses is discussed in Chapters 16 and 17.

Modify Environment

Ways to modify the environment to maintain the ability to participate in occupations of choice include changing the physical environment, recommending use of assistive devices, and assisting the patient to recognize and choose work or leisure environments that accommodate the disability. Examples of each of these are given for a variety of problems. The reader should be able to recognize readily what joint problems these modifications accommodate. The adaptations generally can be done with equipment from a local hardware store.

Change the Physical Environment

The patient and therapist must think about modifying all environments important to the patient's occupational

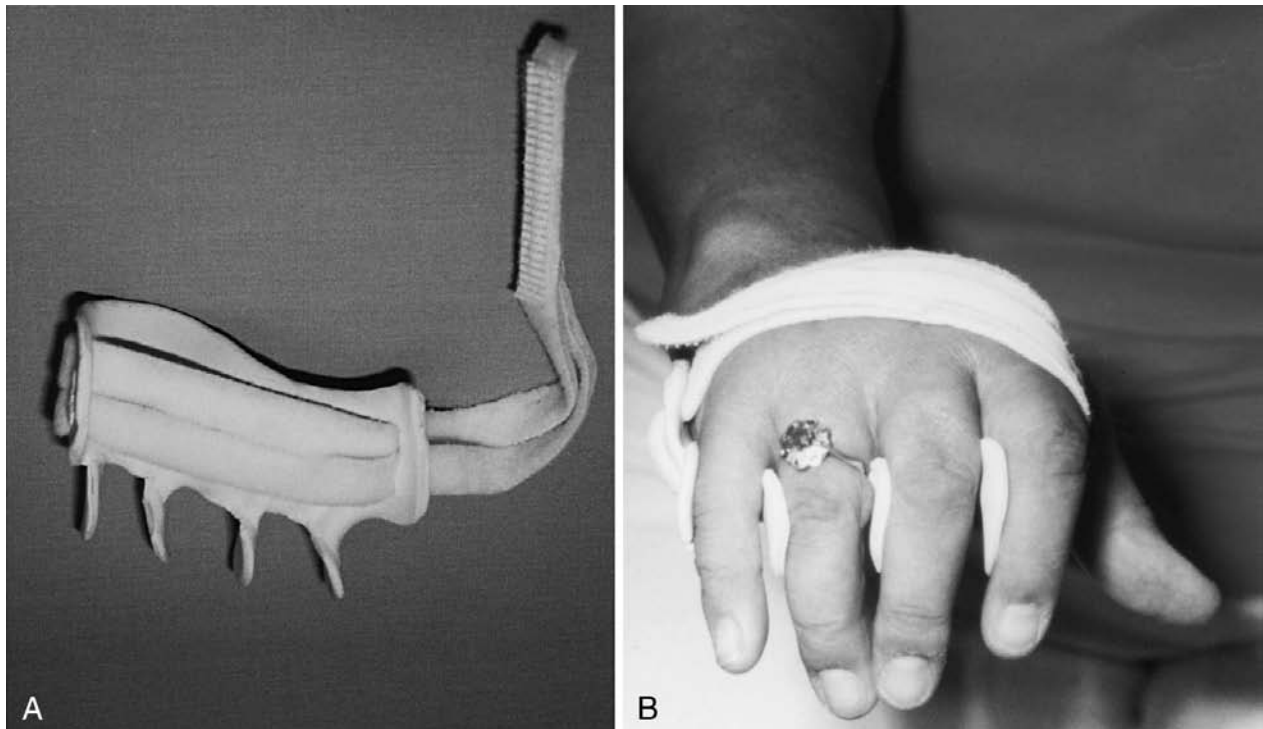

Figure 44-7 Splint to control ulnar deviation of the MCP joints during hand use. **A.** Ulnar deviation correction splint. **B.** Splint in place on the patient's hand. (Courtesy of the Collection of Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

functioning, especially home and work. The following are some examples (Axtell & Yasuda, 1993).

Home:

- Remove doors of cabinets or attach loops to door handles.
- Lower the height of above-counter cupboards.
- Replace shelves in low cupboards with swivel or pull-out shelves.
- Replace standard oven with a microwave oven on a surface that accommodates available reach.
- Replace doorknobs with lever handles.
- Replace faucet handles with long lever handles.
- Use remote control devices to automate on/off switching of commonly used electrical devices, such as light switches.
- Lower closet rods if reach is limited.

Work:

- Organize workstation so that shelves are within reach and the table and chairs are at ergonomically correct heights.
- Attach forearm and wrist supports to computer areas.
- Use hands-free speaker phone.

Recommend Assistive Devices

Many assistive devices are available to the public. These devices can assist the person with RA or OA to limit stresses to joints. It is useful to teach patients joint protection principles so they can search independently for the products that produce the least amount of stress to joints. Criteria to consider when helping patients choose devices are found in Procedures for Practice 44-2. Excellent resources are available for special devices made for people with joint problems when common everyday products do

PROCEDURES FOR PRACTICE 44-3

Commercially Available Common Assistive Devices

- **Self-care**—Buttonhook, dressing stick (various lengths can be used for dressing as well as reach for distant items), sock cone, reacher, long-handled sponge, extended handle for managing toilet paper, long-handled comb, electric toothbrush, pump toothpaste dispensers.
- **Meal preparation**—Rolling cart, knob turner for stove, built-up handles on cooking utensils, knives with right-angled handles (Fig. 44-8), electric can opener, jar opener, spring-lever scissors, cutting board with spikes to stabilize food, electric chopper, high kitchen stool, high stool on roller such as EZ Stand Mobile Stool (Fig. 44-9).
- **Home maintenance**—Long-handled dustpan, bucket on rollers, reachers to pull items out of areas and from floor.
- **Work and school**—Luggage cart, rolling cart, backpack, fanny pack, computer forearm-wrist rest, adapted key holder, built-up handle for writing implements, telephone headset, adapted hand tools, electric stapler and pencil sharpener, car door opener (Fig. 44-10A).
- **Leisure**—Adapted gardening tools, rolling stool for gardening, card holder, reading rack, embroidery hoop holder, rolling golf cart, knob turner (Fig. 44-10B).

not accommodate the problems (Procedures for Practice 44-3 and Resources 44-1). Generally, selection of these products requires professional advice and an opportunity to try the device to ensure that it will serve the purpose desired by the patient. Therefore, it is important for the

PROCEDURES FOR PRACTICE 44-2

Criteria to Consider When Choosing Assistive Devices

- Lightweight, durable, compact, attractive in appearance
- Multipurpose use to prevent need to search for multiple devices
- Simplicity of operation
- Reduce stress to all multilinked joints involved in operating the device
- Suitable for the individual patient's gadget tolerance
- In accord with the self-image of the user

Figure 44-8 Cutting with an angled knife on a cutting board with vegetable spike. (Courtesy of Paul Weinreich, Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

occupational therapy clinic to have an array of devices for trial use (Mann, 1998). Keeping current equipment catalogs and using the Internet to assist patients in finding appropriate items helps patients perform meaningful occupations. When none of the products available in the general or specialty market solves the problems, the occupational therapist can customize tools in the clinic. Common methods of customizing tools are building up or lengthening handles with materials such as foam tubing, low temperature thermoplastics, plastic tubing, or wooden dowels. Creativity on the part of the therapist is needed to meet the patient's requirements.

People with OA who have significant involvement of only a few joints may not seek out rehabilitation care and may be unaware of and reluctant to use assistive devices that can prevent loss of participation in meaningful occupations. Instead, it is fairly common to hear about continued use of involved joints with pain until there is sudden termination of important occupations, when the use of assistive devices could have prevented aggravation to joints. For example, elevated toilet seats and tub benches can be used to eliminate the stress on knees and hips of arising from low surfaces. Using a reacher and

dresser stick to pick up items from the floor prevents stooping.

Assist the Patient to Recognize and Choose Work or Leisure Environments that Accommodate the Disability

To change previously comfortable daily life routines to accommodate disability requires significant effort. The methods used in a study to enable individuals to implement lifestyle redesign can apply to individuals with RA. Lifestyle redesign suggests that people can achieve greater meaning in their lives by examining the occupations that are most meaningful to them and identifying what prevents them from performing these occupations (Clark et al., 1997). In lifestyle redesign, the individual, through a process facilitated by the occupational therapist, determines what is needed to perform these important occupations and develops solutions to overcome these barriers to occupational functioning. Although this was intuitively known by occupational therapists, Clark et al. (1997) showed that, as a result of this lifestyle redesign intervention, people were healthier as demonstrated by scores on tools such as the *Short Form-36*, a quality-of-life measure, in

Figure 44-10 Car door opener (A) and multipurpose knob turner (B). (Courtesy of Rancho Los Amigos National Rehabilitation Center, Downey, CA. Paul Weinreich, photographer.)

contrast to those who did not have this intervention. The intervention included exposure to a number of tasks and activities in small groups. At the same time, each individual approached the task determining what had to be done to meet his or her own needs to perform the task again, independent of the group (Jackson et al., 1998).

In those with RA, these principles of implementing lifestyle changes proposed by Clark et al. (Jackson et al.,

1998) may have to be done periodically or on an ongoing basis as the disease progresses or as exacerbations and remissions occur. Teaching people to implement lifestyle changes by emphasizing occupational self-analysis and achievement of individual goals eliminates the need for professional intervention except when a major crisis in the life of the individual occurs.

Sexual Expression

An area of occupational performance that is sometimes overlooked is sexual expression. The focus of assessment is identifying hindrances to sexual expression related to performance skills, client factors, or context. Majerovitz and Revenson (1994) found an association between greater disability and greater dissatisfaction among 113 couples, of whom 79.6% included one spouse with RA. They suggested that health providers be sensitive to patients' questions and concerns regarding sexuality and openly discuss these issues with both patient and partner. Intervention in the area of sexual expression may include education, development of communication skills, planning for more comfortable sex, and finding positions that are more comfortable.

Patient Education

Topics included in education address the following issues. Pain and stiffness in joints can lead to avoidance or limited sex. Partners may also fear causing pain. Fatigue, which may be part of the disease process, can reduce desire for sex. Some medications cause fatigue or reduce sexual desire.

Development of Communication Skills

Discussion of sex with a partner is difficult for some. Discussion of needs for intimacy and how a partner feels can lead to more extensive discussion of the effects of disease on sexual performance.

Planning for More Comfortable Sex

The following suggestions are from the Arthritis Foundation (1993):

- Plan for sex at a time of day when you generally feel best.
- Time your dose of pain relief medication so that its effect will occur during sexual relations.
- Pace your activities during the day to help avoid extreme fatigue.
- Practice ROM exercises to relax your joints.
- Warm the bed ahead of time with an electric blanket.
- Take a warm bath or shower before sex to relax.
- Find more comfortable positions.

CASE

EXAMPLE # 1

Ms. B.: Rheumatoid Arthritis

Occupational Therapy Intervention Process

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Patient Information

Ms. B. is 45 years old and has a 3-year history of rheumatoid arthritis (RA). She has been followed by a rheumatologist for the entire period, with ongoing use of anti-inflammatory medication. Her current major complaint is bilateral wrist pain. The finger MCPs show very mild inflammation, and she does not report pain in them. There are no other notable pain complaints in other joints. Grasp strength is 20 pounds bilaterally. She is a full-time fourth grade school teacher and lives alone in a one-bedroom apartment on the first floor.

Understand the patient's diagnosis or condition

"Ms. B. has a mild inflammatory process with localized joint problems interfering with occupational functioning at this time."

Know the person

"Ms. B. enjoys teaching and looks forward to seeing children learn. Her desire to stay independent throughout the 3-year history of RA is a positive characteristic that makes her a good candidate for rehabilitation."

Reason for Referral to Occupational Therapy

Ms. B. was referred to occupational therapy to address her complaint of bilateral wrist pain, which is beginning to interfere with her teaching, although she has not had to take time off work. Ms. B. desires to continue to work full time.

Appreciate the context

"Because Ms. B implemented OT recommendations when seen 2 years ago, it is likely that she will do well again with OT recommendations and most likely will be able to continue full-time work as a school teacher."

Assessment Process and Results

Interview with Ms. B. showed that Ms. B. has increased pain after working a full day. Her daily teaching schedule includes an approximate total time of 2 hours writing on the blackboard. She also opens and closes heavy institutional doors at least twice a day. She drives her car to and from work. She carries a full briefcase to and from work. She buys her lunch at the cafeteria daily. The pain subsides over the weekend, when she engages in very few active tasks, such as housecleaning or cooking. She has been having friends cook for her and has let her housecleaning go. Her wrist pain is eliminated over 2-week vacations and the summers, when she is not teaching. Physical examination of Ms. B.'s wrist showed a mild inflammatory process and no deformity. On a *Visual Analog Scale* for pain, Ms. B scored an 8 (out of 10) at her highest level of pain, which occurs following a day of using the blackboard.

Consider evaluation approach and methods

"Reviewing Ms. B.'s typical day schedule revealed problems with occupational functioning. Focusing on her daily schedule enabled me to understand what exacerbated her bilateral wrist pain, which could not easily be understood through physical examination of her wrists, which showed a mild inflammatory process."

Interpret observations

"It appears that Ms. B.'s wrists have increased pain as a result of aggravation of her inflammatory process through daily overuse. This suspicion is further verified by her discussion that the pain is decreased on weekends and summers when she is not performing continued resistive motions to her wrist in her daily activities."

Occupational Therapy Problem List

1. Bilateral wrist pain exacerbated in the course of her work day, especially when she writes on the blackboard.
2. Inability to perform home maintenance.
3. Inability to prepare meals.

Synthesize results

"If Ms. B. continues to aggravate her wrist pain through activity, it may be increasingly difficult for her to continue working full time and to return to performing home maintenance and meal preparation."

Occupational Therapy Goal List

<ol style="list-style-type: none">1. Wear bilateral wrist orthoses for use during performance of occupational tasks.2. Apply alternative means to writing on the blackboard.3. Use joint protection techniques to prevent increased wrist pain during work day and during performance of home maintenance and meal preparation tasks and activities.	Develop intervention hypotheses	“I believe that educating Ms. B. about the potential positive effects of wearing wrist orthoses will make her a good candidate to wear the orthoses and to benefit. With her desire to continue teaching, helping her to find a comfortable alternative solution to the use of the blackboard will lead to an outcome that will be carried out. Since it can be difficult to understand the application of joint protection principles easily to all activities, focusing specifically on her goals and helping her to problem-solve application should help her in new situations as they arise.”
	Select an intervention approach	“Occupational therapy intervention will focus on compensatory, adaptive, and preventive approaches.”
	Consider what will occur in therapy, how often, and for how long	“Ms. B. will be seen in occupational therapy as an outpatient for six sessions over 6 weeks. The sessions will focus on splinting, finding an alternative method to blackboard use, and problem-solving joint protection methods to apply to critical tasks.”

Intervention

<ol style="list-style-type: none">1. Determine and fit appropriate bilateral wrist orthoses to use during function.2. Explore alternatives for writing on blackboard, such as use of overhead projector and transparency pens or chalk holders, to diminish prolonged tight pinch with its secondary effect on intercarpal pressures.3. Explore use of adapted equipment for carrying heavy loads, such as a briefcase. This may include use of a luggage roller, special shoulder straps for carrying the briefcase, or a canvas pack on wheels.4. Review meal preparation activities and adapted aids to decrease use of prolonged grasp and stress to wrists. This may include use of special jar openers, can openers, and knives that use arms instead of the wrists for power.5. Review use of tools that can decrease stress to wrists, such as a rolling cart in the kitchen.6. Identify which activities are the most important to Ms. B. to accomplish each day at work, home, and in the community. Reexamine whether priorities need to be set and whether stress to wrist joints is exacerbated with any of these activities.7. Provide ongoing education on joint protection techniques that emphasize self-analysis of each activity and examination of alternative methods to accomplish important tasks without undue stress to wrist joints.8. Explain wearing time of splints and purpose of splints. Train in appropriate donning, doffing and general care of splints.	Assess the patient's comprehension	<p>“Teaching Ms. B. strategies for joint protection during occupational performance allowed the patient to learn self-analysis with each new activity that she could continue after the end of therapy. Because of the visibility of splinting, which may have negative connotations at work, education was important to assure that Ms. B. was comfortable wearing the splints in the classroom and that she recognized that the splints allowed performance in the classroom without increased pain at the end of the work day. It was important to teach Ms. B. to identify activities that aggravated wrist pain and find alternative ways to perform or use special tools or adapt the environment so that she could assume control over her disease.”</p> <p>“Upon Ms. B.'s return following each visit, Ms. B. demonstrated and described how she applied what she had gained from the previous session. At the end of the sixth visit, the <i>Visual Analog Scale</i> of pain was readministered, and the score was now 1 (out of 10) following a day at work teaching and using an overhead projector instead of a blackboard.”</p>
--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	------------------------------------	----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Next Steps

Ms. B. does not need to return to occupational therapy unless she finds that she has further occupational functioning problems.	Anticipate present and future patient concerns	“Ms. B. understands that she can request an OT referral from her rheumatologist if she has further occupational functioning problems. I believe that Ms. B. will continue to teach full time and enjoy being with her friends on the weekends. She will likely wear her bilateral wrist orthoses during task performance until the inflammatory process subsides. She will likely resume performance of work tasks, home maintenance activities, and meal preparation, applying joint protection principles.”
---------------------------------------------------------------------------------------------------------------------------------	------------------------------------------------	---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

CASE

EXAMPLE # 2

Mrs. S.: Osteoarthritis

Occupational Therapy Intervention Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information Mrs. S. is 55 years old and lives with her husband in their own home. They owned and operated a small café for 15 years until they retired 5 years ago. Mrs. S. has bilateral osteoarthritis (OA) of the knees that has progressed to the degree that she can walk only short distances at home without incurring knee pain that requires sitting or lying down. She also has pain in the CMC joint of the right thumb, which is noted especially when she is attempting to cook or garden. On a <i>Visual Analog Scale</i> for knee pain, her scores after walking short distances in her home are 8 to 10. Her right palmar and lateral pinch strength ranges between 3 and 5 pounds.</p>	<p>Understand the patient's diagnosis or condition</p> <p>Know the person</p>	<p>"X-rays showed that the patient had significant joint narrowing in both knees and the CMC joint of the right thumb. Excessive weight-bearing and resistive use of the right thumb aggravated joint pain secondary to severity of the disease."</p> <p>"I questioned whether her dependency was secondary to lack of desire or lack of knowledge on how to perform tasks without aggravating pain. Mrs. S. had given up many cherished activities because of bilateral knee pain and right CMC joint pain. She had not personally attempted to use methods to control pain through use of alternative methods to perform important occupations."</p>
<p>Reason for Referral to Occupational Therapy Mrs. S. was referred to outpatient occupational therapy because of her complaints about difficulty managing self-care, home skills, and gardening.</p>	<p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>"The physicians felt that Mrs. S. would benefit from knee arthroplasties, but she refused. Occupational therapy could perhaps improve her occupational functioning, despite continuing knee pain.</p> <p>Because of her expressed interest in returning to participation in important occupations and no previous OT intervention, she should be a good candidate to benefit from use of assistive devices, adapted methods, and right CMC thumb splint."</p>
<p>Assessment Process and Results Self-report ADL assessment and verification by observation reveals that Mrs. S. cannot transfer into and out of the bathtub without her husband's assistance. She prefers to stay in her night clothes all day because of knee discomfort when donning and doffing her pants to dress or to use the toilet. There is loss of interest and need to wear day clothes. She has problems grasping and pinching items in her right hand that require any degree of resistance. This includes opening jars, turning doorknobs, managing can openers, and managing dials that require twisting, such as stove knobs.</p>	<p>Consider evaluation approach and methods</p> <p>Interpret observations</p>	<p>"With limited evaluation time, I focused on observation of simulated occupations of importance, self-reported ADL, IADL measures, information obtained from interview for description of a typical day, and physical assessment of the CMC joint of the right thumb."</p> <p>"Mrs. S. had significant knee pain with prolonged ambulation and movement that required extremes of knee flexion, such as transferring to the bottom of a bathtub. She also demonstrated pain on use of the right thumb in resistive tasks. I do not believe that Mrs. S. is avoiding performance of tasks secondary to dependency or lack of desire. Mrs. S. lacks knowledge of assistive devices, splinting, and joint protection methods that can enable engagement in important occupations."</p>
<p>Occupational Therapy Problem List Reduced occupational functioning in ADL/IADL areas listed in the assessment process.</p>	<p>Synthesize results</p>	<p>"I believe that problems are related to joint pain from overuse or resistive use of unstable, narrowed joints."</p>

Occupational Therapy Goal List

1. Educate in joint protection principles related to Mrs. S.'s problems.	Develop intervention hypotheses	"I believe that Mrs. S. will start dressing herself daily in day clothes and participate in occupations of interest once she understands how to avoid aggravating pain in affected joints."
2. Explore use of right CMC thumb splint.		
3. Explore use of assistive devices and alternative ways to accomplish important occupations.	Select an intervention approach	"Occupational therapy intervention will focus on compensatory, adaptive, and preventative approaches."
	Consider what will occur in therapy, how often, and for how long	"Six sessions of 1 hour, one time per week, in outpatient occupational therapy with home assignments after each session should enable Mrs. S. to meet her occupational goals. Because this is the first time that Mrs. S. has had occupational therapy, time will need to be spent educating her and her husband, who is very supportive, on how goals can be achieved and maintained post intervention. It is also important in the therapy sessions that she actually practice her occupations of choice to understand how pain can be reduced through alternative methods to task performance."

Intervention

1. Educate patient and husband regarding the value of thumb CMC splinting. Provide a thumb CMC splint.	Assess the patient's comprehension	"Mrs. S. expressed surprise that her pain was not aggravated throughout the practice sessions in the model kitchen, in which she prepared a light meal, and when she performed gardening tasks in the outdoor garden area at the clinic. I felt this gave Mrs. S. the confidence to perform these occupations at home. Her husband was present throughout the sessions and provided her with additional encouragement."
2. Provide joint protection education for patient and husband. Have patient practice use of joint protection methods.		
3. Teach use of assistive devices for bathing and use of the EZ Stand Mobile Stool (TM) and educate on their value for joint protection.		
4. Practice preparing a light meal using the EZ Stand Mobile Stool (TM) and other joint protection methods in the clinic kitchen. Example of Mrs. S.'s Home Program for Joint Protection:		
A. Use EZ Stand Mobile Stool (TM) to prepare a light lunch at least 3 times during the next week (to decrease excess loading to knee joints). B. Use thumb CMC splint during task performance (to stabilize thumb joint and to decrease excess loading to CMC joint). C. Use adapted equipment (multipurpose knob turner, Zim jar opener, and right-angled knife) to decrease excess loading to thumb CMC joint. D. Avoid pain in activities (e.g., holding pot with handle with 2 hands).		
5. Practice gardening with walker and long-handled gardening tools in the clinic environment.		

Next Steps

Discharge from occupational therapy. Note: Three months after discharge, Mrs. S.'s community rheumatologist reported to the occupational therapist that Mrs. S. has been going to an Arthritis Foundation swim program with her husband weekly and that she is cooking everyday and doing some gardening. She is seriously thinking about having knee arthroplasties soon.	Anticipate present and future patient concerns	"Since Mrs. S. followed through on homework assignments after each session, I felt that Mrs. S. will continue to use her equipment and practice joint protection principles to accomplish her cherished occupations. I did not feel that follow-up sessions were indicated, unless Mrs. S. found a need for further intervention."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Joint Protection Principles Applied to Leisure Skills

Mrs. S. has returned to cooking for herself and her husband. She also goes out to the garden two or three times a week to water the plants. She has told the therapist that she would like to participate in leisure activities in the community. What kinds of activities would you suggest and for what reasons?

The Arthritis Foundation brochure *Guide to Intimacy and Arthritis* describes positions for sex that reduce stress to commonly involved lower extremity joints (see Resources 44-1). Individuals may use the brochure to identify which postures are the least stressful for them. Communicating with a partner is important for trying new postures, letting the partner know what feels good, and finding alternative ways to enjoy sex.

FIBROMYALGIA

Three symptoms are commonly seen in patients with fibromyalgia (FM): widespread soft tissue pain, fatigue, and non-restorative sleep; these symptoms are accompanied by diffuse tender points. FM is reported to occur in 3.4% of women and 0.5% of men (Silver & Wallace, 2002; Wolfe et al., 1995). The prevalence of the syndrome increases with age but is also seen in children. The typical FM patient is a woman between 30 and 50 years of age (Burckhardt, 2001). Melvin (1998) reports that it is likely that many people go in and out of symptoms of FM and never seek a diagnosis and that OT practitioners are likely to see only the most severe cases. The diffuse, soft tissue pain is characteristically concentrated in axial locations such as the neck and lower back, with the proximal trapezius muscles commonly involved. Individuals often report stiffness in the morning, which dissipates with possibly a remaining sensation of joint swelling. The symptoms are chronic but can vary in intensity from day to day. They are commonly exacerbated by various factors, such as moderate physical exercise, inactivity, poor sleep, emotional stress, and humid weather. Despite a common complaint of paresthesias in the upper extremities and swelling in the hands, results on nerve conduction studies are usually normal, and examination of the hands usually fails to confirm actual swelling (Burckhardt, 2001; Freundlich & Leventhal, 1997). A number of conditions are associated with FM, such as chronic fatigue syndrome (50%), bowel disorders (e.g., irritable bowel syndrome, etc.) (40%), increased cardiac awareness (20%), headache (53%), and temporomandibular joint dysfunction (75%); other conditions at lesser percentages include, but are not limited to, heat and cold intolerance, subjective sensation of weakness, and mood disorders (Clauw, 2001; Silver & Wallace, 2002). Approximately 20–40% of people with FM have been reported to have identifiable current mood disorders such as depression or anxiety (Burckhardt, 2001). Cognitive dysfunction, such as forgetfulness and inability to think clearly or work effectively, is among the most distressing symptoms. Onset is usually gradual over a period of months or years, during which time localized or regional pain becomes widespread, although some patients begin with widespread pain after a febrile illness (Burckhardt, 2001). Spontaneous remissions and exacerbations are the

rule (Turk, Monarch, & Williams, 2002). A unifying hypothesis is that FM results from sensitization of the CNS leading to expression of symptoms (Dworkin & Fields, 2005; Mease, 2005;). The central sensitization effect includes stimulus-evoked pain including **allodynia**, which is pain in response to a normally non-painful stimulus, an increased response to painful stimuli (**hyperalgesia**), and an increase in the duration of pain after the stimulation.

Rehabilitation Team Management

Nonpharmacologic therapies found to be helpful include an aerobic exercise program, gentle daily stretching and strengthening, cognitive behavioral therapy, alternative medicine approaches, and occupational therapy. Coordinated effort by a multidisciplinary team is important to achieve outcomes.

Assessment

In obtaining an occupational profile with this population, it is important to examine the patient's occupational history throughout a 24-hour period, since sleep disturbance is a common feature of the condition (Kornblau & Kasyan-Itzkowitz, 2002). During this process, a **daily activity log** and interview will provide clues as to whether there is significant fatigue, sleep disturbance, cognitive dysfunction, mood disorders, musculoskeletal symptoms, and other related problems. Additionally, this typical day examination may also describe at what hours of the day the person's highest energy for performance occurs. If some answers to questions relating to understanding of interfering factors contributing to patient's dissatisfaction with occupational functioning are not obtained from team information or the occupational profile, interview questions might include (Turk, Monarch, & Williams, 2002): (1) What do you do when your pain is bothering you? (2) What activities do you avoid that you used to do? (3) What aggravates symptoms? (4) What makes them better? Answers to these questions can assist with treatment planning. Some upper extremity symptoms associated with FM can be confused with a variety of nerve entrapment syndromes and inflammatory disorders, and a skilled therapist can help evaluate for this difference through a musculoskeletal exam (Russell, Melvin, & Siegel, 2000).

Goal Setting

Using the results obtained from an occupational profile, goal setting can be further identified using an instrument such as the *Canadian Occupational Performance Measure*. In goal setting, not only are the physiological and

psychological symptoms important to consider, but it is also important to consider how readily the individual is able to incorporate changes into his/her life. Some studies have addressed this issue. For example, Finset, Wigers, and Gotestam (2004) found that depression is a predictive factor for limited treatment response.

Intervention

Self-Management Approaches

Self-management approaches, which include encouraging self-efficacy beliefs, have been found to be useful with clients with FM and would be important to use with all occupational therapy interventions (Burckhardt, 2001). Self-management can be taught by teaching patients to self-monitor occupational functioning that increases or decreases symptoms. Buckelew et al.'s (1995) study of patients with FM found that higher self-efficacy was associated with less pain and less impairment on a physical activities measure.

Simple scales on which patients as well as health professionals measure changes in pain, fatigue, sleep, anxiety, or mood from day to day can help them to recognize when self-management techniques are working (Burckhardt, 2001). Examples of useful scales include: (1) rating on a 10-point scale (10 = great deal, 0 = none) the extent that fatigue limits the ability for self-care (bathing, dressing, and grooming), work (either employment or activities around the home), and community activities; and (2) ongoing rating of morning fatigue, mood, and pain on a 10-point scale (10 = the most severe or worst) for tracking improvements in quality of sleep (Russell, Melvin, & Siegel, 2000).

Several authors (Guymer & Clauw, 2002; Melvin, 1998) suggest that patients should keep an activity log to monitor various aspects of symptom management, such as a sleep log to collect data on how their activities and behavioral interventions are altering their sleep or a fatigue journal to aid symptom assessment, which will help design interventions for lifestyle changes to assist with symptom reduction.

Patient Education

Principles of patient education are similar to those described for RA and OA and need to be specific to the intervention being provided (e.g., fatigue management, energy conservation, etc.) (Russell, Melvin, & Siegel, 2000). A useful teaching technique found by Goldenberg (2002) was the use of homework assignments following occupational therapy education sessions, which led to incorporation of appropriate body mechanics, energy conservation, and pacing of activities into the patients' daily routine.

Lifestyle Changes

An overarching occupational therapy intervention is changes to allow engagement in occupations, stay

healthy, and control symptoms. By helping patients modify their lifestyle, practitioners can enable participation in valued occupations. The interventions that follow are some of the methods used to manage the major symptoms of the condition, with lifestyle changes as a desired outcome.

Sleep Hygiene

More than 90% of patients with FM describe disturbed sleep (Moldofsky, 2002). Clinical studies have shown that the soft tissue pain and tender points in specific anatomic regions are related to unrefreshing sleep. Following an occasional night of restful sleep, the patient often finds that pain and fatigue are substantially improved (Moldofsky, 2002). Russell, Melvin, and Siegel (2000) suggest that sleep retraining involves teaching patients about sleep physiology and the skills necessary to implement the recommendations, which may include relaxation training, cognitive behavioral techniques, time management, and how to self-manage depression and anxiety. Sleep hygiene has been included in programs by various health professionals, and occupational therapy practitioners can integrate this into their programs because it is related to helping clients to manage everyday (and evening) tasks for satisfactory performance of daily occupations. A number of basic sleep hygiene measures are advocated by various authors, including the Arthritis Foundation (see Resources 44-1), Guymer and Clauw (2002), Kornblau and Kasyan-Izkowitz (2002), Russell, Melvin, and Siegel (2000), Moldofsky (2002), the National Sleep Foundation (2006), and Silver and Wallace (2002). A few examples include: (1) develop a regular sleep-wakefulness schedule; (2) develop a relaxing routine before bedtime; (3) reduce the irritation of noises inside or outside the room and/or use ear plugs and white noise machines, if needed; and (4) spend some quiet time by one's self before going to bed.

Fatigue Management

Chronic fatigue and easy fatigability in FM may be more problematic than pain (Burckhardt, 2001). The techniques described for intervention for fatigue management for patients with RA and OA apply to those with FM, namely, interventions that enable appropriate pacing, prioritizing, body mechanics, pre-planning, and work simplification (Burckhardt, 2002).

Cognitive Dysfunction

Cognitive dysfunction, especially decreased attention span and short-term memory, may be the most disabling aspect of FM (Clauw, 2001; Melvin, 1998). The causes of these problems are likely related to fatigue, unrefreshing sleep, chronic pain, and psychological distress (Burckhardt, 2001). Until cognitive disturbances are resolved, occupa-

tional therapists can recommend memory aids to compensate for memory difficulties, such as the use of personal data assistants (PDAs) for schedules and alarms to reduce forgetfulness, use of notes posted in prominent places, and keeping a list of tasks to be accomplished (Kornblau & Kasyan-Itzkowitz, 2002). See Chapter 29 for further suggestions.

Pain Management

Progressive increase in response to peripheral stimuli reflects slow temporal summation and has been termed “windup” (Price & Staud, 2005). Windup is likely to be related to mechanisms of central sensitization resulting in some persistent pain frequently reported as dull, aching, or burning. This allodynia of patients with FM, however, is not limited to tender points but, instead, appears to be widespread. Price and Staud (2005) report that almost all studies of patients with FM showed abnormalities of pain sensitivity while using different methods of psychophysical testing, for example, thermal (heat and cold), mechanical, chemical, or electrical stimuli to the skin or muscles. This suggests that teaching avoidance of triggers for pain response through lifestyle changes using any of the occupational therapy interventions described can assist with pain management.

Stress Management

Depending on the role of other team members and the skills of the occupational therapist, the occupational therapist’s role may include stress management training to reduce influences that contribute to symptoms. These might include relaxation training, assertiveness training, guided imagery, and biofeedback (Russell, Melvin, & Siegel, 2000).

Modify or Adapt the Environment

Reisine et al. (2003) found that employed women with FM reported significantly less pain, less fatigue, and better functional status than women who were not employed outside the home. Thus, modifications in lifestyle

and management at work as well as in the home need to be addressed. Reisine et al. (2003) noted that the absolute number of hours devoted to family work is not the critical element, but rather, it is the perceived demands associated with family work and ability to control the pace of family work. Henriksson and Liedberg’s (2000) study of working women with FM showed that it is not only the heavy and physically difficult tasks that cause problems. Short periods of static movements or movements requiring only limited endurance are frequently experienced as difficult to perform and cause increased pain. Many tasks that are considered “light” tend to be highly repetitive and increase the possibility of musculoskeletal pain, suggesting the “windup” phenomenon in action. When necessary, interventions in the work place should be performed and the patient should be advised and supported to carry out necessary changes in daily habits and routines. Examples of employment and home modifications include adjusting the height of a desk and chair, altering the work schedule, avoiding prolonged static sitting by mixing tasks, planning on sharing baby sitting with neighbors to provide time for self, and modifying play with young children by sitting on a sofa with them instead of on the floor.

Clinical Outcomes

The described interventions require that the recipient of services redesign his or her life in a variety of ways, from wearing a hand splint to use of assistive devices or changing the routine patterns of daily living. Change of typical routine is not easy, and it has been estimated that at least 50% of patients with RA are non-compliant with therapy, irrespective of the nature of the intervention (Belcon, Haynes, & Tugwell, 1984; Feinberg & Trombly, 1995). In a study designed to examine the effect of interaction between the patient and the occupational therapist on subsequent splint use, splint use was greater in a group of patients who were treated by a therapist using compliance-enhancing behaviors that included the suggestions in Procedures for Practice 44-4.

PROCEDURES FOR PRACTICE 44-4

Clinical Suggestions for Enhancing Compliance (Feinberg & Trombly, 1995)

Apply Learning Principles to Patient Education

- Patients best remember instructions presented first.
- Emphasized instructions are recalled better.
- The fewer the instructions, the greater the proportion remembered.
- Pace the amount of information to avoid overload.
- Use simple, understandable language without medical jargon.
- Individualize teaching methods to the patient.
- Reinforce essential points by review, discussion, or summary.
- Ask the patient to repeat essential elements of the message.
- Provide written instructions for home reference.
- Devise mechanisms for helping patients to remember advice.

Assess the Patient's Expectations and Experience Concerning the Following

- The clinical encounter
- His or her beliefs and misconceptions about the cause,

severity, and symptoms of the illness and susceptibility to complications or exacerbations

- Goals of treatment
- Perceptions about the costs and risks versus the benefits of treatment
- Existing health-related knowledge, skills, and practices
- Degree of adaptation to the disease
- Sense of self-efficacy or lack of control and hopelessness
- Learning limitations
- Extent of family involvement and influence

Encourage the Patient to Assume Responsibility for Disease Management

- Use behavioral contracts if necessary.
- Use other motivational techniques.
- Encourage the patient that he or she can be successful with self-management.
- Use a facilitating affective tone.
- Listen to the patient.
- Be approachable.
- Appear knowledgeable.
- Inspire trust and confidence.
- Be enthusiastic and expect positive results.

RESEARCH NOTE

Abstract: Reisine, S., Fifield, J., Walsh, S. J., & Feinn, R., (2003). Do employment and family work affect the health status of women with fibromyalgia? *The Journal of Rheumatology*, 30, 2045–2053.

To assess health status differences of women with FM who are employed and not employed and to evaluate whether employment and family work influence the health status of women with FM as it does for women in community studies, 287 women with FM (137 employed and 150 not employed) were compared through completed telephone interviews that collected data on demographic characteristics, health status, symptoms, family work, and social support. The majority of employed and not employed participants reported high levels of symptoms and poor health status. Despite having similar disease duration, employed women reported significantly less pain, less fatigue, and better functional status than those who were not employed. Employment remained a significant factor in explaining number of painful areas, functional status, and fatigue, with employed women reporting better health status than those not employed. The psychological demands of family work were consistently related to all dependent measures of health status, as those with greater psychological demands reported worse health status.

Implications for Practice

- During the occupational therapy assessment process, the importance of work to patients is important to assess. For example, has meaningful employment been abandoned secondary to FM symptoms? Or is current employment becoming compromised secondary to FM symptoms?
- If the patient is working and work is highly valued, FM symptoms interfering with occupational functioning at work need to be closely reviewed, and alterations to the work environment should be recommended.
- If the patient preference is to not be employed outside of the home, the home environment needs to be scrutinized for problems that may be aggravating symptoms, such as fatigue, pain, and/or sleep disturbance. Energy conservation, fatigue management, and other interventions need to be considered to enable successful engagement in occupations related to home management.

Evidence Table 44-1 Best Evidence for Occupational Therapy Practice Regarding Rheumatoid Arthritis (RA), Osteoarthritis (OA), and Fibromyalgia (FM)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Joint protection (RA)	Standard arthritis education program vs. a joint protection program, using educational, behavioral, motor learning, and self-efficacy-enhancing strategies.	65 people were randomly assigned to a joint protection program, and 62 were assigned to the standard program. Groups were similar in age, disease duration, and use of arthritis medications.	Standard: 2.5 hours of joint protection based on typical United Kingdom OT practice (plus 5.5 hours on RA, exercise, pain management, diet, and foot care). Joint protection: four 2-hour weekly meetings as described.	Randomized controlled trial. IA2a	Yes. At 4 years post treatment, the joint protection group continued to have better joint protection adherence, early morning stiffness, and activities of daily living (ADL) scores.	Joint protection behavioral assessment: $p = 0.001$, $r = 0.27$; stiffness: $p = 0.001$, $r = 0.27$; ADL: $p = 0.04$, $r = 0.15$.	Hammond and Freeman (2004)

Evidence Table 44-1 (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Splinting the first CMC joint (OA)	Short opponens splint that maintained the web space and immobilized the CMC vs. long opponens splint that immobilized the wrist, CMC, and first MCP joints. All patients wore both in random sequence.	26 patients (5 men and 21 women) who had radiographic evidence of first CMC OA and joint pain (age, 36 to 88 years; mean age = 57 years). 80% were right-hand dominant; 60% had right-hand involvement. Duration of symptoms ranged from <1 year to >5 years. ⁸ patients had concomitant diagnoses of other impairments.	Patients wore each splint for 1 week at times of feeling symptoms day or night.	Pre-post design; each group and subgroup tested separately before and after splint use. IIIB2b	Yes. Splinting significantly reduced pain in patients with first CMC joint OA. Splinting also significantly reduced subluxation (under stress), especially in the early stages of OA. The splints did not significantly increase pinch strength or lessen the pain associated with pinch, after the splint was removed. Neither splint was more effective than the other. The shorter splint was preferred by most patients.	Pain (<i>Visual Analog Scale</i>): $\chi^2 = 14.0, p = 0.001, r = 0.73$. Percentage of subluxation of first CMC: $F(2,26) = 4.38, p = 0.01, r = 0.45$. Pinch strength: $F(1,24) = 1.38, p = 0.26, r = 0.23$. Pain after 1 week of splint wear: $\chi^2 = 3.92, p = 0.28, r = 0.38$. No significant differences between splints in any tests. ADL (self-rated): 93% of 22 ADLs were easier with the short splint compared with no splint, but 7% were harder; with the long splint compared with no splint, only 16% were reported to be easier. 73% preferred the short splint; 27% preferred the long splint.	Weiss et al., 2000

<p>Interdisciplinary treatment for FM</p>	<p>4-week outpatient program consisting of medical, physical, psychological, and occupational therapies.</p>	<p>67 outpatients with FM (mean age = 48.37 years; SD = 10.99 years).</p>	<p>Pre-treatment 3-hour evaluation (medical, physical, psychological, and self-report inventories). Program was 6.5 day sessions, spaced over a period of 4 weeks. Groups of 4-7 patients attended the program 3 times a week during the first week and once a week for the next 3 weeks. All 4 therapies were administered at each session. OT offered six 1-hour educational sessions regarding body mechanics, energy conservation, and pacing. Patients were given home assignments that were reviewed by the OT at the next session.</p>	<p>One group pre- and post-test design. IIIA3b</p>	<p>Partially. Significant decrease in depression with significant increase in sense of life control (strong effect) and non-significant decrease in sense of perceived disability (small effect).</p>	<p>Results at post treatment significant to OT: <i>Oswestry Disability Index</i> at post treatment: $t_{(66)} = 2.14$, not significant, $r = 0.25$; <i>Multidimensional Pain Inventory—Life Control Subtest</i>: $t_{(66)} = -5.47$, not significant, $r = 0.56$.</p>	<p>Turk et al., 1998</p>

SUMMARY REVIEW QUESTIONS

1. List the primary differences between RA and OA.
2. Describe joint problems that can lead to diminished occupational functioning for people with RA and OA
3. Besides joint problems, what clinical problems can affect occupational functioning for people with RA?
4. Is a patient with only thumb CMC joint involvement and resultant pain on resistive motion more likely to have OA or RA?
5. Describe joint protection techniques used for people with RA to prevent or restore occupational functioning.
6. Name several resources for patients with RA and OA to find adapted tools to enhance their occupational functioning.
7. How is splinting used for people with RA and OA to enhance occupational functioning?
8. What assessments are used to optimize occupational functioning for people with RA, OA, and FM?
9. What are the major symptoms of FM that lead to diminished occupational functioning?

CHAPTER 45

Burn Injuries

Monica A. Pessina and Amy C. Orroth

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Differentiate between superficial, superficial partial-thickness, deep partial-thickness, and full-thickness burn injuries.
2. Explain the rationale for splinting and positioning programs for patients with burn injuries.
3. Outline occupational therapy treatment techniques for each phase of burn recovery.
4. Describe potential complications and treatment strategies for hand burns.
5. Discuss the effects of a burn injury on a patient's psychosocial functioning.

Glossary

Anti-deformity positions—Positions opposite to common patterns of deformity used to prevent contractures.

Blanch—Apply sufficient pressure to interrupt blood flow temporarily; an assessment of capillary flow rate.

Deep partial-thickness burn—Thermal injury that destroys cells from the epidermis to the deep dermal layer.

Debride—Remove eschar and loose or necrotic tissue to prevent infection and promote healing.

Dermis—Layer of skin below the epidermis that contains blood vessels, nerve endings, hair follicles, and sweat and oil glands; supports the regrowth of new epithelial tissue.

Epidermis—Most superficial layer of the skin; acts as a barrier. It is continually sloughed and replaced.

Eschar—Burned tissue.

Full-thickness burn—Thermal injury in which the epidermis and dermis are destroyed.

Superficial burn—Thermal injury that involves only cells in the epidermis.

Superficial partial-thickness burn—Thermal injury in which the epidermis and upper portion of the dermal layer are destroyed.

Wound contracture—Part of normal healing in which myofibroblasts in the wound bed contract to minimize the skin defect.

Z-plasty—Surgical procedure in which a Z-shaped incision is made and tissue is transposed to increase tissue length.

Approximately 1.25 million burn injuries occur in the United States each year, resulting in 5,500 fire- and burn-related deaths (Brigham & McLoughlin, 1996). Thermal damage to the skin can be caused by fire, contact with a hot object or hot liquid (scald burn), radiation, chemicals, or electricity. Almost 80% of burn injuries occur in and around the home, and hot food and liquid spills are the most common source of burns to children (Brigham & McLoughlin, 1996). On average, 45,000 acute hospital admissions occur annually for burn injuries. Approximately half of these patients are admitted to regional burn centers designated by the American Burn Association; the remainder are treated at local or regional hospitals (Burn Foundation, 1999). Therefore, every occupational therapist should understand the principles of care and rehabilitation of patients with burn injuries. Treatment of these injuries requires a comprehensive approach by a qualified burn treatment team, including a skilled occupational therapist. This chapter explores the unique role of occupational therapy in treatment of burn patients, from the initial injury to the patient's return to independent function. Topics include various phases of burn rehabilitation, scar management, psychosocial issues, and reconstructive surgery. We hope to convey the unique and rewarding aspects of working with patients with burn injuries.

BURN CLASSIFICATION

In the past, burn depth was classified as first, second, or third degree. Today, the preferred classification system more accurately describes the level of cellular injury. The

terms in use are superficial, superficial partial-thickness, deep partial-thickness, and full-thickness. Burns typically have mixed depths, which necessitates that the burn team carefully assess the appearance and progress of each area of the wound site. Disruption of any portion of the skin has the potential to interfere with its normal functions, which include temperature regulation, excretion, sensation, vitamin D synthesis, and acting as a barrier against infection and dehydration (Falkel, 1994). Occupational therapists may treat patients with all levels of thermal injury. It is important to differentiate among the classifications to plan appropriate intervention.

Superficial Burns

Superficial burns damage cells only in the epidermis (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994) (Fig. 45-1). These injuries are painful and red. They heal spontaneously within approximately 7 days and leave no permanent scar (Malick & Carr, 1982).

Superficial Partial-Thickness Burns

Superficial partial-thickness burns damage cells in the epidermis and the upper level of the **dermis** (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994). The most common sign of a superficial partial-thickness burn is intact blisters over the injured area (Staley, Richard, & Falkel, 1994). These injuries are also painful because of the irritation of the nerve endings in the dermal layer. Superficial partial-thickness burns heal spontaneously within 7–21 days and leave minimal or no scarring (Staley, Richard, & Falkel, 1994).

Figure 45-1 Cross-section of the skin. (From Willis, M. C. [1996]. *Medical terminology: The language of health care* [p. 90]. Baltimore: Williams & Wilkins.)

Deep Partial-Thickness Burns

Deep partial-thickness burns cause cell injury in the **epidermis** and severe damage to the dermal layer (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994). These injuries appear blotchy, with areas of whitish color interspersed throughout the wound (Malick & Carr, 1982). The injury site is painful. Pressure sensation is intact, but light touch is diminished (Staley, Richard, & Falkel, 1994). Spontaneous healing of deep partial-thickness burns is sluggish (3–5 weeks) because vascularity in the dermal layer is impaired. Therefore, the risk of significant scarring is increased (Staley, Richard, & Falkel, 1994). For this reason, deep partial-thickness burns are often grafted to expedite healing and minimize scarring.

Full-Thickness Injury

In a full-thickness injury both the epidermis and the dermal layer are destroyed (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994). These wounds appear white or waxy and are inherently insensate because of the complete destruction of

the dermal nerve endings (Malick & Carr, 1982). Full-thickness burns require surgical intervention, such as skin grafting (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994), since there are no dermal elements to support the regrowth of epithelial tissue. Some burns, such as electrical burns, may damage structures below the dermis, including subcutaneous fat, muscle, or bone.

RULE OF NINES

A commonly used technique to determine burn size in adults is the rule of nines (Fig. 45-2). To determine burn size in children and infants, a modification of this technique, the Lund-Browder chart, is used. The percentage of total body surface area (TBSA) that has been burned is used for the following:

- Calculating nutritional and fluid requirements
- Determining level of acuity to establish the level of medical treatment needed (i.e., admission to an intensive care unit)
- Classifying patients for use of standardized protocols

Figure 45-2 Rule of nines. (Reprinted with permission from Malick, M. H., & Carr, J. A. [1982]. *Manual on management of the burn patient* [p. 10]. Pittsburgh: Harmarville Rehabilitation Center.)

PHASES OF BURN MANAGEMENT AND REHABILITATION

Identifying specific phases of burn management helps to describe the role of occupational therapy for patients with burn injuries. These include the emergent, acute, and rehabilitation phases. Each of the phases, along with accompanying occupational therapy considerations, are described.

Emergent Phase

The emergent phase of a burn injury is considered to be from initial injury to approximately 72 hours post burn (Grigsby deLinde & Miles, 1995).

Medical Management

During the emergent phase, the medical team attempts to stabilize the patient. This may include fluid resuscitation, establishment of adequate tissue perfusion, and achievement of cardiopulmonary stability. Associated injuries, such as fractures, are evaluated and treated during this time.

Inhalation Injury

An important consideration in the emergent phase is the possibility of an inhalation injury. Damage to the upper airway as a result of inhaling either hot particles or noxious gases results in an inhalation injury. This damages the respiratory epithelium and can impair gas exchange. Inhalation injuries can significantly increase mortality rate (Cioffi & Rue, 1991). Singed eyebrows, soot around the nares, and facial edema are indications of an inhalation injury (Cioffi & Rue, 1991). Diagnosis is confirmed by analysis of arterial blood gases, chest radiographs, and bronchoscopy. In addition, edema can quickly develop in the airway and constrict breathing. Therefore, patients with significant burn injuries are usually intubated (placed on mechanical ventilation) to maintain an open airway until the risk of airway closure due to edema has diminished.

Escharotomy and Fasciotomy

Circulation can be compromised when burn injuries girdle a body segment. This is due to the inelasticity of the **eschar** (burned tissue) combined with increased internal pressure within fascial compartments. Local increase in pressure in the extremities compresses blood vessels and reduces blood flow (Sheridan et al., 1995). Symptoms of increased compartmental pressure include paresthesias, coldness, and decreased or absent pulses in the extremities. In the trunk, inelastic eschar can act as a corset, limiting lung expansion and preventing adequate respiration. In both cases, surgical intervention (escharotomy and/or fasciotomy) is required to relieve the pressure and prevent tissue death. An escharotomy is a surgical incision through the eschar, whereas a fasciotomy is a deeper incision extending through the fascia. Unless exposed tendon is present, the escharotomy region can be mobilized during therapy (Grigsby deLinde & Miles, 1995).

Dressings

After the initial burn assessment, the nursing staff applies dressings. The functions of dressings include protecting the wound against infection, maintaining contact between the topical agent and the wound, superficially **debriding** the wound, and providing comfort for the patient (Grigsby deLinde & Miles, 1995). Debriding is the removal of devitalized tissue from the wound site. Types of topical agents vary widely, although most are wide-spectrum antimicrobials. Examples include mafenide acetate (Sulfamylon), silver sulfadiazine (Silvadene), and 0.5% silver nitrate solution (Duncan & Driscoll, 1991). As a rule, the nursing staff changes the dressings; however, by periodically participating in dressing removal and application, the occupational therapist makes opportunities to view the healing wounds. This allows the therapist to monitor healing and adjust the therapy program accordingly.

PROCEDURES FOR PRACTICE 45-1

Hand Washing

Hand washing is the easiest and most effective thing you can do to prevent infections for you and your patients.

When to Wash

- Before and after all patient contact
- After removing gloves used to perform a task involving contact with blood, body fluids, or infectious material
- After handling possibly infectious devices or equipment
- Before and after preparing and eating food

General Procedure

- Dispense paper towel
- Push up long sleeves
- Wet hands and wrists
- Apply antiseptic solution or soap
- Use friction to clean between fingers, under nails, and palms and backs of hands; effective scrubbing lasts at least 20–30 seconds
- Rinse hands and towel dry
- Turn off faucet using paper towel
- Dispose of paper towel in appropriate trash barrel
- Waterless hand cleaner can be used until hand washing facilities are available

Infection Control

One of the functions of the skin is to act as a barrier against infection (Falkel, 1994). Therefore, a patient with a burn injury is susceptible to infection. It is essential that all staff, family, and visitors adhere to infection control procedures. This includes frequent hand washing, use of gloves when necessary, and avoiding cross-contamination through instruments and equipment (Procedures for Practice 45-1).

Contracture Formation

Patients with burn injuries are at significant risk for contractures. **Wound contracture**, a normal physiological response to an open wound (Greenhalgh & Staley, 1994; Staley, Richard, & Falkel, 1994), combined with prolonged immobilization, creates an opportunity for permanent soft tissue contracture. Contractures tend to occur in predictable patterns, usually flexed, shortened positions (e.g., elbow flexion, shoulder adduction, knee flexion) and can considerably limit the patient's ability to perform activities

of daily living (ADL). For example, decreased elbow extension may limit the patient's ability to dress.

Occupational Therapy Assessment During the Emergent Phase

During the emergent phase, the occupational therapist performs a screen of the patient's needs. A full evaluation is deferred until after the emergent phase, when the patient is more medically stable. During the screen, the therapist notes the distribution of the burn and which joints are involved. This allows the occupational therapist to establish an appropriate splinting and positioning program. It is also during this time that the therapist begins collecting information regarding the patient's functional status before admission, including individual interests and social supports.

Occupational Therapy Intervention During the Emergent Phase

Occupational therapy in the emergent phase focuses on the prevention of early contracture formation through the use of splints and positioning programs. It is ideal to initiate occupational therapy intervention as early as 24–48 hours after burn because collagen synthesis and contracture formation begin during the initial response to thermal injury (Evans & McAuliffe, 1995; Institute for Healthcare Quality [IHQ], 1997).

Splinting

Ideally, splints are fabricated and applied in the initial visit, and a positioning program is established and communicated to the team. Table 45-1 describes common contracture patterns, **anti-deformity positions**, and appropriate splints. Generally, any joint involved in a superficial partial-thickness injury or worse has the potential for contracture and is usually splinted. Splint wearing times are determined by the patient's ability to use the involved extremity. That is, a decrease in active movement indicates the need for increased splint wearing time. For example, a heavily sedated patient cannot perform active movement and, therefore, requires splinting at all times except for therapy and dressing changes. An alert patient who can use his or her affected extremity for functional tasks, such as self-feeding or prescribed exercises, may require the use of splints only at night. Splints are applied over the burn dressing and secured with either gauze wrap or Velcro straps.

Positioning

Anti-deformity positioning, which is used as an adjunct to splinting for prevention of contractures, can be initiated in the first visit. For example, if a patient is unable to be fitted with a custom wrist extension splint, supporting the hand on a rolled pillow can, at least temporarily, maintain appropriate joint position. Elevating the upper extremity

Table 45-1. Anti-Contracture Positioning by Location of Burn

Location of Burn	Contracture Tendency	Anti-Contracture Positioning and/or Typical Splint
Anterior neck	Neck flexion	Remove pillows; use half-mattress to extend the neck; neck extension splint or collar
Axilla	Adduction	120° abduction with slight external rotation; axilla splint or positioning wedges; watch for signs of brachial plexus strain
Anterior elbow	Flexion	Elbow extension splint in 5–10° flexion
Dorsal wrist	Wrist extension	Wrist support in neutral
Volar wrist	Wrist flexion	Wrist cockup splint in 5–10° flexion
Hand dorsal	Claw hand deformity	Functional hand splint with MP joints 70–90°, IP joints fully extended, first web open, thumb in opposition (safe position; see Chapter 42)
Hand volar	Palmar contracture Cupping of hand	Palm extension splint MPs in slight hyperextension
Hip-anterior	Hip flexion	Prone positioning; weights on thigh in supine; knee immobilizers
Knee	Knee flexion	Knee extension positioning and/or splints; prevent external rotation, which may cause peroneal nerve compression
Foot	Foot drop	Ankle at 90° with foot board or splint; watch for signs of heel ulcer

Reprinted with permission from Pessina, M. A., & Ellis, S. M. (1997). Rehabilitation. *Nursing Clinics of North America*, 32, 367.

ties can also help to minimize upper extremity edema. Elevation can be done with foam wedges, pillows, or specialized arm troughs attached to the bed. A risk of upper extremity elevation is the potential for brachial plexus strain. Symptoms of brachial plexus strain include tingling, numbness, and cold fingers.

Acute Phase

The acute phase begins after the emergent phase and continues until the wound is closed, either by spontaneous healing or skin grafts (Grigsby deLinde & Miles, 1995). The acute phase can last several days to several months, depending on the extent of the burn and the amount of grafting required.

Support and Psychosocial Adjustment in the Acute Phase

All patients with burn injuries, regardless of age, exhibit some of the same psychological responses, including withdrawal, denial, fear of death, regression, anxiety, depression, and grief (Wright, 1984). In addition, various factors can influence a burn patient's psychological status. These include emotional trauma arising from the hospital stay, the length of the hospital stay, adjustment to physical changes, adjustment to others' reactions, and location and depth of the burn injury (Baker et al., 1996; LeDoux et al., 1996). Baker et al. (1996) refer to two stages of psychosocial recovery: the first alert stage and the pre-discharge stage. Performance can vary considerably between the two phases. During the first alert stage, the patient initially orients to the burn

injury; a severely burned patient may simply be happy to be alive (Baker et al., 1996). It may not be until later, as the patient enters the rehabilitation phase and approaches the pre-discharge stage, that he or she begins to deal with the limitations in physical function. The patient, however, may also exhibit early signs of depression and withdrawal, and early assessment of the patient's psychosocial status is essential. LeDoux et al. (1996) state that the burn team can foster healthy coping strategies while working with the burn patient by using these techniques:

1. Identify strengths that each patient can emphasize, reminding him or her of the strength already involved in surviving a painful and frightening experience.
2. Validate sadness and fear.
3. Assist patient to achieve goals; this helps to show hope for the future.
4. Instill a belief that the patient can succeed.

Team Communication

Communication with all members of the team, including the patient and the patient's family and/or support system, throughout hospitalization is essential. During this acute phase, collaboration between the occupational therapist and the burn team is essential for several reasons, including (Pessina & Ellis, 1997):

1. Alerting the team to developing contractures and response to therapeutic intervention
2. Planning for perioperative splinting

3. Clarifying range-of-motion orders based on graft integrity
4. Teaching the team about environmental modifications or communication systems
5. Advocating on the patient's behalf regarding eventual outpatient needs

Medical Management

Skin grafting, which occurs primarily in the acute phase, is required when the dermal bed is sufficiently destroyed to prevent or significantly impair spontaneous regrowth of the epithelial tissue (Grigsby deLinde & Miles, 1995). If reepithelialization of the burn site has not occurred within 14 days of the injury or is not expected, grafting would be considered (Kagan & Warden, 1994). Skin grafting is generally performed for all **full-thickness burns** and for large, deep partial-thickness burns. Skin grafting entails both excision of necrotic (dead) tissue and the placement of skin or a skin substitute over the wound bed.

Types of Grafts

A variety of grafting procedures are available to the burn team. According to the size of the burn and the medical stability of the patient, the team may opt to use one or more of the graft types described next.

AUTOGRAFTS

Skin harvested from an unburned area of the patient is an autograft. Split-thickness autografts, the most frequently used, are taken at the level of the mid dermis (IHQ, 1997; Staley, Richard, & Falkel, 1994). Donor sites are ideally selected for the best match of color and texture to the affected area. As donor sites produce mild scarring, their location, when possible, is in an inconspicuous site, such as the upper thigh. The harvested skin can be left as a solid sheet (sheet graft) or perforated to increase surface area (meshed graft) (Staley, Richard, & Falkel, 1994). Meshing allows the surface area of the harvested skin to cover up to four times the original area. Both sheet and meshed grafts have advantages and disadvantages. A sheet graft has the best cosmetic outcome and is thus preferred for the face and hands (Duncan & Driscoll, 1991). Infection and the development of hematoma under a sheet graft, however, can cause complete graft loss and require regrafting. A meshed graft, although less cosmetically appealing (the meshed pattern is retained permanently), covers large areas when the donor site is limited. In addition, meshed grafts allow drainage of blood and exudate, which prevents hematomas and improves graft adherence (Duncan & Driscoll, 1991).

TEMPORARY GRAFTS

In cases of extensive burn injuries, where there is not sufficient donor skin to cover all of the affected area with auto-

graft, the burn team may opt to use temporary grafts until the donor site has healed sufficiently for reharvesting. These temporary dressings aid in wound management by decreasing infection, stimulating healing and preparing the wound bed for autograft skin, decreasing pain, and protecting exposed tendons, nerves, and blood vessels (Duncan & Driscoll, 1991). Examples include xenografts (medically manipulated bovine skin), allografts (cadaver skin), and biological dressings, such as Biobrane.

Occupational Therapy Assessment During the Acute Phase

During the acute phase, the occupational therapist performs a detailed initial evaluation. This includes a thorough chart review to determine the history of the wound and associated injuries. Previous medical history is also important. Associated diagnoses that may limit occupational performance, such as psychiatric illness, diabetes, or lung disease, are to be noted and accounted for during occupational therapy treatment planning. Areas specifically assessed by the occupational therapist during the initial evaluation include:

- ADL and instrumental activities of daily living (IADL)
- Psychosocial status and support systems
- Behavior and communication
- Cognitive-perceptual status
- Neuromuscular status (range of motion, strength, sensation)
- Activity tolerance

Evaluation can consist of observation during task performance, interviews with patient and family, and the use of standardized tests such as the *Functional Independence Measure* (Uniform Data System for Medical Rehabilitation, 1997). The potential for permanent scarring and disfigurement may cause significant anxiety and limit the patient's ability to participate in rehabilitation. Thus, early identification of the patient's support systems can improve functional outcomes.

Occupational Therapy Intervention During the Acute Phase

Due to the acute medical nature of many burn injuries, treatment in the acute phase focuses on capacities and abilities such as range of motion and strength. These are addressed through continued splinting, positioning, exercise, and activity. Other potential treatment activities include environmental modifications, pain remediation, environmental adaptation, and patient and family education. In the acute phase, the individual's ability to participate in treatment related to self-care and functional retraining is often limited by complex medical issues. These areas are addressed in detail during the rehabilitation phase.

Splinting and Positioning

During the acute phase, the splinting and positioning programs established in the emergent phase are continually monitored and adjusted. Splinting schedules are adjusted according to the individual's ability to participate in an exercise and positioning program. For example, if a patient consistently uses an affected elbow for self-feeding and ADL during the day, decreasing the wearing time for the elbow splint to nights and rest periods is appropriate. Conversely, a patient who cannot follow through with an exercise and positioning program because of impaired alertness or poor motivation should wear a splint continuously except for dressing changes and therapeutic activity. It is imperative to check all splints daily to ensure proper fit and function. In addition, teaching the nursing staff proper fit and application of splints can decrease the potential for complications (Pessina & Ellis, 1997).

Exercise and Activity

In the acute phase, splinting and positioning are used in combination with exercise and activity. Exercise is especially important to control edema and prevent muscle atrophy, tendon adherence, joint stiffness, and capsular shortening (Harden & Luster, 1991). Exercise types include passive range of motion, active range of motion, active assistive range of motion, and functional activity. If the patient cannot participate in active exercise or activity because of poor medical status or impaired level of alertness, passive range of motion is indicated. Active exercise is encouraged whenever possible, however, (Burke Evans et al., 1996; Wright, 1984), and it is the role of the therapist to guide the patient toward function. Within a single treatment session, a patient may participate in all of these forms of exercise. In fact, functional activities may be used to improve active range of motion. Exercise and activity programs are performed up to five times daily (Wright). Contraindications to exercise include exposed tendons, recent autografts (approximately 5–10 days), acute medical complications, and fractures (Duran-Coleman, 1991; Grigsby deLinde & Miles, 1995; Staley, Richard, & Falkel, 1994). In addition, periodic inspection of the wound by the occupational therapist is essential to determine status of wound healing and skin integrity as related to tolerance of the exercise program.

Perioperative Care

The 5–10 days after a skin graft procedure is the perioperative period. A patient with a large burn injury may make many trips to the operating room for skin grafting. Each surgical procedure begins a new perioperative stage. For example, a patient needing grafting on the trunk, arms, and legs may make three trips to the operating room, with each successive area requiring proper perioperative care. The role of the occupational therapist in the perioperative period is to fabricate custom splints to immobilize the

newly grafted areas in anti-deformity positions. Ideally, splints are fabricated immediately prior to or during surgery and applied at the conclusion of the surgery. These splints usually stay in place, along with the primary dressing, for 5–10 days (Duran-Coleman, 1991; Grigsby deLinde & Miles, 1995). During this time, range-of-motion exercises are contraindicated to allow for graft adherence. After the primary dressing is removed, the burn team assesses the graft adherence, and a determination is made regarding the appropriateness of resuming exercise.

Pain Management

The occupational therapist must address pain issues that arise during treatment. Many patients in intensive care cannot verbalize subjective response to manipulation, such as during dressing changes or exercise. In these cases, the therapist monitors objective responses to pain, such as blood pressure, heart rate, and respiratory rate, and adjusts the treatment accordingly. If necessary, the time of the treatment may be changed to allow pain medication to be administered. Decreased repetitions and increased rest breaks during exercise sessions may also be appropriate. Other techniques used to manage pain throughout recovery include distraction techniques, meditation, and visualization. Activity context and emotional state can also affect perception of pain (Dubner & Ren, 1999).

Environmental Adaptation

Beginning in the acute phase and throughout recovery, the occupational therapist provides modified call buttons and bed controls, voice-activated telephone systems, and modified utensils (Fig. 45-3) and self-care items. These modifications, combined with patient, staff, and family education, can increase a patient's sense of control and independence. The development of environmental modifi-

Figure 45-3 Modified utensils can increase independence in the acute phase.

cations is limited only by the patient's motivation and the therapist's creativity.

Patient and Family Teaching

The occupational therapist provides members of the patient's support system with guidance regarding ways to interact with and support the patient during recovery. They may be encouraged to make tape recordings and posters or to bring in favorite music or foods. They may need to learn new ways to touch or comfort their loved one. In addition, the family and friends provide a source of information regarding the patient's vocational and avocational roles and available community resources if the patient cannot communicate this information. An educated family and/or support system can be an important asset for ensuring follow-through of exercise and splinting programs and for encouraging participation in functional activities (Duran-Coleman, 1991).

Discharge Planning

Since hospital stays are generally short, discharge planning begins as soon as possible after admission (Fletcher & Hickerson, 1995; Rivers & Jordan, 1998). Many patients in the acute phase are discharged directly home or leave a burn center for continued care on a rehabilitation unit. Elements to consider during discharge planning are the availability of community resources for outpatient or follow-up care, support systems available to the patient, and physical demands of the home environment. When patients who have sustained major burns cannot return to the hospital where they received acute care, it is important for the inpatient occupational therapist to establish a relationship with a therapist in the patient's community to ensure continuity of care throughout the rehabilitation phase. In accordance with the knowledge and experience of the community therapist, the discharging therapist provides appropriate literature and written, photographic, and/or videotaped descriptions of the rehabilitation program. This establishes a communication channel for the community therapist so questions and concerns can be addressed in a timely manner. Whenever possible, all authorization from third-party payers should be established prior to discharge (Fletcher & Hickerson, 1995) to avoid delays in the initiation of outpatient therapy. If a patient cannot be discharged directly to home, transfer to an inpatient rehabilitation facility is appropriate; again, early communication with the receiving therapist is necessary to ensure continuity of care. Regardless of the discharge setting, well-briefed patients are best able to advocate for appropriate care.

Rehabilitation Phase

The rehabilitation phase follows the acute phase and continues until scar maturation (Rivers & Jordan, 1998). Scar maturation can take 6 months to 2 years (Rivers & Jordan,

1998; Staley, Richard, & Falkel, 1994). It is considered complete when the scar becomes pale and the rate of collagen synthesis levels off (Grigsby deLinde & Miles, 1995). The level of direct involvement of the occupational therapist during this extended time is varied. It may range from daily inpatient treatment to weekly outpatient treatment to annual clinic visits.

Occupational Therapy Assessment During the Rehabilitation Phase

During the rehabilitation phase, the occupational therapist continues to assess capacities and abilities such as range of motion and strength. In addition, functional assessments specific to self-care and homemaking are valuable in guiding treatment planning and preparing for discharge. Standardized tests, such as the *Functional Independence Measure* (Uniform Data System for Medical Rehabilitation, 1997) and the *Valpar Work Samples* (Resources 45-1) are important because they provide objective data.

Occupational Therapy Intervention During Rehabilitation Phase

The overall goal of this phase is to facilitate the patient's return to his or her previous level of occupational performance. Patients are encouraged to take increasing responsibility for their care, including helping to establish meaningful goals. In addition to range of motion and strength, occupational therapy also focuses on activity tolerance, sensation, coordination, scar management, and self-care and home management skills.

Range of Motion

In the rehabilitation stage, the patient continues to benefit from daily stretching routines established in the acute

phase of care. In the early part of this phase, the rate of collagen synthesis is increased (Staley, Richard, & Falkel, 1994), requiring the patient to stretch frequently throughout the day. As the scar matures and collagen synthesis slows, decreased frequency of stretching is required. At all times, skin integrity must be monitored during stretching to prevent tearing. Massage using a non-water-based cream should precede stretching to help prevent dry skin from rupturing (Rivers & Jordan, 1998). An appropriate stretch consists of bringing the tissue to the point of **blanching**, or becoming pale, and holding it in that position for several seconds. The patient should report tension but not pain. Overzealous stretching can result in tissue tears and edema, which increase joint stiffness. Stretching is initially performed by the occupational therapist. With training, however, the patient and/or caregiver can also complete stretching routines.

Strength

Resistive exercise and graded functional activities can improve strength. For example, a patient may be taught an independent exercise program with resistive rubber ribbon or tubing, such as Theraband, to increase proximal upper body strength. Patients also gain strength as they perform self-care activities, such as progressing from sitting to standing for hygiene activities.

Activity Tolerance

A key feature of rehabilitation is mobilizing the patient as much as possible, thereby increasing the patient's activity tolerance. For an inpatient, this includes increased time spent out of bed and trips to the gym and off the nursing unit. For an outpatient, this may mean resuming leisure activities and going on community outings.

Sensation

Newly healed skin and grafted skin may be hypersensitive. Hypersensitivity can be addressed effectively by systematic desensitization. This can be achieved by asking the patient to manipulate objects with varying textures in the environment. Initially, the patient practices holding soft textures, such as cotton balls or lambswool, and then progresses to manipulating objects with rougher textures, such as Velcro or burlap. Sometimes a formal system such as the Downey desensitization program (Barber, 1990) is used (see Chapter 27).

Coordination

Coordination can be impaired by a variety of factors, including limited range of motion, strength, or sensation. Coordination can be improved through the use of selected progressive tasks designed to challenge the patient's skills. For example, a patient may be asked first to take lids

Figure 45-4 Coordination can be addressed with use of simulated or actual functional tasks.

off large jars and then smaller containers (Fig. 45-4). The patient may also trace large letters or patterns before attempting to work a crossword puzzle.

Scar Management

Scar tissue formation is a natural response to wound healing (Grisby deLinde & Miles, 1995). It begins in the emergent phase and may take up to 2 years (Poh-Fitzpatrick, 1992). A hypertrophic scar is an aberration of the normal healing process and presents as a red, raised, and inelastic scar (Abston, 1987) (Fig. 45-5). A hypertrophic scar contains an increased number of fibroblasts as compared to normal skin, and the collagen fibers are arranged in a nodular as opposed to parallel fashion (Abston, 1987). There is thought to be a disruption in the balance between collagen synthesis and lysis (Grigsby deLinde & Miles, 1995). The tendency for hypertrophic scarring is unique to each individual. In general, patients with large amounts of pigment in the skin and young patients are most prone to hypertrophic scarring. Hypertrophic scarring is also inversely related to the depth of the initial burn wound (Staley, Richard, & Falkel, 1994). In addition to being cosmetically unappealing, hypertrophic scars can limit functional skills by restricting joint range of motion.

OCCUPATIONAL THERAPY ASSESSMENT OF SCARS

The *Burn Scar Index* (*Vancouver Scar Scale*) is the most widely used standardized scar assessment tool and is used to rate the pliability, vascularity, height, and pigmentation of scars (Sullivan et al., 1990). Used periodically, the *Burn Scar Index* can help guide the occupational therapist in determining effective scar management and evaluating the stage of scar maturation. Other assessments include the *Patient and Observer Scar Assessment Scale* (Draaijers et al., 2004) and the *Matching Assessment of Scars and Photographs* (Masters, McMahon, & Svens, 2005).

Figure 45-5 Hypertrophic scars on the neck (A) and hand (B). The hypertrophic scar on the dorsum of the hand causes claw hand deformity.

OCCUPATIONAL THERAPY INTERVENTION AND SCAR MANAGEMENT

The occupational therapist attempts to prevent or limit the development of hypertrophic scars. Treatment methods include a combination of techniques, including massage, pressure therapy, and the use of specialized inserts.

Massage

Massage may be useful in reducing scar contracture (Staley, Richard, & Falkel, 1994). Scar massage is initiated when it is determined that the injured area can withstand slight friction. In addition, scar massage maintains suppleness,

as normal sweat and oil gland function is often disrupted. Scar massage also aids in desensitization. Scar massage is performed several times daily with deep pressure (enough to blanch the scar temporarily) in either a circular pattern or perpendicular to the long axis of the scar. Lotion is used during massage to reduce friction. Perfume-free lotions are preferred to decrease potential irritation to newly healed skin. Initially, scar massage is the responsibility of the occupational therapist so that skin integrity and tolerance can be monitored. Once an established routine has been developed, the therapist teaches the patient and/or caregivers to assume responsibility for daily scar massage.

Pressure Dressings and Garments

Pressure dressings and garments are another form of scar management that has been advocated in the literature (Chang et al., 1995; Ward, 1991). The flattened, smooth, supple appearance of the scar after application of pressure has been reported clinically, but objective support has been inconclusive (Grigsby deLinde & Miles, 1995; Ward, 1991). The occupational therapist initiates the application of gentle pressure via Tubigrip, elastic bandage wraps, Coban, or Isotoner gloves (Fig. 45-6). Initially pressure dressings are applied for 2-hour intervals. Wearing time is gradually increased by 2-hour increments until 24-hour wear is tolerated. Tolerance is determined by lack of blisters or open areas. At this point, increased pressure using customized products such as Jobst or Bioconcepts garments is indicated (Fig. 45-7). Staley, Richard, and Falkel (1994) suggest that the application of 25 mm Hg of pres-

Figure 45-6 Gentle pressure is applied using Coban and Tubigrip.

Figure 45-7 Custom pressure garments can be worn while performing simulated functional activity.

sure is ideal to aid in collagen organization, which ultimately helps decrease scar tissue formation. Custom garments cause notable shearing during application and removal and thus should be used only when the skin is healed sufficiently to withstand these forces. Wearing of custom garments continues until the scar is inactive, or mature, as described earlier. The therapist's role is to initiate the ordering of custom garments and oversee their use. Most providers of custom garments send trained personnel to measure the patient for custom fitting. For facial burns, the patient may use a transparent facial orthosis secured by elastic straps to provide even pressure distribution. These orthoses are usually fabricated by a specially trained orthotist at the request of the therapist.

Inserts are often used in conjunction with pressure garments. They may be constructed from products such as Otoform, Elastomere, or closed cell foam. Their purpose is to increase pressure in concave areas, such as the web spaces and the sternoclavicular depression. Silicone inserts have also been demonstrated to be effective in improving some characteristics of hypertrophic scars

(Ahn, Monafo, & Mustoe, 1989), although the mechanism of action remains to be determined. The design of a scar management program is determined by the available resources, careful clinical observation, and the patient's ability to comply with the program (Evans & McAuliffe, 1995). Periodic outpatient visits to occupational therapy or an established burn clinic throughout the rehabilitation phase allow for monitoring and adjustments of the scar management program.

Self-Care and Home Management Skills

If neuromuscular limitations impede the patient's performance of functional tasks, the therapist may provide adaptive equipment, such as built-up handles for impaired grasp or long-handled utensils for decreased elbow flexion. Teaching adaptive techniques, such as performing certain activities using two hands for extra support, may also improve function.

Patient and Family Teaching

Patients should understand the rationale for each of the splints and techniques used in their care. They participate in the development of goals, so that they are invested in achieving them. Skin care is an important element in discharge teaching. Patients practice monitoring their skin for breakdown and caring for their skin, including the daily use of a moisturizer. They learn to use a sunscreen with an SPF of at least 15 (reapplied frequently) if they anticipate exposure to the sun (Staley, Richard, & Falkel, 1994). In addition, patients should have a basic understanding of wound healing and tissue response to exercise and scar management techniques.

Support and Psychosocial Adjustment During the Rehabilitation Phase

Although the patient and family typically focus on survival immediately after injury, many other issues arise during rehabilitation. For example, guilt or embarrassment regarding the injury may lead the patient to withdraw. The patient may also begin questioning his or her ability to return to the role of a parent or provider, which creates anxiety. Patients may have fear about their ability to maintain relationships and be concerned regarding sexual functioning. The increase in activity in the rehabilitation phase not only assists physical rehabilitation but also assists patients to discover how their injury affects their daily lives. Emotional reactions to the realization of loss may produce a wide range of behaviors, such as crying and expression of anger. Patients may also have responses related to post-traumatic stress disorder, such as flashbacks.

One of the most difficult challenges for the burn therapist is caring for patients as they grieve for a functional limitation or alteration in body image (Pessina & Ellis, 1997). The occupational therapist supports the patient by encour-

aging questions and verbalization of feelings about the burn injury (Pessina & Ellis, 1997). The occupational therapist also chooses treatment activities to restore confidence and self-esteem. Group activities provide opportunities for socialization and sharing of concerns in a safe environment (Summers, 1991). Given the extensive contact with the patient throughout all phases of recovery, the occupational therapist is in a unique position to identify and address psychosocial issues, but consultation with other specialists on the burn team (e.g., nursing staff, family members, social workers, and psychologists) is essential.

Potential Complications

In addition to the potential for soft tissue contractures and loss of joint range of motion, other complications may occur in any phase of burn recovery.

Pruritus

Pruritus (persistent itching) is a common complication (IHQ, 1997; Staley, Richard, & Falkel, 1994), presumably due to nerve regeneration. It usually resolves within 2 years of the initial injury (Poh-Fitzpatrick, 1992). The use of compression garments, skin moisturizers, cold packs, and medications such as antihistamines may alleviate itching (IHQ, 1997).

Microstomia

Patients with facial burns in the area of the mouth are at risk for oral commissure contracture (microstomia) (Rivers & Jordan, 1998), which is tightening of the musculature around the lip area that limits mouth opening. In extreme cases, urgent surgical revision is required. This risk is exaggerated if the patient has undergone prolonged periods without eating or speaking because of intubation or respiratory compromise. In addition to daily scar massage, the therapist can teach the patient facial stretching exercises, such as yawning or grinning widely and pursing lips together. The exercises can be combined with the wearing of a microstomia splint to stretch the oral commissure. The splint may be worn as tolerated, usually starting with 10 minutes and gradually increasing to 60 minutes twice a day. These devices can be purchased or constructed by the occupational therapist. The cognitive level of the patient is an extremely important factor in use of a microstomia device because of the risk of an unexpected airway emergency. For example, a heavily sedated or confused patient may attempt to swallow the device.

Heterotopic Ossification

Heterotopic ossification, or myositis ossificans, is the development of new bone in tissues that normally do not ossify. It occurs in up to 13% of patients with major burns (Dutcher & Johnson, 1994). The most common location in the burn-

injured population is the elbow, although the shoulder, knee, and hip can also be affected (Dutcher & Johnson, 1994). Heterotopic ossification causes pain, swelling, and rapid loss of range of motion. The therapist must be aware of the symptoms and alert the team so treatment options, including medications and surgery, can be discussed.

Aggressive range of motion is contraindicated.

Heat Intolerance

Heat intolerance is caused by loss of sweating, as split-thickness skin grafts do not contain sweat glands (Grigsby deLinde & Miles, 1995; Rivers & Jordan, 1998). To compensate for this, patients may sweat excessively in remaining unburned areas. Patients in extremely hot climates may require additional air conditioners in the home to maintain comfort (Rivers & Jordan, 1998). The lack of sweat glands also makes healed grafts susceptible to extreme dryness (Grigsby deLinde & Miles, 1995; Staley, Richard, & Falkel, 1994), and patients are encouraged to use moisturizing cream often throughout the day.

RECONSTRUCTIVE SURGERY

An important element in burn recovery is the planning and execution of reconstructive procedures. Despite diligent efforts by the burn team and patient, contractures may develop. Reconstructive surgery can be useful in correcting these deformities. Surgery is typically performed once the scar tissue is mature; however, it may be necessary to perform reconstructive surgery before scar maturation if a severe functional deficit is present (Robson et al., 1992). For example, an axillary contracture, which limits abduction to 80°, may significantly interfere with dressing and hygiene. A surgical procedure, a **Z-plasty**, can be performed to elongate soft tissue (Robson et al., 1992; Staley, Richard, & Falkel, 1994). A skin graft to cover the deficit may be necessary once the contracture is released.

Occupational Therapy Assessment Related to Reconstructive Procedures

When results of functional assessment suggest that the patient's progress toward his or her self-management goals has ceased because of a contracture, the occupational therapist communicates to the burn team the possible need for surgical release of the contracture.

Occupational Therapy Intervention Related to Reconstructive Procedures

Post-operatively, the occupational therapist provides a custom splint to immobilize and protect the graft in its new lengthened position. After approximately 10–14 days,

the therapist initiates an exercise program beginning with gentle active range of motion and progressing to more aggressive exercise and activity as skin integrity tolerates. Pressure therapy over the newly grafted area minimizes scarring. This includes the use of a pressure garment and an insert fabricated to match the contours of the new graft.

RETURN TO WORK

Returning to work before final scar maturation preserves function and improves the patient's self-concept (Rivers & Jordan, 1998). The physician provides medical clearance for return to work. During the initial evaluation in the acute phase, the occupational therapist gathers information regarding the work history of the patient and specific job demands the patient previously encountered daily. With this information, the occupational therapist can guide treatment activities to prepare for return to the previous level of functioning. For example, if the patient was employed as a mechanic prior to injury, tool use should be incorporated into treatment activities as soon as possible. Patients may need job retraining if the extent of the injury renders the original job demands now unrealistic. In this case, the occupational therapist works with the patient and employer to explore appropriate job modifications.

Return-to-work parameters are ideally based on the percentage of body surface area affected, whether the job requires the use of the affected body part, and the depth of the burn (IHQ, 1997). Fletchall and Hickerson (1995) investigated the effectiveness of a daily 6-hour outpatient program beginning immediately after discharge. Patients in this program, with burns to the upper extremity and hands averaging less than 25% of TBSA, returned to work in an average of 8 weeks; patients in a similar population who participated in traditional outpatient therapy returned in an average of 19 weeks. In addition, the experimental program was shown to reduce the overall costs to the health care payer (Fletchall & Hickerson). Assignment of a case manager early during the inpatient phase also facilitated the progression from rehabilitation to return to work (Fletchall & Hickerson).

SPECIAL CONSIDERATIONS FOR HAND BURNS

Hand burns resulting in significant functional limitations occur quite frequently (Wright-Howell, 1989). The high rate of injury to the hand is because individuals use their hands to protect themselves or to extinguish the fire (Tani-

gawa, O'Donnell, & Graham, 1974). Dorsal hand burns occur more frequently than palmar injuries (Tanigawa, O'Donnell, & Graham, 1974). As previously noted, significant edema usually occurs in response to thermal injury. This pulls the hand into a position of deformity (Sheridan et al., 1995) characterized by thumb radial abduction, digital metacarpal hyperextension, interphalangeal joint flexion, and flattening of the palmar arches (Wright-Howell, 1989). If this position is maintained, the result is joint contracture and severe functional limitation.

Evaluation of Hand Burns

A comprehensive hand evaluation includes determination of whether range-of-motion limitations are due to joint stiffness, intrinsic muscle tightness, extrinsic muscle tightness, or inelasticity of skin. Other factors that limit hand flexibility and decrease range of motion include pain, bulky dressings, exposed tendons, and the presence of eschar, which is inelastic. Once the clinician determines the cause of range-of-motion limitations, an effective treatment plan can be devised.

Treatment of Hand Burns

The occupational therapist must provide appropriate splinting and exercise programs to prevent contracture and expedite functional use of the burned hand. The appropriate splinting position of the hand is described in Table 45-1. In this position, the collateral ligaments of the metacarpophalangeal (MP), proximal interphalangeal (PIP), and distal interphalangeal joints are positioned at length, preventing ligamentous contracture so that maximum digital range of motion is preserved.

Two distinct options exist for thumb position. Radial abduction maintains the first web space at maximum length. We prefer palmar abduction, however, as this is a position of function. Hand burns are typically dorsal. When present, a deep palmar burn can lead to palmar contracture. In this case, a volar hand extension splint is appropriate. When using this position, however, careful monitoring of MP flexion is critical to prevent shortening of the collateral ligaments. Unfortunately, evidence is lacking regarding specific splint positions and schedules. According to Richard and Ward (2005), "Controversy about splinting in burn care is not based on the rationale for and success of splinting, but exists because of the paucity of validation of its use." A list of splinting options for the conditions previously discussed follows (see Chapter 16 for splint illustrations):

- Dynamic PIP extension splint such as Capaner, LMB, or banana splints for PIP stiffness: start 10 minutes three times a day, increase wearing time as tolerated, not to exceed 60 minutes at a time.

Figure 45-8 Dynamic flexion glove.

- Dynamic flexion splint in which the MPs are blocked in full extension while the IPs are passively flexed (for intrinsic muscle tightness): start 10 minutes three times a day, increase wearing time as tolerated, not to exceed 60 minutes at a time.
- Forearm-based dynamic flexion splint that offers composite MP-IP flexion (Fig. 45-8) (for extrinsic extensor tightness or inelastic skin that limits composite flexion): start 10 minutes three times a day, increasing as tolerated but not to exceed 45 minutes.
- Volar forearm-based static extension splint (for extrinsic flexor tightness): wear at night.
- Forearm-based dynamic extension splint (for extrinsic flexor tightness): wear periodically during the day, starting with 10 minutes three times per day and progressing to 45 minutes as tolerated.

Often, individuals do not present with a single limitation; rather, a combination of factors limits the individual's range of motion. The clinician must determine which factor is the primary source of dysfunction and modify the treatment accordingly. Appropriate splints are always used in conjunction with exercises, functional activities, and scar management techniques. Splints should never be used to the extent that they limit or prevent performance of ADL activities.

Potential Complications of Hand Burns

Normal hand anatomy can be characterized by a balance of levers and pulleys that work harmoniously to achieve motion. Damage to this balanced network results in significant functional limitations.

Extensor Tendon Injury

Extensor tendon injury is often associated with dorsal hand burns because they lie superficially on the dorsal

Figure 45-9 C-splint in radial abduction.

aspect of the hand. Limitations can be due to direct thermal injury or tendon ischemia (Wright-Howell, 1989). Due to the close proximity of structures, the formation of scar tissue can greatly limit tendon excursion and create imbalance. This can result in contracture development. Boutonniere and swan-neck deformities are the result of extensor tendon damage (Evans & McAuliffe, 1995; Rosenthal, 1995; Wright-Howell, 1989).

Web Space Contractures

Web space contractures can be due to overgrafting of the web spaces, muscle shortening (contracture of the adductor pollicis brevis resulting in a first web space contracture), joint stiffness, or skin graft contracture in a normal response to tissue healing. Splints, scar management, and exercise are effective treatment modalities. First web space contractures (between the thumb and index finger) respond well to a web space C-splint (Fig. 45-9) that is lined with Otoform, a silicon gel sheet, or Elastomere. This is usually worn at night for 6–8 hours. During the day, the individual performs stretching, massage, and functional activities that encourage full range of motion of the affected area. For example, an individual with a first web space contracture is asked to pick up containers of various sizes, using palmar abduction to promote full abduction of the thumb. A dynamic splint with an insert that exerts pressure over the second, third, and fourth web spaces can be appropriate for digital web space contractures. Another option is the addition of web space inserts under a Jobst or Isotoner glove.

OUTCOME STUDIES

Long-term outcomes and quality of life after major burn injuries are of significant concern to those working in the

field of burn rehabilitation. A research tool that has been established to address this issue is the *Burn Specific Health Scale (BSHS)* (Blalock, Bunker, & DeVellis, 1994). This scale is a 31-item instrument that includes items in seven categories: simple functional abilities, work, body image, interpersonal relationships, affect, heat sensitivity, and treatment programs. When the scale was administered to 244 patients from eight burn centers, it was found both reliable and valid (Blalock, Bunker, & DeVellis, 1994). Subjects were asked to report their functioning using a 5-point scale, with 1 indicating extremely good function and 5 indicating none at all. The mean values for employed patients in the categories of simple functional abilities, body image, and interpersonal relationships were 4.77, 3.74, and 4.60, respectively (Blalock, Bunker, & DeVellis, 1994).

Baker et al. (1996) performed an outcome study using the *Burn Specific Health Scale* to identify factors affecting physical functioning and psychological status of 31 adult patients who had sustained burn injuries. The study concluded that minor first-degree burns can significantly affect an individual's physical and psychological functioning (Baker et al., 1996). These results highlight the fact that patients whose burns are not severe may undergo physical and psychological ramifications similar to those of patients with major burn injuries (Baker et al., 1996). Baker et al. also state that the psychosocial influence of a burn injury may, in some cases, provide a growth experience and actually enhance self-esteem as the patient takes pride in the tremendous accomplishment of recuperation.

LeDoux et al. (1996) administered to 32 burn survivors two standardized instruments that measured self-perception of competence and adequacy. Many of the patients used denial as a coping mechanism, and this was found to be beneficial to their perception of competence. The study demonstrated that the patients did not accept feelings of being helpless or hopeless but rather seemed to change their value systems to reflect areas they could control. They placed less value on social acceptance, athletic competence, and physical appearance and more value on job competence, romantic appeal, and scholastic appeal—areas they believed they could control and develop (LeDoux et al., 1996).

Another study investigated hand function after acute hand burns (Sheridan et al., 1995). The study examined 659 patients with a total of 1047 hand burns. It was reported that normal function was resumed in 97% of patients with superficial injuries and 81% of patients with deep dermal or full-thickness injuries. Of the patients with severe injuries, which included tendon damage or joint capsule or bone involvement, only 9% had normal function, while 90% were able to compensate for this and independently perform ADL (Sheridan et al., 1995).

A more recent study published by Sheridan et al. in 2000 investigated the long-term outcome of children surviving major burn injuries (>70% TBSA) using a validated quality-of-life scale administered an average of 14 years post injury. The authors reported that most children had a satisfying quality of life. The majority of the subjects (72%) were either full-time students or gainfully employed. Statistical analysis revealed that key factors such as early return to pre-burn activities and comprehensive burn care that included experienced multidisciplinary aftercare played an important role in recovery (Sheridan et al., 2000). The authors are careful to note that, "Children who survive massive burns will have major cosmetic and functional impairments that can never be completely corrected" (Sheridan et al., 2000).

When outcomes were assessed in adult survivors of severe burn injuries, the results were similar (Druery et al., 2005). Using an abbreviated form of the *BSHS* to assess function and quality of life in adults surviving burns >40% TBSA, it was determined that the majority of these burn survivors developed functional independence and a good quality of life (Druery et al., 2005).

Although evidence is growing that patients who sustain burn injuries can expect generally positive outcomes, little evidence is available to guide the occupational therapy clinician in choosing specific treatment approaches and modalities. The lack of evidence in this field prevents a formal assessment of evidence related to occupational therapy practice. It highlights the need of occupational therapists to participate in outcome-based research related to the treatment of patients with burn injuries. As specialists in the evaluation and treatment of function, occupational therapists have a responsibility to continue to enhance the knowledge base in this area (see Resources 45-1).

CASE

EXAMPLE

Mrs. J.: Burn Rehabilitation

Occupational Therapy Process

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Patient Information

Mrs. J. is a 42-year-old woman who sustained a 45% TBSA burn as a result of a house fire. She presented to the emergency department with superficial and superficial partial-thickness burns to her face and neck and deep partial- and full-thickness burns to both upper extremities and hands (dorsal aspect only), chest, and proximal aspect of her bilateral lower extremities. She also sustained an inhalation injury and was intubated and sedated. She was admitted to the intensive care unit. No significant medical history was reported. Split-thickness skin grafts (STSGs) were performed to her chest and upper thighs 3 days after admission. STSGs were performed to her arms and hands 10 days after admission. After skin grafting was complete, Mrs. J. was extubated and moved to a private room. She was on a regular diet and could walk independently. She was noted to be withdrawn and was concerned regarding her ability to care for her 3-year-old daughter. Her husband and sister were present and supportive throughout her hospitalization.

Understand the patient's diagnosis or condition

"Split-thickness skin grafts have the potential for contracture, which means we will have to work hard to ensure full return of her upper extremity function. In addition, STSGs may result in some scarring, which means a scar management program will need to begin as soon as possible."

Know the person

"From the pictures her family has brought in, it seems she took great pride in caring for her daughter—doing her hair, getting her dressed, etc. I can work with her to create goals related to care for her daughter that will be motivating for her and will reassure her that she will, in fact, be able to resume care for her child. Also, it appears that Mrs. J. has good family support. I wonder how available her husband and sister will be now that Ms. J. is beginning rehabilitation. It seems that often, after the acute crisis is over, many family members need to return to their jobs, at least to some extent."

Reason for Referral to Occupational Therapy

Mrs. J. was referred to occupational therapy during the acute phase to prevent contractures that might result in deficits in occupational functioning, to provide patient and family education, and to address psychosocial sequelae related to the burn injury.

Appreciate the context

"I am going to suggest regular team meetings to discuss goals and monitor Mrs. J.'s progress. It will be important for the team to recognize if she is becoming more withdrawn or depressed. I will also need to know what services will be available as she prepares for discharge. I anticipate that OT intervention can help in many aspects of recovery, from restoring performance skills, such as range of motion, to returning to important life roles such as caring for her family."

Develop provisional hypotheses

Assessment Process and Results (performed on transition to rehabilitation phase)

Assessment of wound healing: Immature scar noted on bilateral forearms and dorsum of both hands
 Assessment of cognitive/social status: Awake and alert for several short periods throughout the day; also noted to appear withdrawn, not seeking social interaction
 Biomechanical assessment—range of motion (ROM) and strength: Decreased elbow flexion, decreased grasp (MP flexion limited) and decreased upper extremity strength bilaterally
 Role and interest assessment: Ability to care for daughter is of primary importance
 Functional assessment: Observed having difficulty using utensils and difficulty using nurse call button and observed to fatigue easily

Consider evaluation approach and methods

"Mrs. J. has many services throughout the day and has limited activity tolerance. In my experience, observational methods are the most efficient way to gather this information during this phase of burn recovery."

Interpret observations

"Mrs. J.'s limited ROM is not unexpected at this stage of recovery. Fortunately, these patients usually respond well to OT treatment. In addition to working to remediate her biomechanical limitations, I would like to try to quickly improve her independence in activities by issuing some adaptive equipment as well. This may help her feel more in control and less dependent."

Occupational Therapy Problem List

- Unable to feed or dress independently because of impaired strength and range of motion in both upper extremities
- Impaired ability to care for her daughter
- Withdrawn behavior
- Activity tolerance limited to 5 minutes

Synthesize results

“Biomechanical limitations are affecting her ability to perform tasks independently. Before the fire, Mrs. J. was so competent and in control of her activities. I’m sure that her current functional status is also contributing to feelings of dependence and poor self-esteem.”

Occupational Therapy Goal List

- Mrs. J. will use splinting, positioning, exercise, and activity to prevent loss of ROM in her upper extremities.
- Mrs. J. will be able to perform 10 repetitions of active assistive ROM of bilateral upper extremities.
- Mrs. J. will improve ability to grasp utensils by increasing flexion in her right MP joints from 40 to 75°.
- Mrs. J. will eat 90% of her meal independently, using adaptive equipment as needed.
- Ms. J. will be able to comb her daughter’s hair for 5 minutes while sitting independently.
- Mrs. J. will cope with anxiety and withdrawal by attainment of goals and through increased knowledge of the burn recovery process.

Develop intervention hypotheses

“I believe that through the use of carefully selected activities, Mrs. J. will regain basic skills, as well as quickly gain confidence in her ability to perform tasks that are important to her.”

Select an intervention approach

“The most limiting factors in her task performance are her biomechanical limitations. Therefore, I need to address these as a priority. However, I will accomplish biomechanical goals by using activities that also address psychosocial needs.”

Consider what will occur in therapy, how often, and for how long

“In my experience, OT treatment six times a week is appropriate for the remainder of Mrs. J.’s acute hospitalization (2–3 weeks). Initially, she may be frustrated and discouraged. However, I expect that, with the proper motivation, she will quickly regain function. This means that her goals will need to be continually reviewed and adjusted appropriately. I really want her to feel like she is part of setting the goals for treatment, so she can take pride in her achievements in therapy.”

Intervention

Occupational therapy occurred six times a week. Bilateral elbow and hand splints were fabricated. Adaptive equipment, such as modified call button and built-up utensils, were provided. The therapist encouraged the family to bring in tapes of get-well messages that Mrs. J. could listen to with headphones. Mrs. J. was taken to the occupational therapy gym as much as possible, and private time with her daughter was added to her daily schedule.

Assess the patient’s comprehension

“Mrs. J. is slowly beginning to ask me and the other team members appropriate questions regarding her treatment. She is demonstrating beginning awareness of the course of recovery and expected outcomes from this type of injury. She is smiling more and appears more open as she realizes that she will be able to resume activities that are meaningful to her. Her family is responding well to her new brightness. This is a nice cycle that is further motivation for Mrs. J.”

Understand what she is doing

Compare actual to expected performance

Know the person

Appreciate the context

Next Steps

As the scars matured, Mrs. J. was provided with both verbal and written instructions regarding scar management and skin care. As discharge neared, a local therapist was contacted to follow Mrs. J. three times a week.

Anticipate present and future patient concerns

“As Mrs. J. transitions to home, she may be initially fearful of being home again, but we will plan close follow-up to quickly address any new issues that arise. Also, as she becomes more competent in her daily activities, her focus may shift to concerns about her appearance. She will likely have many questions in the next few months. I believe that the more she knows about the scar maturation process and scar management treatments, the more empowered she will feel. A burn garment will be needed, and I will order it prior to discharge, so trials can begin under the supervision of an experienced therapist.”

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“I will need to be sure that I have opened the lines of communication with her local therapist who may also have questions about types of treatment, appropriate goals, and so on.”

“In addition to local follow-up, I would like to see Mrs. J. in the Burn Clinic in 1 month to assess outpatient care and provide additional recommendations as needed.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Outpatient Occupational Therapy after Burn Injury

As Mrs. J. is discharged home, she continues to have limitations that affect her ability to resume tasks and roles of importance. How would you characterize her phase of recovery once she is discharged home? Based on the description of her background, scope of injury, and progress to date, write three possible short-term goals as she begins outpatient treatment.

SUMMARY REVIEW QUESTIONS

1. In your own words, what is the primary goal of burn care?
2. How is the role of the occupational therapist unique to the burn team?
3. Describe key differences between superficial, superficial partial-thickness, deep partial-thickness, and full-thickness burns.
4. What splinting and positioning program would you establish for a patient who is intubated in the intensive care unit with deep partial-thickness burns to the axilla, elbow, and wrist?
5. How would your approach differ with the same patient awake and alert?
6. Describe the correct positioning for a deep dorsal hand burn and explain the anatomical justification behind your answer.
7. What factors would you consider when designing a scar management program for your patient?
8. As the occupational therapist on the burn unit, how would you help to address the psychosocial issues of your patients?
9. List five complications you might encounter as your patient recovers from a significant burn injury.
10. What might you, as an occupational therapist, find difficult about treating a patient with a burn injury? How would you address these issues?

ACKNOWLEDGMENT

We thank the patients, physicians, and staff of the Sumner Redstone Burn Unit at Massachusetts General Hospital and the staff of the occupational therapy and hand therapy departments.

CHAPTER 46

Amputations and Prosthetics

Kathy Stubblefield and Anne Armstrong

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Discuss prosthetic components available and appropriate for upper limb amputation levels.
2. State options for creating prosthetic prescriptions.
3. Plan treatment programs for persons with transradial and transhumeral amputations.
4. Design treatment for pre-prosthetic and prosthetic management of upper and lower limb amputation.
5. Describe the psychological implications of amputation for the patient in social and other contexts and their impact on therapeutic management.

Glossary

Acquired amputation—Surgical amputation after birth as a result of trauma or disease.

Body power (BP)—Person's own effort, without an external power source.

External power—Electric or other motor that provides impetus to move the prosthesis or terminal device.

Pre-prosthetic therapy program—Period from the post-surgical procedure until the permanent prosthesis is received.

Terminal device (TD)—Prosthetic hook, hand, or other prehensile device that is inserted into the wrist unit of the prosthesis.

Transfemoral amputation—Amputation across the axis of the femur; previously called above knee (AK).

Transhumeral amputation—Amputation across the axis of the humerus; previously called above elbow (AE).

Transradial amputation—Amputation across the axis of the radius and ulna; labeled by the larger of two adjacent bones; previously called below elbow (BE).

Transtibial amputation—Amputation across the axis of the fibula and tibia; labeled according to the larger of two adjacent bones; previously called below knee (BK).

Voluntary closing (VC) mechanism—TD that remains open until tension is applied to the control cable for grasp.

Voluntary opening (VO) mechanism—TD that remains closed until tension is applied to the control cable to open it.

Amputation can result from several causes:

- Traumatic injury that occurs as a result of accidents as in the use of machinery or motor vehicle accidents
- Disease such as vascular disease, tumors, or infection
- Congenital limb deficiencies that present as missing or partially developed limbs

This chapter addresses only adults with **acquired amputation**, that is, amputations that occurred after birth. Discussion of the role of the occupational therapist in providing therapy for adults with lower limb amputation is also included.

INCIDENCE, LEVELS, AND CLASSIFICATION OF AMPUTATION

More than 150,000 persons in the United States have amputations, with the ratio of arm to leg amputations estimated to be 1:3. Some 57% of arm amputations are transradial, that is, below the elbow through the radius and ulna (Esquenazi, 1996; Leonard & Meier, 1998). Trauma rather than disease is the primary cause (close to 75%) of upper limb amputations in adults, with injury occurring primarily to males aged 15–45 years in work-related accidents (Leonard & Meier, 1998). Amputations of upper limbs can also result from other events, such as gunshot wounds and electrical burns. Disease is the primary reason for lower limb amputations, with peripheral vascular disease and diabetes being the most common causes in people over 60 years of age. Trauma causes 20% of acquired lower extremity amputations, with 5% due to tu-

mors (Leonard & Meier, 1998). Currently available official statistics do not reflect war-related injuries since Vietnam. It is known, however, that the incidence of amputation has steadily declined since the Civil War due to improved management of extremity trauma resulting in limb salvage. In more recent conflicts, the survival of combatants has increased with the use of body armour, so the number of individuals surviving the loss of limbs has increased the number of amputated individuals in the general population (Ramalingan, Pathak, & Barker, 2005).

When amputation is necessary, the surgeon's aim is to preserve as much limb length as possible and still retain healthy skin, soft tissue, blood supply, sensation, muscles, bones, and joints (Leonard & Meier, 1998). A residual limb that is pain free and functional is the final surgical goal.

Acquired amputations were previously described by such terms as short above elbow (AE), standard AE, very short below elbow (BE), and long BE. Other terminology has been adopted by the International Standards Organization and endorsed by the American Academy of Orthotists and Prosthetists, the American Academy of Orthopedic Surgeons, and the International Society for Prosthetics and Orthotics (Schuch & Pritham, 1994). The term *trans* is now used to describe an amputation across the axis of a long bone, as with **transhumeral** to replace AE, or **transradial** for radius-ulna, or BE. The levels of amputation for the upper extremity are illustrated in Figure 46-1. Often the level of amputation directly affects the use of a prosthesis. The higher the amputation, the more difficult it is to use a prosthesis because fewer joints and muscles are available for control. Furthermore, the weight of the prosthesis is greater, and more complex systems are needed for active control. A patient may choose not to wear a prosthesis for many reasons, including the individual's psychological reaction to the amputation.

Figure 46-1 Levels of amputations.

PSYCHOLOGICAL ASPECTS OF LIMB LOSS

Amputation of an upper limb results in a change in the ability to grip, feel, and manipulate objects; physically engage in social interaction; and communicate through gestures. This loss can profoundly influence the person's body scheme, self-esteem, and sense of efficacy. Reactions to amputation are as complex as the unique nature of each human, and an individual's personality and belief system influence how he or she responds to amputation. Often, an early response to limb amputation is shock and disbelief; when both upper extremities are amputated, a feeling of helplessness is common. It is also natural for the person to grieve (Dise-Lewis, 1989; Winchell, 1995) and feel a multitude of painful emotions. For example, some may respond with anger, feelings of guilt, denial, hopelessness, bitterness, revulsion, or depression. Sometimes the patient may project negative feelings onto the therapist. The therapist must encourage open discussion, instill a climate of trust and respect, and work with the

team members to facilitate the patient's psychological adjustment and reintegration into previous roles. Amputation affects not only physical function but also the patient's competence and satisfaction in life roles: maintenance of self, family, and home; self-enhancement, such as engaging in leisure and community activities; and self-advancement as a worker or student (see Chapter 1). What can the occupational therapist do?

- Give the patient information. Explanation of therapy and realistic outcomes can clarify the patient's expectations and reduce the patient's fear and anxiety. The therapist can prepare the patient during the preprosthetic phase by showing prostheses that are appropriate to the amputation level and by discussing their features while listening to the patient and understanding the patient's life roles. A collaborative relationship between therapist and patient instills a sense of control in the patient.
- Introduce the patient to another person with a similar amputation to facilitate sharing of life and recovery experience, as well as problem-solving strategies. This is an important action the therapist can take to help the patient adjust. Referring the patient to self-help amputee support groups in the area and recommending internet resources can acquaint the patient with several perspectives.
- Provide the patient with reference material; topics can include information on coping and adjusting to the amputation, information on prosthetic options, tips on how to manage one's occupations (daily life skills) independently, and a list of organizations for persons with upper and lower limb amputation (Resource 46-1).
- Communicate with (and, when necessary, refer the patient to) the psychologist, spiritual counselor, and other team members throughout the psychosocial intervals, described by Van Dorsten (2004), of survival, recovery, and reintegration after amputation.

REHABILITATION: A TEAM APPROACH

The core members of the professional team are the physician, prosthetist, occupational therapist, and physical therapist. The social worker, psychologist, and vocational counselor should be called in as needed. Patients are always active, equal members of the team and must be given the opportunity to explain their needs, preferences, and goals. The occupational therapist is critical to the rehabilitation process, since this professional works so closely with the patient and can influence the patient's adjustment. Some aspects of the rehabilitation program may be addressed by other team members, as in the acute post-operative period, when management of the

residual limb may be rendered by a physical therapist or a nurse.

**PRE-PROSTHETIC THERAPY**

The **pre-prosthetic** therapy program occurs from the post-surgical period until the patient receives the permanent prosthesis. This is a preparatory time for emotional and physical healing.

Post-Operative Care

Post-operative care, required immediately after surgery, addresses wound care, maintenance of skin integrity, joint mobility, reduction of edema, prevention of scarring, and control of pain (Atkins & Meier, 2004a; Malone, Fleming, & Robinson, 1984). This usually occurs in an acute-care setting, with surgeon, nurse, and physical therapist most involved, and continues in an outpatient setting. Outpatient therapy can be provided in a rehabilitation unit, rehabilitation center, or hand clinic. Inpatient admission

may be necessary for multiple amputations or other complications, such as extensive burns.

Phantom Limb Sensation

The perception of the presence of the amputated limb is a universal phenomenon that is remarkably real to the patient. The cause of phantom limb sensation is still not clearly understood and research into it is continuing (Hunter, Katz, & Davis, 2003). Phantom limb sensation is most common in traumatic amputations. According to Melzack (1989), the neural system exists within the brain even when the body input is cut off by amputation. These perceptions are strongest with amputations of upper extremities, and the hand and fingers are felt more vividly than the arm.

With time, the patient may feel that the distal portions of the phantom limb have moved closer to the site of the amputation. Phantom limb sensation often remains, and ordinarily, the patient accepts it. The patient may view it as an annoyance if the sensation is mild burning or tingling or may find it useful, as when learning myoelectric control for externally powered prostheses.

Open discussion with the patient regarding this common phenomenon is imperative.

Phantom Limb Pain

Phantom limb pain is even less clearly understood, and its causation and management remain controversial; again, research continues (Hompland, 2004). This pain can be felt as extremely intense burning or cramping sensations or shooting pain and is most common in traumatic amputations. Peripheral nerve irritation, abnormal sympathetic function, and psychological factors are thought to be contributory factors.

Often, pain increases with stress. The therapist is advised to avoid emphasizing pain when possible. Treatments for those with severe pain include analgesics and surgery, such as nerve blocks and neurectomies. In the rehabilitation setting, limb percussion, ultrasound, and transcutaneous electrical nerve stimulation (TENS) have been used (Jones & Davidson, 1996). Acupuncture, psychotherapy, hypnotherapy, and relaxation techniques have also been instituted. No one approach, however, has proven to be clearly successful.

Pre-Prosthetic Program Guidelines

Occupational therapy during the pre-prosthetic period for the upper extremity includes providing emotional support, ensuring maximal limb shrinkage and shaping, desensitizing the residual limb, maintaining range of motion and strength, and facilitating independence in activities of daily living.

Provide Emotional Support

Establish an ongoing supportive, trusting relationship with the patient and family to facilitate open discussion (see Chapter 15). Collaborate with the team regarding the patient's needs, and refer the patient for counseling if needed. Introduce the patient to others with similar amputations and comparable circumstances, such as similar levels of amputation or vocation.

Instruct in Limb Hygiene and Expedite Wound Healing

- Instruct the patient to wash the limb daily with mild soap and dry it thoroughly.
- Provide wound cleansing, such as debridement or use of a whirlpool; this may be the responsibility of the physical therapist or nurse.
- Use creams to massage at the suture line to loosen crustlike formations.

Maximize Limb Shrinkage with Limb Shaping

The goal is to shrink and shape the residual limb so that it is tapered at the distal end; this allows for optimal

prosthetic fit. The following interventions can be used to achieve this goal.

- *Elastic bandage.* The patient is taught to wrap the limb and is expected to do so independently unless physical or mental limitations prevent it. In this case, a family member, friend, or caregiver is instructed in the process. The residual limb must be wrapped in a figure-of-eight diagonal configuration, with most pressure applied at the end of the limb. ***The limb must never be wrapped in a circular manner, as this causes a tourniquet effect and restricts circulation.*** The bandage must conform firmly to the limb and be wrapped in a distal to proximal direction (Fig. 46-2). The wrap should be worn continuously and reapplied immediately if it loosens. ***The patient is advised to remove the bandage two to three times daily to examine the skin for any redness or excessive pressure. A clean bandage should be applied at least every 2 days.*** Bandages can be washed with mild soap and laid flat to dry but not squeezed or machine dried.
- *Elastic shrinker.* An elasticized sock can be worn in lieu of the bandage if the patient or family members have difficulty following proper wrapping procedures using the elastic bandage. The shrinker tends to loosen, however, as the limb shrinks. Although the shrinker can be less effective than the bandage, it is preferable to improper application of the elastic bandage.
- *Removable rigid dressing.* A socket can be fabricated using plaster bandages or fiberglass casting tape. This may be the method of choice for those unable to wrap the limb (Olivett, 1995); however, this cast must be replaced or altered frequently as the limb shrinks.
- *Immediate post-operative prosthesis.* The immediate post-operative prosthesis is, as the name suggests, applied directly after surgery (Maiorano & Byron, 1995; Malone, Fleming, & Robinson, 1984). This is probably the ideal approach if the rehabilitation team members are available to ensure success.
- *Early post-operative prosthesis.* The early post-operative prosthesis is strongly recommended for bilateral amputations (Uellendahl, 2004) to reduce dependency for self-care activities. This temporary prosthesis may ensure acceptance and use of the permanent prosthesis. Studies support the premise that early fitting tends to ensure acceptance of the prosthesis and its use (Kejlaa, 1993; Pinzur & Angelats, 1994).

Desensitize the Residual Limb

The aim is to desensitize the residual limb so that it will accommodate touch and pressure in preparation for encasement in the socket. This goal can be met through the following interventions (see also Chapter 27).

- The patient bears weight on the end of the limb against various surfaces. These surfaces are graded from very

Figure 46-2 Wrapping technique for transhumeral amputation. Repeat diagonal turns as necessary to cover the limb with no constriction.

resilient, such as soft foam, to variously resistant and textured, such as layers of felt, rice, and clay (Fig. 46-3). The patient is to push the limb down into the surface for 5-second intervals and increase the contact time and pressure as tolerated.

- Massage is useful for desensitizing but is primarily used to prevent or release adhesions and soften scar tissue.

Figure 46-3 Weight bearing into materials of various textures (here, rice) to desensitize limb.

- Tapping and rubbing the residual limb and applying a vibrator are also useful.
- Residual limb wrapping contributes to desensitizing the limb.

Maintain or Increase Range of Motion and Strength of the Limb

A physical conditioning regimen can be instituted to increase or maintain the range of motion of all joints proximal to the amputation. Increasing muscle strength of the residual limb and shoulder area are also goals. Include the contralateral side if limitations are noted. For patients with high-level amputations, a shift of weight and center of gravity can occur. Core strengthening will promote postural control, balance, and endurance and prevent asymmetry. Mobilization of the limb also increases circulation and reduces edema. This conditioning regimen should be practiced at home. Encourage the patient with unilateral limb loss to incorporate the residual limb into bilateral tasks during daily activities.

Facilitate Independence in Daily Living Activities

It is important that the patient develop skills to be proficient without the prosthesis. Ordinarily, the patient with a unilateral amputation receives only one prosthesis; therefore, there may be times when the prosthesis is being repaired and the patient will have to manage without it.

Unilateral Amputation

For persons with amputation of the dominant limb, change of dominance activities, such as writing, must receive special attention. Although the patient will instinctively use the remaining extremity for activities of daily living, the therapist can introduce a wide variety of activities and provide tips for one-handed techniques or recommend adaptive equipment for home management, communication, desk activities, and community participation (see Chapters 30–32).

Bilateral Amputation

Establishing some degree of independence is essential for the patient who has undergone bilateral amputations, and this must be addressed promptly (Lehneis & Dickey, 1992) to lessen feelings of dependency and frustration. Immediately provide the patient with a universal cuff, which is useful for holding a utensil or toothbrush; this is a temporary substitute for grasp. Early fitting with a temporary prosthesis on at least one limb is by far the best approach. Adapted devices may be needed (Friedmann, 1989) to assist the patient in performing basic self-maintenance tasks, such as eating, toileting, grooming, and some dressing. Use of the feet should be encouraged if at all possible, and other modifications of performance can be suggested, such as use of the chin, knees, and teeth (Edelstein, 2004). The therapist and patient can analyze tasks and solve problems together. Ordinarily, the longer limb will be chosen as the dominant extremity.

Explore Prosthetic Options

The occupational therapist and prosthetist educate the patient about prostheses appropriate to the level of amputation to guide the patient to establish realistic expectations. If appropriate, a meeting can be arranged between this patient and a former one, preferably someone with a similar level of amputation, so that they can talk candidly about any issues of concern, including negative and positive features of prostheses.

Myoelectric Site Testing and Training

Muscle site testing must be instituted for patients choosing a myoelectric prosthesis. The prosthetist and therapist can collaborate to determine whether the patient is a candidate by evaluating electromyographic (EMG) signals. At that time, the optimal location for the control site or sites is chosen. The goal is to find a site where the patient can hold a steady contraction for at least 1–2 seconds and relax for that time. A myotester or computer program can be used as well as the electronic hand. Ordinarily, the agonist and antagonist are chosen, such as biceps and triceps for transhumeral amputation and typically wrist extensors and flexors for transradial amputation. It is possible to

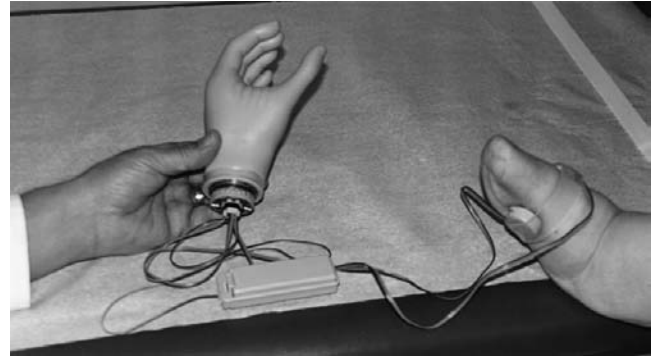

Figure 46-4 Finding the best site for electrode placement for consistent control of electric hand.

use only one muscle to control two functions: a strong contraction controls one function, and a weaker contraction controls another; relaxation turns the system off. The skin electrodes are strapped to the limb or encased in a test socket (Fig. 46-4), with the electronic controls attached to a motorized hand, computer, or myotester. A biofeedback unit can also be used to train the patient (see Chapter 20).

PRESCRIBING THE PROSTHESIS

As a member of the prosthetic team, the occupational therapist contributes to the prescription of the prosthesis. The therapist has come to know the patient in some depth during the pre-prosthetic program and can contribute information regarding the patient's social and cultural contexts (Procedures for Practice 46-1).

PROCEDURES FOR PRACTICE 46-1

Prescribing the Prosthesis

Consider these factors:

- Residual limb: length, range of motion, skin integrity, strength
- Preference for cosmesis and function
- Hand dominance
- Activities at work, home, school, and community and recreational interests
- Motivation and attitude
- Financial coverage: health care insurance, ability to pay privately, and alternative funding sources
- Cognitive abilities to learn to use prosthetic controls

Prosthetic Components

The components of a prosthesis are frequently categorized in the following sequence, from distal to proximal:

1. **Terminal devices (TD)**
 - Active prehensors
 - Passive terminal devices
2. Wrist units
3. Forearm component or sockets
4. Elbow units or hinges
5. Upper arm component or sockets
6. Shoulder units or hinges
7. Suspension or harness

Prosthetic Control Choices: Body Powered (Definition 46-1)

Terminal Devices

Terminal devices (TD) are considered the most important components of the prosthesis. The components for the wrist, elbow, and upper arm are needed to position the arm in space to enable efficient TD use.

TD PREHENSORS

TD prehensors can be classified as operating by a **voluntary opening (VO) mechanism** or **voluntary closing (VC) mechanism** (Table 46-1). The fingers of a VO device remain closed by springs for a mechanical hand or by rubber bands for a hook. The force of pinch on the hook can

be increased by adding rubber bands, approximately 1 pound for each band, and by adjusting the spring mechanism for the hands. The Therapeutic Recreational Systems (TRS) VC mechanism adjusts the amount of pinch force by decreasing or increasing the amount of tension the patient applies on the cable to close the TD.

VOLUNTARY OPENING HOOKS

The voluntary opening hook is most widely used, and Hosmer-Dorrance is the primary manufacturer (Fig. 46-5). Hooks of aluminum, titanium, or stainless steel come in several sizes; some have neoprene rubber-lined fingers. The neoprene lining provides a firm grip and prevents slippage. Aluminum hooks are lighter (4 ounces) than stainless steel (8 ounces) and are used for routine activities.

The stainless steel work hook has special features that facilitate holding tools and can withstand the rigors of heavy mechanical activity; however, it weighs 10 ounces. The Hosmer hooks come in right or left and can be differentiated by holding the hook with fingers in pronation; the thumb post closest to the midline indicates its orientation to side. For example, a right hook, when pronated, has the thumb post closest to the body or midline.

VOLUNTARY CLOSING TERMINAL DEVICES

The TRS GRIP voluntary closing terminal device is fast becoming the TD of choice in this category (Fig. 46-6). Strong variable prehension is controlled by the amount of force the individual can exert. It is conceivable that a grasp of more than 30 pounds can be attained. A locking mechanism is employed to sustain grip. These devices are available in aluminum and steel and can be plastic coated. This TD is particularly appealing for people who are active in sports, heavy physical work, or recreational activities.

VOLUNTARY OPENING MECHANICAL HANDS

The Hosmer-Dorrance or Otto Bock mechanical hand is most frequently selected. The VO hands operate similarly to the VO hooks except that, in the hand, the thumb and first two fingers open when the cable is pulled. These fingers oppose in a three-point prehension pattern. This is different from the Hosmer hook, in which the cable is attached only to the thumb post so that one finger moves while the other finger remains stationary.

VOLUNTARY CLOSING MECHANICAL HANDS

The APRL VC hand is available only in men's sizes. The thumb can be manually adjusted and locked in two positions to achieve a 1.5- or 3-inch opening. Otto Bock offers VC hands in several sizes, all of which weigh less than the APRL hand. The VC hands are less popular than the VO hands. TRS also provides VC hands.

COSMETIC GLOVES

All prosthetic hands have rubberized coverings (Fryer, Michael, & Stark, 2004). These gloves are available in a

DEFINITION 46-1

Types of Prostheses

Body-Powered (BP) Prosthesis

Body motion is used to apply tension on the control cable to activate the TD and elbow unit.

Externally Powered Prosthesis

Motors for the TD, wrist unit, and elbow components are electrically controlled either by a microswitch or by electromyographic (EMG) signals.

Myoelectric Prosthesis

This externally powered prosthesis uses EMG signals to activate electric components. Electrodes embedded inside the prosthetic socket are in contact with the patient's skin and pick up EMG signals as the muscle contracts. The signals are amplified and relayed to the electronic TD, wrist unit, or/and elbow unit.

Hybrid Prosthesis

Hybrid prostheses combine BP and electrical power control systems.

Table 46-1. Hooks and Hands Compared

Features	Hooks VO (Body Power)	VC TRS Grip (Body Power)	Hands (External Power)	Hands VO (Body Power)	Greifer (External Power)
Cosmesis	Unfavorable	Unfavorable	Favorable	Favorable	Unfavorable
Pinch force	1 lb/rubber band; more rubber bands yield stronger grip but require more effort to open	Controlled strong grip >40 lb dependent on force exerted on cable	Strong grip, 22 lb; may have proportional control	Pinch stronger than VO hook but weaker than externally powered TD; relies on internal springs, adjustable	Strong pinch, 32 lb
Prehension pattern	Precise, exact pinch	Pinch more precise than hand, less than hook	Cylindrical grasp 3-point pinch; configuration same as BP hand	Cylindrical grasp, 3-point pinch; configuration same as external powered hand	Precise pinch and cylindrical grasp
Weight	Lighter than hands; aluminum to stainless steel; 3–8.7 oz	Aluminum, polymer, stainless steel; 4–16 oz	Heavy; 16.2 oz	Heavy; 10.5–14 oz	Heavy; 19 oz
Durability	Durable; stainless steel is strongest	Durable and rugged; especially stainless	Not durable; delicate internal electronics and glove	Not durable; delicate inner spring mechanism and glove	Durable and rugged
Reliability	Very good; requires minimal service	Very good; requires minimal service	Good if not used for rugged activities	Good if not used for rugged activities	Very good
Feedback	Some proprioceptive feedback from tension on harness and limb in socket when operating TD/elbow	Better proprioceptive feedback, as tension on cable must be maintained for sustained grasp	Some feedback through intensity of muscle contraction, particularly for proportional control	Feedback similar to VO hook	Same as externally powered hand
Ease of use	Effort increases with more rubber bands	More effort to sustain grasp; lock available	Low effort to activate	More effort to open; can relax for grasp	Same as externally powered hand
Use in various planes	Difficult for high planes	Similar to VO hook	Very good for transradial amputation	Similar to VO hook/hand because of harness	Same as externally powered hand
Visibility of items grasped	Very good	Good; less than VO	Poor for small items	Poor for small items	Poor for small items
Cost	Lowest	Higher than hook, less than hand	Highest cost	Higher than hooks; lower than externally powered hand	About the same as externally powered hand

Figure 46-5 Hooks. **A.** Stainless steel work hook. **B.** Titanium hook; as strong as steel but less weight. **C.** Aluminum plastisol coated with canted fingers. (Photo courtesy of Hosmer-Dorrance Corp., Campbell, CA.)

variety of colors and sizes to cover mechanical, passive, and electric hands. A reverse mold of the remaining hand is sent to the manufacturer. The glove is replaced by the prosthetist when damaged. Some of the available choices are described here.

A stock (production) glove is ordered by the prosthetist. The skin color choices are made from a selection of sample swatches. These polyvinyl chloride (PVC) gloves are the least expensive but are susceptible to staining from contact with such items as newsprint, clothing dyes, and ballpoint ink. The glove can deteriorate with temperature extremes and in sunlight.

A silicone covering is more expensive than PVC. A wider range of color choices is available, and details, such as veins, are painted on the glove to render a more realistic covering. These silicone gloves can withstand extremes of temperature and do not stain as easily as those of PVC.

A custom-sculpted silicone glove, also called an anatomical cover, truly attempts to replicate the individual's remaining hand (Figs. 46-7 and 46-8). The remaining hand is cast in silicone, which duplicates its contours in great detail. It is then reversed. A cosmetic restorationist adds to the

Figure 46-7 Partial hand amputation.

Figure 46-6 Voluntary closing prehensors. **A.** Grip 3 with polyethylene gripping surface. **B.** Grip 2S made with titanium, stainless steel, and aluminum materials. (Photo courtesy of TRS, Inc., Boulder, CO.)

realistic appearance of the hand by painting the glove and adding veins and other features. This glove is the most costly.

Passive cosmetic hands and prostheses are chosen when appearance is valued more than function. These prostheses are available to replace any part of a limb, from a single digit to a whole arm.

THE FINAL CHOICE: HOOKS OR HANDS?

Fortunately, the patient can choose from several TDs. It is possible to have several interchangeable hooks and hands. The hook is viewed as most functional for the following reasons:

- Small items can be grasped with precision.
- Visibility is good, an extremely important feature, since tactile sensation is absent.
- It weighs less than the hand.
- It costs less than the hand.

Figure 46-8 Cosmetic anatomical covering for this partial hand. (Courtesy of Michael Curtain, Alternative Prosthetic Services, Southport, CT.)

- It is more reliable and requires less maintenance than the hand.
- It can fit in close quarters.

Many people prefer the hand, however, because it is cosmetically more appealing, although heavier, more delicate, and more expensive than hooks.

The continued development and refinement of externally powered hands has led to electric hands being chosen over mechanical hands, particularly by those with transradial amputations, since they offer greater pinch force, can be activated with more ease, and do not require a harness. A mistaken notion is that the electric hand provides more dexterity than the mechanical hand. To the contrary, both move identically, with the thumb and first two fingers moving as a unit, in a three-point prehension pattern. They differ in the control system only; the mechanical hand is controlled through cable or **body power (BP)**, and the electric hand is controlled through myoelectric signals or switches, that is, **external power**. Individuals with bilateral amputations continue to prefer BP hooks because function is of paramount importance. Some individuals choose a different TD for each limb, for example, a BP hook for the dominant side and a myoelectric hand for the other. How can the ideal TDs be chosen? Listen to the patient and consult with the other team members to get varied perspectives. These options are presented to the patient, who makes the ultimate choice.

Wrist Units

The wrist unit provides a means to attach the TD to the forearm. It also provides an important function: the terminal device can be rotated to positions of supination, pronation, or midposition before engaging in an activity. This pre-positioning is an important substitution movement for reduced or absent active forearm rotation. Several types of wrist units are available; the ones described here are the most popular:

- Constant friction. This wrist unit contains a nylon threaded insert that surrounds the stud of the TD to hold it in place. An Allen wrench is used to turn a small set screw that applies pressure against the nylon insert, which causes constant pressure against the stud of the TD. Just enough friction must be applied to allow the individual to rotate the TD but not so little that the TD inadvertently rotates while it is being activated by the cable pull. The therapist teaches the patient to use the wrench to make adjustments.
- Quick change. These units provide easy disconnection of different TDs. The TD is pressed down into the wrist to eject the TD or to lock it into position.
- Wrist flexion. There are two versions of this unit: (1) The Hosmer wrist flexion unit can be manually placed in neutral, 30° of flexion, or 50° of flexion. (2) The

dome-shaped Sierra wrist flexion unit can be screwed into a standard wrist unit and can be rotated and flexed to the same angles as the Hosmer unit. Wrist flexion units are indispensable for the person with bilateral amputations because of their usefulness in reaching the midline for toileting, dressing, and eating.

- Ball and socket. This unit can be pre-positioned around the ball, but it cannot be locked in position.

Transradial (BE) Components

FOREARM SOCKET DESIGNS

The residual limb is encased in the socket of the prosthesis with total contact. A standard forearm socket (Fig. 46-9) encases two-thirds of the arm length but can be cut down to allow for more active pronation and supination for a long limb. The supracondylar socket (modified Muenster) is a frequent choice for the short transradial limb; the proximal brim grips the humeral lateral and medial epicondyles and the posterior olecranon (Fig. 46-10). This design is widely used for the myoelectric prostheses. It is self-suspending, with no harnessing necessary.

ELBOW HINGES

Elbow hinges connect the socket to the triceps cuff or pad on the upper arm. These can be flexible straps of Dacron or leather or rigid metal hinges. The flexible hinge allows for flexibility around the joint, whereas the rigid hinge offers stability at the elbow joint.

Figure 46-9 Standard transradial prosthesis. 1, Axilla loop; 2, Northwestern University (NU) ring; 3, Control-attachment strap; 4, Inverted Y strap; 5, Triceps cuff; 6, Flexible elbow hinge; 7, Cable; 8, Socket; 9, Wrist unit; and 10, TD. (Illustration by Gregory Celikyol.)

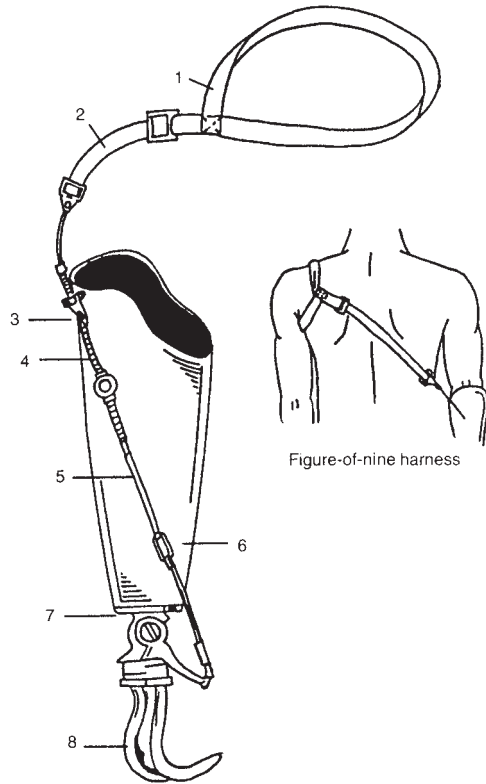

Figure 46-10 Supracondylar prosthesis. 1, Figure-of-nine harness; 2, Control attachment strap; 3, Lift loop; 4, Housing; 5, Cable; 6, Supracondylar socket; 7, Wrist unit; and 8, TD. (Illustration by Gregory Celikyol.)

TRICEPS CUFF

The triceps cuff on the upper arm is connected to the socket by the elbow hinge. It serves as a point of attachment for the cable housing of the control attachment strap.

HARNESS AND CONTROL SYSTEM

The harness serves two purposes: (1) to suspend, or hold, the prosthesis firmly on the residual limb and (2) to allow for force (through body motion) to be transmitted to the control cable that operates the terminal device. Three types of harnesses are most popular for the transradial prosthesis: figure-of-eight, figure-of-nine, and chest strap with a shoulder saddle. The figure-of-eight harness is most often used. Its axilla loop serves as the anchor point (reaction point) from which the other straps are attached; the inverted Y support strap attaches to the anterior support strap of the harness. These two attachments are important because they stabilize the socket to the harness and prevent displacement when heavy loads are carried or lifted. The chest strap with shoulder saddle may be suitable for the patient who cannot tolerate the axilla loop pressure or when stability is needed for heavy work. The shoulder saddle distributes the pressure over a larger area. The figure-of-nine harness is used with the supracondylar socket. Since the socket configuration provides self-suspension,

only a control attachment strap is needed to attach the axilla loop to the cable control system.

Transhumeral (AE) Components

SOCKET DESIGNS

The conventional socket edge is generally just near or above the acromion, depending on limb length. Another design is often selected because it provides more rotational stability, as with the Utah arm. A transhumeral prosthesis with an internal locking elbow is shown in Figure 46-11.

ELBOW UNITS

Two elbow units are available for the AE prosthesis: (1) an internal elbow locking unit for a standard or short transhumeral amputation and (2) an external elbow locking unit for a long transhumeral or elbow disarticulation amputation.

FRICTION UNITS

The friction unit must be manually flexed into place. It is lightweight and is used with passive prosthetic arms. Manual elbow components are also available with a locking mechanism.

Figure 46-11 Standard transhumeral prosthesis. 1, Axilla loop; 2, Northwestern University (NU) ring; 3, Lateral support strap; 4, Control attachment strap; 5, Elastic anterior support strap; 6, Socket; 7, Elbow lock cable; 8, Turntable; 9, Internal elbow lock unit; 10, Lift loop; 11, Housing; 12, Cable; 13, Wrist unit; and 14, TD. (Illustration by Gregory Celikyol.)

EXTERNAL SPRING LIFT ASSIST

The external spring lift assist is a clock spring mechanism that is added to the medial side of the elbow. Tightening the mechanism causes increased tension for elbow flexion and assists in initiating this motion. The patient can adjust it.

SHOULDER HINGES

The shoulder hinges can be manually positioned into flexion or extension or abduction or adduction for placement of the arm in space.

Shoulder Disarticulation and Scapulothoracic Components

Most socket designs for shoulder disarticulation and scapulothoracic prostheses consist of a plastic laminated shoulder cap or frame socket with carbon fiber reinforcements. Another choice is an endoskeletal passive arm that is lightweight and contains an internal pylon shaft. It is covered with resilient foam contoured to the shape of the arm. A chest strap harness suspends the prosthesis.

HARNESS AND CONTROL SYSTEMS

The harness and control systems for a transhumeral amputation are usually of the figure-of-eight or chest strap design. For a shoulder disarticulation prosthesis, the elbow lock can be activated using a chin nudge lever or a manual elbow lock mechanism.

*Externally Powered Prosthetic Components***ELECTRIC TERMINAL DEVICES**

Electric-powered hands and hooks can be activated through myoelectric or switch control (Heckathorne, 2004). The electric-powered prehensors are heavier (approximately 1 pound) but provide stronger pinch force (20–32 pounds) than the BP types. The two speed systems are: (1) digital control (constant speed), in which muscle contractions cause opening and closing at a given speed; and (2) proportional control (variable speed), in which the speed and pinch force increase in proportion to the intensity of muscle contraction.

ELECTRIC HANDS

Otto Bock electric hands (Fig. 46-12) are the most popular models. They are available in several sizes. Either a PVC or silicone glove can cover them. The motor in the hand mechanism drives the thumb and first two fingers as a unit to provide palmar (three-point) prehension. A recent development in externally powered TDs is the Otto Bock Sensor Hand. The hand automatically increases force on an object if it detects slippage, thereby reducing the mental load of the user. Constant visual contact with the object in the hand is unnecessary.

ELECTRIC HOOKS

The Otto Bock electric Greifer TD is interchangeable with the Otto Bock hand and may be preferred for work

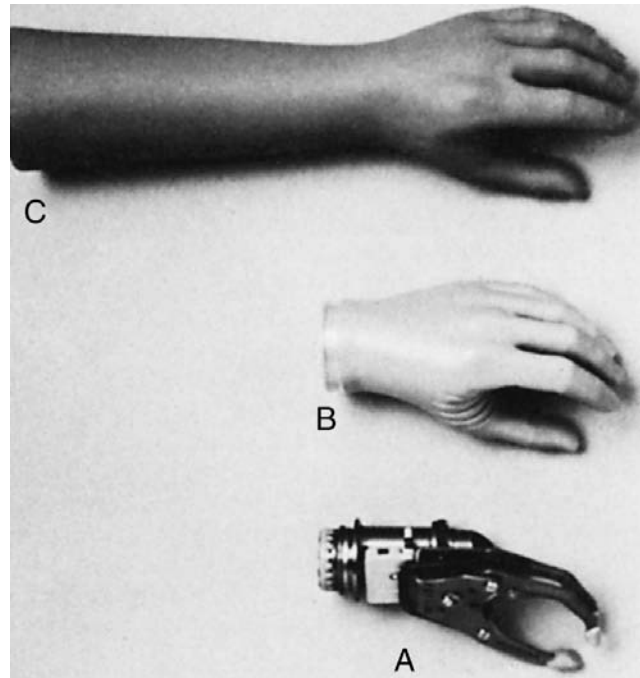

Figure 46-12 Electronic hand. **A.** Internal mechanism. **B.** Hand shell covering. **C.** Glove. (Photo courtesy of Otto Bock Orthopedic Industry, Minneapolis, MN.)

that requires prehension force up to 32 pounds. It is bulky, encased in a hard plastic shell with no glove covering, and is less delicate than the hand. It is available in one size. The two “fingers” move symmetrically in opposition to one another for precision pinch while a more proximal, expanded contact area provides for a cylindrical grasp (Fig. 46-13).

Figure 46-13 Electric Greifer TD in open and closed position. (Photo courtesy of Otto Bock Orthopedic Industry, Minneapolis, MN.)

The Hosmer NU-VA Synergetic Prehensor contains two motors geared to drive each of the two hook fingers differently. One finger can be made to move quickly for fast opening and closing, while the other finger applies the force for secure grip. Therefore, in grasping, one finger closes quickly on an object while the other finger applies the force for secure grip.

ELECTRIC WRIST ROTATION UNITS

Wrist rotation units, used for pronation and supination, are being prescribed more often. Sears and Shaperman (1998) present a strong case for their use by persons with unilateral and bilateral amputations.

ELECTRIC ELBOWS

The following three electric elbow mechanisms are the most popular: the Boston elbow, the NY electric elbow (Hosmer), and the Utah (Motion Control) elbow (Fig. 46-14). These elbows can be controlled by electromechanical switches or by myoelectric control. The Boston and Motion Control elbows can accommodate wrist and hand components as well.

The Final Prescription: A Discussion

“In the upper extremity, the prosthesis meets its greatest challenge. Here the lost function can only be imitated. . . . We must fit the prosthesis not only to the patient’s limb but to his whole personality.” (Kessler, 1947, p. 5)

Motivation is the most important factor in the acceptance and use of the prosthesis. In addition, clinician expertise, appropriateness of the prosthetic prescription to meet patient goals, and the final fit and function of the artificial limb contribute to the ultimate outcome. The prosthesis is chosen just when the patient is most confused and vulnerable. The patient’s desire for a prosthesis is

Figure 46-14 Utah arm with externally powered hand and elbow. (Photo courtesy of Motion Control, Salt Lake City, UT.)

strongest after surgery and may wane as time passes, particularly for those with unilateral amputations, since compensatory one-handed techniques are soon perfected. The patient with a bilateral amputation needs function and is likely to accept and use the prostheses.

What defines a successful wearer? When the prosthesis is viewed as necessary or meaningful for any activity, such as leisure activities, or for cosmesis, it has added to the quality of life and is therefore successful (Fraser, 1998; Wright & Hagen, 1995). A patient with a unilateral amputation may use the prosthesis for particular activities, such as for sports, and these interests can change with time. Two sets of prostheses are strongly recommended for the person with high-level bilateral amputations; this ensures that the patient will always have use of the prostheses should one set need repairs.

The end goal of a therapeutic program is to ensure the highest level of independence and competency in life roles that the patient views as meaningful. This does not always assume prosthetic use. It is, however, the team’s responsibility to present the options to the patient.

PROSTHETIC TRAINING PROGRAM

The minimal training time is 6 hours for persons with transradial amputation; 15 hours for transhumeral, shoulder disarticulation, and bilateral transradial amputations; and 20 hours for bilateral transhumeral amputations.

Initial Stage of Treatment

The initial stage of treatment can generally be covered in one or two therapy sessions. Procedures for Practice 46-2 has treatment guidelines for this stage.

PROCEDURES FOR PRACTICE 46-2

Treatment Guidelines for Initial Stage of Treatment (ideally within 4–12 weeks of surgery)

- Evaluate the prosthesis.
- Explain program goals to the patient.
- Describe the functions of each component; give the patient an illustration of the prosthesis with components labeled.
- Teach the patient to don and doff the prosthesis.
- Discuss the wearing schedule with the patient.
- Teach limb hygiene care.
- Teach care of the prosthesis.
- Begin controls training using the terminal device.

Evaluation of the Prosthesis

On the first visit, the therapist checks out and evaluates the prosthesis before instituting training. The evaluation's purpose is to determine (1) compliance with the prescription, (2) comfort of fit of the socket and harness, (3) satisfactory operation of all components, and (4) appearance (features) of the prosthesis and its parts. Table 46-2 lists methods and standards for evaluation.

First Therapy Session

Generally, patients with unilateral amputations attend therapy on an outpatient schedule of 2 or 3 days a week; therefore, the first visit is a critical one. The aim from the

outset is to minimize negative experiences to ensure acceptance and use of the prosthesis. In addition to evaluation of the prosthesis, the following must also be covered during the first visit: (1) donning and removing the prosthesis, (2) wearing schedule, and (3) hygienic care of the residual limb if the patient did not receive pre-prosthetic care in the clinic.

Donning and Removing the Prosthesis

Donning and removing the prosthesis can be achieved by one of two methods that simulate putting on a coat or pullover shirt. To use the coat method, the residual limb is inserted into the socket (Fig. 46-15), which is held in place with the intact hand, with the harness and axilla loop

Table 46-2. Chart for Evaluating a Prosthesis

Activity	Y	N	Comments
1. Does the prosthesis comply with the written prescription?			
2. Is the length of the prosthesis equal to the length of the sound arm? (Measure tip of TD to ground and compare to tip of thumb of sound hand to ground when the patient is standing. Compare elbow length for each side.)			
3. Are appearance and workmanship satisfactory? (Examine for smooth edges, smooth interior of socket, no loose rivets or screws, finished harness edges, and satisfactory arm color.)			
4. Can the socket tolerate a downward pull of 50 lb without displacing more than 1 in?			
5. a. Is there pain or discomfort while the limb is in the socket? b. Does the limb show abrasions or discoloration when the prosthesis is removed?			
6. a. Does the housing cover the cable without restricting elbow flexion? b. Is the cable free of sharp bends?			
7. a. Is the axilla loop small enough to keep the figure-eight harness below the seventh cervical vertebra and slightly to the unamputated side? b. Is the axilla loop covered and comfortable? c. Are all straps of adequate length and in proper alignment?			
8. a. Does the triceps cuff fit firmly without gapping? b. Can the turntable be rotated manually with relative ease and remain in position?			
9. a. Do the TDs and wrist unit function smoothly? b. Is the glove covering for the hand satisfactory in color and fit? c. Does the TD have full opening, closing? d. Can the TD be fully opened and closed at the hip, at 90° of elbow flexion, and at the mouth?			
10. Can forearm rotation that is at least 50% of rotation without the prosthesis be achieved?			
11. Can elbow flexion that is only 10° less than flexion with prosthesis off be achieved?			
12. For transhumeral amputation: a. Can 90° of shoulder abduction and flexion and 30° of arm extension be achieved? b. Can the prosthetic elbow be flexed by flexing the humerus 45° or less?			

Figure 46-15 One method of donning a unilateral prosthesis.

dangling behind the back. The intact arm reaches behind and slips into the axilla loop; a forward shrug of the shoulders positions the prosthesis in place. For the pullover method, the patient places the prosthesis in front of him or her, and the intact arm is placed through the axilla loop

while the residual limb is placed into the socket. Both limbs are raised to lift the prosthesis and harness over the head as the harness falls into place (Fig. 46-16). Initially, the prosthesis can be placed on a bed or dresser to support it as the patient slips into the prosthesis.

Wearing Time

The patient must increase wearing time gradually to develop tolerance to the socket and harness. The initial wearing time may be 15–30 minutes. Each time the prosthesis is removed, the residual limb must be examined for excessive redness or irritation, and it must not be reapplied until any redness subsides. *Redness that does not disappear after approximately 20 minutes should be reported to the prosthetist for adjustment to the prosthesis.* Otherwise, prosthetic wearing time can be increased in 30-minute increments until the prosthesis can be worn all day. The importance of gradually increasing the wearing time cannot be overemphasized, particularly for patients with decreased sensation and scar tissue.

Figure 46-16 A. Donning bilateral harness overhead. B. Completing the process by inserting limbs into the sockets.

Limb Hygiene

Since the residual limb is enclosed in a rigid socket where excessive perspiration can macerate the skin, it is important to instruct the patient to wash the limb daily with mild soap and lukewarm water and pat dry. The therapist can recommend that the patient wear a tee shirt or equivalent covering so that the harness system of a BP prosthesis is not in direct contact with the skin. This provides padding and absorbs perspiration. For the same reason, the patient is instructed to wear a sock over the residual limb. A roll-on silicone liner may be issued to those who perform heavy work; it provides secure suspension and minimizes piston action, but can cause excessive perspiration.

Care of Prosthesis

Mild soap and warm water are recommended to clean the interior of the socket. It can also be wiped with rubbing alcohol every several weeks. The patient must be cautioned about agents that may stain or damage gloves. The hook is more rugged, but care must be taken during work in areas where there is excessive dirt, grease, or water. The patient must be especially careful with externally powered components.

Intermediate Stage of Treatment

Training for Use of Body-Powered Prosthesis

The therapy program for the BP prosthesis is addressed in two phases: (1) prosthetic controls training and (2) prosthetic functional use training.

Prosthetic Controls Training

Therapy for controls training begins with teaching the operation of each control, beginning with the TD (Procedures for Practice 46-3). The therapist guides the patient to practice repetitive activation of each component. Transradial prostheses have a single control system that activates the TD by cable pull. Patients are instructed to activate the TD (Figs. 46-17 and 46-18) by using humeral flexion and scapular abduction (protraction). Transhumeral prostheses have a dual control system for the TD and elbow. The motions required to lock and unlock the elbow are a combination of humeral extension, abduction, and depression (Fig. 46-19). TD activation is achieved in the same manner as with the transradial controls except that the elbow must be locked. The patient with a transhumeral prosthesis may also have to learn to

PROCEDURES FOR PRACTICE 46-3

Controls Training for Body Powered Prostheses

Component	Movement	Intervention
Terminal device	Humeral flexion with scapular abduction (protraction) on side of amputation; bilateral scapular abduction for midline use of TD or when strength is limited.	Manually guide patient through motions. For transhumeral prostheses, keep elbow unit locked in 90° flexion; teach TD control first.
Wrist unit	Rotate TD to supination (fingers of hook up), midposition (fingers toward midline), or pronation (fingers down). For unilateral amputation, patient uses sound hand to rotate TD. For bilateral amputation, rotate TD against stationary object, between knees, or with contralateral TD.	Have patient analyze the task and determine the most efficient approach for grasp, avoiding excessive or awkward movements. Examples: TD in midposition for carrying a tray, in pronation for grasping small box from table.
Elbow unit	Depress arm while extending and abducting humerus to lock or unlock elbow mechanism. Practice flexing and locking elbow in several planes.	Manually guide patient through motions. Begin with elbow unlocked. Patient listens for click as lock activates. Have patient exaggerate movements initially. Use a mirror. Use humeral flexion to flex the elbow; go beyond desired height, since the arm will drop with gravity pull as patient is in process of locking the elbow unit.
Turntable	Rotate elbow turntable toward or away from body using sound hand. With bilateral amputations, push or pull against stationary object to rotate.	Teach patient to analyze task to determine need to use this component for more efficiency.

Figure 46-17 A. Teaching activation of VO TD. With elbow locked, therapist pulls the patient’s upper arm forward to open TD. B. Teaching elbow lock and unlock. The therapist pushes the patient’s arm back (*arrow*) into extension, abduction, and depression. It is brought back to the vertical plane between cycles. (Illustration by Gregory Celikyol.)

use the turntable to rotate the arm and possibly a shoulder joint to position the shoulder.

Practice in control drills requires coaching the patient in patterns of reach, grasp, and release for objects that vary in weight, size, texture, and configuration. Ordinarily, the sequence is from large, hard objects to small, fragile ones.

These assortments are subject to the therapist’s ingenuity and patient’s interests. Initially, objects are placed on a tabletop for prehension practice; they are then transported to various locations in the room. The therapist instructs the patient to determine the most natural and efficient position for the TD before grasping an item and to rotate it in the wrist unit. This is called pre-positioning the TD.

Figure 46-18 Activation of voluntary closing TD. A. The TD remains open at rest B. The TD closes with forward flexion. (Illustration by Gregory Celikyol.)

Figure 46-19 Motions (*arrows*) necessary for elbow lock or unlock for a transhumeral prosthesis. A. Abduction with depression. B. Extension. C. Combined movement pattern of extension, depression, and abduction. (Illustration by Gregory Celikyol.)

Eventually the therapist instructs the patient to perform motion patterns in different planes, such as overhead, at tabletop, and at floor level. Overhead use is the most difficult because it is hindered by the harnessing system; it is particularly difficult, sometimes impossible, for persons with high amputations. The person with bilateral amputations has a harness system that is bilaterally attached; therefore, the patient must practice relaxing the musculature on the contralateral side while using one prosthesis.

Prosthetic Functional Use Training

Spontaneous, automatic skillful prosthetic use is a goal for functional use training. Another is completion of activities within a reasonable length of time while using minimal extraneous movement and energy expenditure. Figures 46-20 to 46-23 show functional tasks. The therapist encourages patients to analyze and see similarities among situations and reminds them of relevant principles. This prepares the patient to respond with a sense of control in unpredictable situations.

A person with a unilateral amputation can be expected to use the prosthesis primarily for sustained holding or for stabilization and to use it more slowly compared to the unaffected extremity. Table 46-3 suggests how some activities can be accomplished; Atkins and Meier (2004b) offer more comprehensive lists. An interesting study (Lake, 1997) revealed that individuals who received training surpassed those who did not in efficiency of use, skill, and spontaneity (Evidence Table 46-1).

Several factors affect the degree of independence of the person with bilateral amputations, the major one being the level of amputation. Some adaptations may be necessary for those with high-level bilateral amputations. These may range from a simple buttonhook or dressing frame—a stand in which coat hooks are inserted

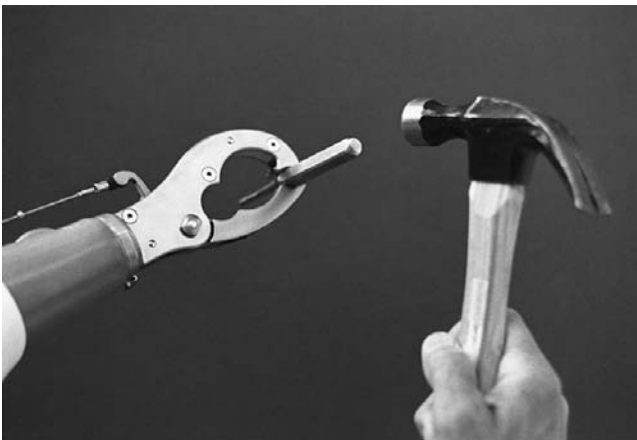

Figure 46-20 Use of the voluntary closing TRS Grip for bimanual task. (Photo courtesy of TRS, Inc., Brooklyn, NY.)

Figure 46-21 Grasping a fork using this method provides stability while the sound hand cuts the food.

to hold clothing—to high-tech solutions, such as electronic aids for daily living (Lehneis & Dickey, 1992) and computers controlled by breath, voice, or mouthstick. The therapist is advised to encourage foot use when patients show potential and are agile. Persons who have developed this ability at an early age have a high degree of independence. Feet have the advantage of having sensibility, which serves them well in all activities and surpasses prosthetic use.

Myoelectrically Controlled Prostheses

Myoelectric prostheses are fast becoming standard choices and are frequently prescribed for transradial amputations. Figure 46-24 depicts a two-state system whereby two separate muscle groups are used to operate the TD. The intent is to choose muscles that physiologically closely correspond to the outcome motion and also produce strong electrical signals when contracted. It is also essential that the contractions can be isolated from one another. Cocontraction may be used to switch between functions (i.e., wrist rotation and TD control). Wrist flexors and extensors are commonly chosen to achieve grasp and opening of the TD. For transhumeral amputations, the common choices are the biceps and triceps. For higher level amputations, as in shoulder disarticulation or forequarter amputations, the choices for control may be trapezius, latissimus, infraspinatus, or pectoralis muscles.

Figure 46-22 One way to open a jar using bilateral prostheses.

Most of the principles and treatment goals previously mentioned for BP prosthesis training apply to myoelectrically controlled prostheses. The therapy program begins with evaluation of the prosthesis, with special emphasis on the control system (Spiegel, 1989). Factors to be addressed include:

- Are the electrodes aligned along the direction of the muscle fiber and placed over the site offering the best muscle control potential?
- Is there good contact between the electrodes and the skin? (An imprint should be visible on the skin when

Figure 46-23 The myoelectric hand can hold delicate objects in bimanual activities.

the prosthesis is removed but should not be deep enough to cause irritation.)

- Can the patient open and close the hand in various planes?
- Can the patient remove and replace the battery with ease?

The therapist should consult with the prosthetist for guidance with any concerns. Donning and removing the prosthesis may require collaboration with the prosthetist to determine the simplest method for the patient. Often, a slight twisting of the forearm when inserting the limb is helpful. Sometimes baby powder or a lubricant can be used to ease donning, but these may inhibit electrode functioning.

Care of the socket requires daily cleansing with a damp cloth and mild soap to remove any residues of powder, lubricants, and perspiration. Other special concerns are care of the batteries, methods of charging the batteries, and operation of the on-off switch. Care of the glove was discussed earlier.

Controls and functional use training goals are similar to those for the BP prosthesis. This assumes that the patient has already received muscle site controls training during the pre-prosthetic period. When a myoelectric tester is used (a biofeedback unit can also be used), the goals are to isolate muscle contractions and increase muscle strength (see Chapter 20). If sustained grasp is required for an extended period, when one might inadvertently contract muscles that open the hand, a manual lock mechanism can be installed in the hand. This can be controlled by pushing it in with the remaining hand.

Final Stage of Treatment: IADLs

In the final stage, prosthetic functional use skills are further refined, and daily living activities that are more demanding are introduced. Discharge planning should

Table 46-3. Suggested Approaches for Functional Activities: Unilateral Upper Limb Amputation

Task	Prosthesis	Sound Limb
Eating Cut food Butter bread Fill glass from faucet Carry tray Peel fruit	Hold fork Stabilize bread Hold glass TD in midposition to hold Stabilize with TD	Cut with knife Spread toward body Turn knob or lever Hold in midposition Peel
Dressing Don and doff shirt or blouse Put clothing on hanger Buckle belt Tie bow Button cuff on sound side Use zipper	Don: prosthesis in sleeve first; doff: remove sound arm first Hold hanger Stabilize belt Stabilize lace Use buttonhook (or sew on button with elastic thread) Hold fabric with TD	Don: sound arm last; doff: remove prosthesis last Place clothing on hanger Push belt through buckle Manipulate and make loops Hold cuff in place with fingertips while using buttonhook Pull zipper
Desk skills Write Insert letter in envelope Use phone, dial, take notes Draw line with ruler; use paper clip	Stabilize paper Hold, stabilize envelope at end Hold receiver: TD or with chin and shoulder Stabilize ruler; hold paper	Write Insert letter and seal Dial and write Draw line; apply clip
General skills Take bill from wallet Wrap and unwrap package Thread needle	Hold wallet or stabilize on table Stabilize box and paper Hold needle	Manipulate wallet and remove bill Manipulate box, paper; tie Thread needle

include exploration of vocational and recreational interests and driving and/or the use of public transportation. An adaptation for driving may be a simple knob or driving ring attached to the steering wheel. Foot controls can be installed for those with very high level bilateral amputations. The therapist can consult companies that do van conversions (see Chapter 31).

Visits to the community, home, school, and work are strongly advised. This brings the patient and therapist into the actual environment, away from simulated, static settings. Patients may be referred to a self-help group. These organizations vary in their goals, but most provide a forum wherein people can interact and share experiences. Many groups provide ongoing educational programs on new prosthetic developments or on sports and recreational activities.

Sports and Recreation

Increasing numbers of individuals with amputations are pursuing recreational activities, and as a result, several customized prosthetic components are available for sports and recreational activities (Radocy, 2004; Radocy & Furlong, 2004). Figures 46-25 to 46-27 show modifications used to enable participation in sports activities. The

Internet is a good source of information for this and related topics (see Resources 46-1).

Discharge Planning

At discharge, the team schedules a follow-up appointment for the clinic; this may be one to several months after discharge. The patient is encouraged to contact the prosthetist for repairs or maintenance as needed and to make an appointment for a clinic visit at any time. Patients' needs do not remain constant; as they resume their lives, they may want special modifications or different prostheses.

PARTIAL HAND AMPUTATIONS

As with any amputation, the surgeon performing a partial hand amputation attempts to preserve length with intact sensibility. At this level, retaining residual digits with adequate skin coverage and some degree of mobility and sensation is far superior to any prosthesis (Bunnell, 1990) and is the goal. The principles of pre-prosthetic therapy (discussed earlier) apply to this level of amputation as well. Devices available for persons with partial

CASE

EXAMPLE

Mr. C.: Training with a Myoelectric Prosthesis for Transradial Amputation

Occupational Therapy Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information Mr. C., aged 53 years, sustained a crush injury of his dominant right arm in machinery at work that required a transradial (BE) amputation. His role as plant manager in a recycling plant is comprised of tasks including worker supervision, activities including machinery adjustment, and habits including lifting. Other self-maintenance roles are husband, parent of two teenaged children, and sole wage earner for the family.</p> <p>Mr. C. received occupational therapy to use a body-powered prosthesis with interchangeable hook and hand. He chose to use the hand rather than the hook, as appearance was important to him. He developed exceptional dexterity in his remaining hand and has continued to improve writing skills. Full day-wearing tolerance and independence in self-care skills were achieved with the body-powered prosthesis. However, Mr. C. continued to have difficulty grasping objects above shoulder level and occasionally grasping items at floor level because of harnessing strap restrictions. Mr. C. has returned to work part time and resumed his position as plant manager.</p>	<p>Understand the patient's diagnosis or condition</p> <p>Know the person</p>	<p>"Mr. C. has experienced a type of amputation that is not uncommon for workplace injuries and has achieved appropriate goals, which include dominance retraining for fine motor demands, tolerance and control of a body-powered prosthesis, and independence in self-care activities. Harnessing configuration that is used for a transradial body-powered prosthesis interfered with overhead reach and made it difficult to maintain grasp on items at floor level."</p> <p>"Mr. C. had demonstrated his motivation to integrate prosthesis use into job tasks but desired improved performance with some job tasks. As sole wage earner of his family, successful job performance is critical. Cosmesis is also important as indicated by Mr. C.'s choice of a hand rather than a hook terminal device."</p>
<p>Reason for Referral to Occupational Therapy Mr. C. has requested a myoelectrically controlled prosthesis with a hand terminal device. Approval was received from the insurance company for the prosthesis and indicated therapy services. Mr. C. was scheduled for occupational therapy to determine whether he is a candidate and to provide training if eligible.</p>	<p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>"During the 2 months that Mr. C. received occupational therapy, I consulted and treated with the prosthetist as needed to ensure best results with prosthesis fit and use. It was helpful to further discuss Mr. C.'s vocational requirements and performance with his employer, ensure that Mr. C.'s expectations were realistic, and arrange for a job site visit. Because Mr. C. had expressed some anxiety about returning to work full time, a psychologist's consultation was arranged. Based on his desire and ability to complete most job responsibilities with a body-powered prosthesis, I anticipated that Mr. C. would successfully incorporate his requested myoelectric prosthesis into self-advancement activities."</p>
<p>Assessment Process and Results Mr. C. was tested with the myotester and was able to achieve a sufficient, although inconsistent, level of muscle contraction in wrist flexors and extensors.</p>	<p>Consider evaluation approach and methods</p>	<p>"The myotester provided more accurate measurement of isolated and sustained muscle contraction than palpation or manual muscle testing so that the prosthetist and I could determine the best positions for the electrode placement."</p>

	Interpret observations	“Because he demonstrated sufficient muscle contraction in the desired muscle groups, I focused Mr. C.’s pre-prosthetic training on improving consistency, endurance, and control of these contractions.”
<p>Occupational Therapy Problem List</p> <ul style="list-style-type: none"> • Inconsistent demonstration of developed capacity to maintain strong muscle contractions • Inconsistent demonstration of developed capacity to isolate muscle contractions • Inability to demonstrate developed capacity of grading (increasing or decreasing) volitional muscle contractions, which relates to use of proportional control in the prosthesis • Decreased ability to reach overhead or to floor with body-powered prosthesis, especially during vocational activities 	Synthesize results	“The inconsistency of maintained and isolated muscle contractions was a result of fatigue and disuse of the wrist flexors and extensors while the body-powered prosthesis was worn. Mr. C. benefited from the visual feedback available during pre-prosthetic training as well as use of simulated and actual self-advancement activities.”
<p>Occupational Therapy Goal List</p> <p>Pre-Prosthetic Goals (anticipated length of treatment: six 1-hour sessions)</p> <ol style="list-style-type: none"> 1. Mr. C. will achieve maximal muscle contraction (as measured by myotester or myosoftware) of wrist flexors and extensors. 2. Mr. C. will maintain the level of contraction of the agonist while relaxing the antagonist muscle. 3. Mr. C. will control (or grade) the magnitude of contractions. 4. Mr. C. will demonstrate improved performance of identified tasks with dominant left hand. <p>Myoelectric Prosthetic Training Goals (anticipated length of treatment: eight 2-hour sessions)</p> <ol style="list-style-type: none"> 1. Mr. C. will demonstrate control of the myoelectric hand during clinic drills. 2. Mr. C. will use the prosthesis during self-maintenance and self-enhancement task-specific training. 3. Mr. C. will consistently use the prosthesis as a functional assist at work. 	<p>Develop intervention hypotheses</p> <p>Select an intervention approach</p>	<p>“Mr. C.’s ability to achieve isolation, consistency, and control of wrist contractions during the pre-prosthetic training allowed for optimal prosthetic outcomes. Prosthetic training progressed from demonstration of basic skills to consistent incorporation of the myoelectric hand as a functional assist during work tasks.”</p> <p>“Visual feedback from the myotester and myosoftware not only promoted Mr. C.’s learning, but also provided positive feedback, which encouraged him to participate and improve during the sessions. Because I had experience and training with myotesters and myosoftware programs, I was able to provide the treatment recommended. Contact was made with the prosthetist as questions or problems arose.”</p> <p>“I chose clinical drills and task-specific training that allowed Mr. C. to master control of the myoelectric hand when grasping, holding, releasing, and reaching for different objects. When indicated, I increased the level of difficulty, requiring him to handle crushable objects and perform manipulative bilateral tasks before performing occupational tasks. In the clinic environment, I instructed and observed Mr. C., analyzing and grading his tasks and activities.”</p>
	Consider what will occur in therapy, how often, and for how long	“The intervention approaches I chose could be completed in the 2-month time frame anticipated.”
<p>Intervention</p> <p>Pre-Prosthetic Intervention</p> <p>Mr. C. was instructed to flex and extend the sound wrist/hand and imitate the contractions with the residual limb. The visual feedback of the myotester and training software allowed Mr. C. to improve proportional control, isolation, and endurance of muscle contractions. Mr. C. was able to open and close an electronic hand (held by therapist or placed on a stand) using refined muscle contractions. Mr. C. received the permanent myoelectric prosthesis, which contains a supracondylar socket without harness straps and a proportionally controlled electronic hand.</p>	<p>Assess the patient’s comprehension</p> <p>Understand what he is doing</p> <p>Compare actual to expected performance</p> <p>Know the person</p> <p>Appreciate the context</p>	<p>“Mr. C. was able to demonstrate understanding of specific muscle contractions of the wrist flexors and extensors by producing these movements consistently during pre-prosthetic training. The visual feedback provided by the myotester and myosoftware engaged him in the training process as he improved his muscle strength and control. By using the practice electronic hand, Mr. C. further refined the natural movement speed and appearance required for grasp and release of objects. The myoelectric prosthesis socket fit Mr. C. comfortably. He was able to open and close his hand consistently, indicating accurate placement and contact of the electrodes on the muscles.”</p>

Prosthetic Intervention

Mr. C. learned to don and remove the prosthesis, clean the socket and electrodes, and change the battery. Instruction was given for precautions with prosthesis use and care of the prosthesis glove. He practiced maintaining grasp and grading control of pressure on objects.

The therapist obtained job requirements from Mr. C.'s employer, and Mr. C. simulated tool use and lifting/placement of items from floor to shelves at shoulder height.

During a job site visit, Mr. C. was observed performing his job tasks, and recommendations for modification of activity or environment were discussed with Mr. C. and his employer. A plan for gradually increasing Mr. C.'s hours and responsibilities were also discussed, decreasing the anxiety he initially expressed.

“Following instruction from the prosthetist and therapist, Mr. C. independently cared for and wore his prosthesis. He understood the progression of occupational therapy treatment, demonstrating controlled grasp and release of various items in all arm movement ranges before practicing simulated work tasks. In the clinic, adaptive equipment or techniques were used when needed so that Mr. C. could incorporate his myoelectric hand as an assist when using tools, performing desk activities, and lifting items unilaterally or bilaterally.

The job site visit allowed Mr. C. to demonstrate his competence with the performance of self-advancement activities to his employer. Mr. C. was encouraged by the support of his employer and actively participated in applying the activity and environmental modification recommendations.

Mr. C. was no longer apprehensive about returning to work because he was confident about the cosmesis and function of his myoelectric hand.”

Next Steps

- Mr. C. was discharged from occupational therapy but was encouraged to contact the therapist for problems or questions if needed.
- Mr. C. saw his psychologist to address any remaining concerns about occupational adjustment and participated in a monthly support group for amputees.
- Mr. C. continued with periodic doctor and prosthetist appointments as indicated. The myoelectric prosthesis needed to be replaced within 2 years, and the gloves were replaced more frequently.
- Mr. C. was given a list of written and Internet resources so that he could increase his knowledge about myoelectric prostheses and, if desired, contact others with similar life circumstances.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“After observing Mr. C. at work, I was confident that he would successfully use his myoelectric prosthesis effectively. He had expressed satisfaction with the appearance and performance of the myoelectric hand. He had demonstrated good generation and application of adaptive problem-solving during his therapy course. Mr. C. had established a strong support network and was motivated to use the appropriate resources so that he could achieve the best possible outcome in his occupational roles.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Myoelectric Prosthesis Training**

Mr. C. has demonstrated effective use of a body-powered hand prosthesis but is challenged by lifting items that require bimanual grasp in various planes and in maintaining a firm grasp when adjusting machinery. How can the therapist design a program that will address these issues? What information is necessary to quantify the job requirements?

Evidence Table 46-1 Best Evidence for Occupational Therapy Practice Regarding Upper Extremity Amputations

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Training with bilateral training prostheses	One group received training at home, while the control group was given the same tools and activities but not specific training.	10 individuals without amputations, using training prostheses, randomized to experimental and control groups. Mean age = 48.5 years.	Four sessions of 2 hours each.	Randomized trial. IC2b	Greater improvement in efficiency and skill in the group who received training as reflected on the <i>University of New Brunswick (UNB) Test of Prosthetic Function</i> (Sanderson & Scott, 1985; Burger, Brezovar, & Marinček, 2004).	The trained group performed significantly more skillfully than the untrained group on one of the subtests ($p = 0.03$, $r = 0.59$) and significantly more efficiently on two of the subtests ($p = 0.006$, $r = 0.79$; $p = 0.04$, $r = 0.55$). Statistical significance was not attained on all subtests, however, probably due to small sample size. Not applicable.	Lake, 1997
Fitting of bilateral transhumeral, low-temperature plastic prostheses with utensils to address specific patient goals: feeding, dressing, and writing	Patient was fit with 2 sockets, figure-eight harness, 2 utensil holders and several utensil devices, a dressing hook, and a typing bar. Patient was trained to change and adjust utensils.	One right-handed subject with bilateral transhumeral amputations resulting from electrical burn injury. Initially fitted with bilateral transhumeral body-powered prostheses.	10 hours of training with initial prosthetic prescription, spread over 1 month; 1 hour of training with "utensil" prostheses.	Single-subject case report. Unrated.	After 10 years, subject reports successfully using the "utensil" prostheses to accomplish his stated goals more than 8 hours per day. He scored 100 (highest score) on the <i>Barthel Index</i> .		Hung & Wu, 2005

Figure 46-24 Myoelectric prosthesis, a two-state system in which two separate muscle groups operate the terminal device. **A.** 1. The muscle contracts and creates an electrical signal that can be measured in microvolts (1 millionth of a volt). 2. The EMG signal is detected by the surface electrode. 3. The EMG signal is processed by the electronics and transmitted to the electronic relay in the hand. **B.** 1. When the electronic relay receives an EMG signal from the wrist flexors, the circuit is complete, and the electricity from the battery runs the motor to close the hand. 2. When the relay receives an EMG signal from the wrist extensors, the motor runs in the opposite direction to open the hand. (Illustration courtesy of Jack Hodgins, CPO, Kessler Institute for Rehabilitation, West Orange, NJ.)

hand amputations can be described as cosmetic, passive functional, or active functional prostheses.

Some patients with a partial hand amputation want a prosthesis that closely replicates the look of the hand and provides dexterity as well. Although cosmetic hand coverings are truly artistic endeavors, once they fit over the residual hand, tactile sensation is lost, which limits function. The passive functional prosthesis may be a highly specialized device that is task specific, or it may be a simple post to provide opposition.

An active functional prosthesis may be cable driven by scapular or humeral movements, requiring restrictive harnessing. This, however, may be the best option for the person with bilateral amputations (Weir, Grahn, & Duff, 2001).

MANAGEMENT OF LOWER LIMB AMPUTATIONS

The therapeutic program for persons with lower limb amputations requires collaboration between the physical therapist and occupational therapist. The physical therapist is responsible for skin care, limb wrapping, lower limb strengthening exercises, range of motion, and ambulation training. Training in some daily living activities may be shared, for example limb bandaging, bed mobility, and transfers. Critical care pathways can identify specific goals within a time frame for all professionals involved with patient care, ensuring maximum functional outcome (Esquenazi, 1996). The therapist can refer to a functional

Figure 46-25 TRS Super Sport Passive Mitt, used for gross grasp. (Courtesy of Bob Rodocy, TRS, Inc., Boulder, CO.)

outcome guideline (Leonard & Meier, 1998) that lists specific daily living activities with expected outcomes for transfemoral amputation and transtibial amputation and to the *Locomotor Capabilities Index* (Gauthier-Gagnon, 1998) for an example of a questionnaire used to determine patients' perceived levels of independence in locomotor activities.

Often, functional conditioning and educational groups are conducted by an occupational therapist. These are examples of topics included in such group sessions:

- Upper extremity strengthening exercises
- Safety precautions related to specific activities
- Principles of energy conservation and body mechanics
- Use of adaptive devices
- Review of dietary restriction when appropriate

Other staff may present topics in their areas of expertise, such as the dietitian on special diets.

Occupational Therapy Program Guidelines

The occupational therapist analyzes occupational performance, assesses physical and mental status, and obtains information on secondary diagnoses that may affect function. Safety is a major concern with lower limb amputations, particularly for elderly patients. They may have a primary diagnosis of diabetes or vascular disease with secondary complicating factors that affect therapy, such as kidney disease, cardiovascular disease, chronic infection, respiratory disease, and arthritis. In the elderly, impaired vision and memory deficits may influence safe performance in activities of daily living. Energy expenditure 25–40% above normal can be expected for unilateral transtibial amputation, 68–100% above normal for unilateral transfemoral, more than 40% above normal for bilateral transtibial, and 100% above normal for bilateral transtibial–transfemoral amputation (Esquenazi, 1996).

From the outset, coordination with the physical therapist will determine the wearing schedule and the amount of assistance or assistive device needed, as well as readiness for any standing or ambulation activities. The occupational therapist and physical therapist can address activities of daily living in the following sequence: bed mobility; hygiene and grooming; dressing, including donning and removing the leg prosthesis; and wheelchair propulsion and management. Transfer skills are practiced with and without the prosthesis. Practice sessions include transfers to the bed, toilet, furniture, and car. The therapists teach the family the transfer techniques when safety is a concern. The occupational therapist addresses energy, effort, and mobility skills in the kitchen while the patient is using

a wheelchair and/or ambulating with the prosthesis. The therapist includes other self-maintenance skills as appropriate, such as housecleaning and bed making. Home and community visits with the patient and a staff member may be indicated. During standing and ambulation, special attention is paid to balance, posture, and equal weight bearing through both legs.

Appropriate application of the prosthesis is crucial and always begins with skin inspection. Stump socks, liners, or sheaths and inserts are applied, and then the hard socket (Fig. 46-28). The socks should have no wrinkles, and seams should not be over bony areas or the scar. The transfemoral prosthesis should be applied in standing because weight bearing will ensure total contact. This may be challenging for the elderly individual. Consultation with the physical therapist should be ongoing to determine the amount of support and assistance the patient requires in this process.

The therapist may recommend home modifications and equipment to the patient and family. Equipment often includes transfer tub bench or seat and toilet safety arm rails. These rails fit around the toilet and provide a means of arm support that assists with lowering and coming to

standing. The therapist makes the referral for driving assessment and training when appropriate. Installation of a left-foot accelerator bar and pedal is necessary for a person with a right-leg amputation. Hand controls can be installed for persons with bilateral leg amputations (see Chapter 31).

EMERGING TRENDS IN PROSTHETICS

Recent improvements in lower extremity prosthetic devices related to materials include suspension sleeves and gel interfaces in direct contact with the skin and the use of carbon fiber and graphite combined with improved mechanical and electro-mechanical components. Innovations have enabled more successful participation in ADLs, including recreational sports activities.

As mentioned in the introduction to this chapter, the ratio of upper to lower limb amputations is about 1:3; this ratio is reflected in the motivation for research in lower limb prosthetics. Research and development activities increase

Figure 46-28 A. Donning the transfemoral prosthesis beginning with the silicone liner with attached lanyard, and socks (to compensate for volume changes in the residual limb). B. Donning the transfemoral socket. C. Securing the suspension of the transfemoral prosthesis is done in standing to ensure total contact in the socket. The lanyard attaches with Velcro.

during times of armed conflict, as is currently the case in the Iraq war. As a result, attention is focused on the increase in numbers of amputations in a young, previously healthy population, whose members will hopefully live long, productive lives using prosthetic devices. The infusion of funds may further develop the technology supporting upper limb prosthetics (signal processing, electronics, and micro-processors) while fostering development of improved hardware. In articles by Atkins and Heard (1996) and by Kyberd and Beard (1998), users identified the following features needing improvement: better suspension and cable systems, additional wrist movement, more precision of pinch with more dexterity, coordinated motions of two joints, and improved reliability for electronic hands.

Recent developments include the Otto Bock Sensor Hand, which incorporates “reflex” action, that is, sensors in the hand can detect slip and automatically adjust grip, thereby reducing the mental load required of the user to visually monitor grasp. Although no commercial electric shoulder is currently available, LTI-Collier has developed an electric lock actuator to lock the manually positioned shoulder. Wrist flexion and rotation units are available on both body-powered as well as electric TDs. Motion Control has a mechanical flexion/rotation component to incorporate with the electric TD.

Current Research Topics

The surgical approach called osseointegration requires the implantation of a titanium peg fixed to the bone to which a prosthesis can be attached. This approach has been reportedly successful for lower limb amputations (Jones & Davidson, 1996) and has further potential for upper limb prosthetics. This approach provides a stable fixation for prosthetic attachment and would eliminate the need for harness suspension if successful in higher level upper limb amputations. It has the added advantage of enhanced proprioceptive feedback from the artificial limb (Brånemark et al., 2001).

Targeted hyper-reinnervation is a surgical technique being pursued to increase the number of myoelectric control sites available in a higher level amputation. After limb loss, the brachial plexus and peripheral nerves may remain intact in the residual limb. This procedure takes advantage of expendable regions of remaining muscle by denervating and hyper-reinnervating sections of tissue. When successful, this can result in myoelectric sites that correlate physiologically with prosthetic functions: the radial nerve innervates musculature that contracts when the subject attempts to extend the elbow; the distal radial nerve reinnervated area contracts to open the hand; the median nerve area contracts to close the hand. Early indications are that sensory reinnervation may be tapped to enhance control of multiple functions in the artificial arm (Kuiken et al., 2004).

Currently, surface EMG will only allow up to four channels of control in the forearm, but 18 extrinsic muscles supply the hand and wrist. Development is proceeding on implantable myoelectric sensors (IMES) small enough to be injected. The potential is for myoelectric control of multiple degrees of freedom in the hand, simultaneously (Weir et al., 2003).

Future advances in engineering, medicine, and prosthetics promise technical improvements in the fit and function of artificial limbs. As with research and development, the therapeutic program must be driven by the patient’s needs. As the patient masters the basics of prosthetic control systems and practices their use in activities, with the therapist’s guidance as facilitator or teacher, the patient chooses tasks that he or she values. The approach of analyzing tasks and problem solving on how best to use this tool, the prosthesis, regardless of its complexity, serves the patient well throughout life.

EVIDENCE

Research addressing upper limb prosthetics in occupational therapy literature is limited because the incidence of acquired upper limb amputations is proportionally small and geographically diverse. Considerable variation is found as well within that small population concerning amputation level, dominance, etiology, post-operative or pre-prosthetic care, and prosthetic prescription, with occupational therapy intervention frequently occurring only after the delivery of the prosthesis. Outcome measures are generally focused on functional task accomplishment with some attention to quality of performance, ability to incorporate prosthesis, and wearer satisfaction with task performance. To date, most formal assessment tools have been developed for a pediatric population. Frequently, the literature describing occupational therapy intervention is in a case study format. Although it is generally accepted that training with a prosthesis will improve outcomes, seldom is there a significant concentrated population of individuals with comparable levels of recent arm amputation who are willing to forego training to constitute a control group.

SUMMARY REVIEW QUESTIONS

1. Why is the residual limb wrapped with elastic bandaging? How is it done?
2. What are the most common causes of acquired upper and lower limb amputations?
3. Which body movements are required for a patient with a transhumeral amputation to operate a conventional BP terminal device and elbow unit?

4. What are the positive and negative features of a hook? A hand?
5. Describe the differences between a VO and a VC terminal device.
6. What is myoelectric control?
7. What is the purpose of controls training and use training?
8. Why might a prosthesis be rejected?
9. What are the functional expectations for a person with a unilateral transhumeral amputation or a bilateral transhumeral amputation?
10. What is the role of the occupational therapist in the rehabilitation of the patient with lower extremity amputations?

ACKNOWLEDGMENT

The authors wish to acknowledge the work of Felice Gadaleta Celikyol, the author of this chapter for the fourth and fifth editions.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Recognize the signs and symptoms of exercise/ activity intolerance.
2. Identify the common cardiac diagnoses and their treatment in occupational therapy.
3. Understand various cardiac and pulmonary diagnostic studies and how these tests assist with treatment planning in occupational therapy.
4. Know the controllable risk factors for heart disease and ways to ameliorate their effect.
5. Be able to instruct patients with pulmonary disease in breathing techniques.
6. Know resources for further guidelines in cardiac and pulmonary rehabilitation.

CHAPTER 47

Cardiac and Pulmonary Diseases

Nancy Huntley

Glossary

Glossary

Acute coronary syndrome (ACS)—A term including unstable angina and myocardial infarction (MI), both non-ST elevation MI (non-STEMIs) and ST elevation MIs (STEMIs). This designation is used to triage and manage patients with symptoms of myocardial ischemia (Kim, Kine, & Fuster, 2004).

Angina—A temporary lack of blood flow to the myocardium, which causes the sensation of chest pain, fullness, tightness, or pressure. The pain or discomfort from angina can be referred to the teeth, jaw, back, ear, or arm. Angina is relieved with nitroglycerin or rest.

Atherogenic—Causing the development of plaque in an artery.

Atrial fibrillation—A rapid firing of cells in the atria of the heart with irregular response of the ventricles causing a fast irregular heart rhythm. With uncontrolled atrial fibrillation, the patient often feels short of breath and fatigued.

Cardioversion—Electrical shock delivered to the heart to stop a serious dysrhythmia, with the hope that the heart will restart in a normal sinus rhythm.

Congestive heart failure (CHF)—A condition where the heart's pumping function is impaired from a variety of etiologies. This impairment results in the heart's inability to rid the body of excess fluid, which then collects in the lungs and extremities.

Diaphoresis—A cold clammy sweat that comes on suddenly.

Oxygen saturation (O₂ Sat)—Measurement of the amount of oxygen carried by the hemoglobin in the blood. A normal O₂ Sat is greater than 95%.

Sternotomy—A procedure used in open heart surgery where the sternum is split in half to allow the surgeon access to the chest cavity. After surgery, it is wired together.

Tachypnea—Rapid shallow breathing.

INCIDENCE OF CARDIAC AND PULMONARY DISEASE

Heart disease is the leading cause of death in the United States. Annually, 41% of all deaths in the United States are caused by coronary artery disease. Fifty-seven million, or 45%, of all Americans are living with some form of the disease (American Heart Association [AHA], 2005). According to 1998 Heart and Stroke Statistical Update, “about two thirds of the people who survive a heart attack do not make a complete recovery, but 88% of those people under the age of 65 years will be able to return to their usual work” (AHA, 1998, p. 11).

Pulmonary disease is also a significant cause of death in the United States. Chronic Obstructive Pulmonary Disease (COPD) is the fourth leading killer of Americans (American Lung Association, 2004). Lung disease is not only a killer; it is also chronic and significantly alters the lives of those who have it. Seventy percent of persons with COPD say it limits their ability to do normal exertion (American Lung Association, 2004).

Even though a clinician is not working in either cardiac or pulmonary rehabilitation, the diagnosis of cardiac or pulmonary disease in a patient's medical history has implications for the occupational therapist's treatment plan. For instance, a patient may carry the primary diagnosis of a recent stroke. If that stroke occurred shortly after coronary artery bypass surgery, certain precautions should be taken to protect the patient's sternum. When the patient has a history of heart disease, the therapist should also routinely measure their heart rate and blood pressure both

at rest and with activity to determine the patient's cardiovascular response to rehabilitation. The occupational therapist must, therefore, be aware of these disease processes and know how they will influence treatment.

HEART DISEASE

Heart disease may be due to a blockage of the coronary arteries, diseases of the heart muscle, or structural anomalies of the heart. Heart attacks are the single leading cause of death in men and women in the United States (AHA, 2005). A **myocardial infarction (MI)**, or heart attack, is death of the heart muscle caused by lack of blood flow due to an obstruction of a coronary artery by plaque or spasm. The patient's clinical history, along with several diagnostic tests, is considered when diagnosing a heart attack. The patient may first have an onset of symptoms known as **acute coronary syndrome (ACS)**, which indicates acute myocardial ischemia (Kim, Kine, & Fuster, 2004). The patient may first have symptoms such as chest pain or pressure, which may radiate to the teeth, jaw, ear, arm, or mid-back. These symptoms may be accompanied by **diaphoresis**, shortness of breath (SOB), nausea, vomiting, and/or fatigue. The patient may present with one or more of these symptoms, and the severity and intensity varies from person to person. (Not everyone who has these symptoms will have a heart attack, but it helps to triage them to the appropriate treatment.) An electrocardiogram (EKG) will show where the damage to the heart muscle occurred. Meanwhile, blood tests for certain structural pro-

teins and cardiac enzymes will confirm a heart attack and give an idea of the amount of damage done to the heart muscle.

If a person realizes he or she is having a heart attack and comes to the hospital immediately, a drug called a thrombolytic agent may be given to stop the damage to the heart muscle. Thrombolytics break up the clot in the coronary artery, thus restoring blood flow. They must be given quickly after the onset of symptoms and are most effective within the first hour. The benefit decreases incrementally from 1–12 hours post symptom onset. From 12–24 hours, thrombolytics have only a minimal effect (Antman, 2005), so the sooner the patient receives the thrombolytic, the more heart muscle can be saved.

The left ventricle is the main pump of the heart. It pumps the blood from the heart to the rest of the body. Since the left ventricle does more work, it has a higher oxygen requirement than the rest of the heart. It is usually the first area of the heart to suffer from any coronary artery perfusion deficiency.

Types of MI

In evaluating an MI, an EKG is an important adjunct in determining the location of the MI and the severity of the infarction. An MI that involves all three layers of the heart muscle is called transmural, and it usually produces ST elevation on the EKG. It is referred to as an ST elevation MI, or STEMI. Three fourths of these MIs will later produce a Q wave over EKG leads affected by the MI (Antman & Braunwald, 2005). A Q wave is an identifying characteristic showing where damage occurred. In STEMI MIs, the size of the infarct is important. If the STEMI is large or if the STEMI is small to moderate in a person with previous STEMIs, the prognosis is poor (Antman, 2005). An anterior STEMI is considered the most serious because of the large amount of muscle mass lost and decrease in the effectiveness of ventricles pumping action (Meyers, 2005). (See Definition 47-1 for a review of common diagnostic procedures.)

When the thrombus in the coronary artery is incomplete, less damage is done, and it is called a non-ST elevation MI or a non-STEMI. The majority of these MIs do not develop a Q wave. These MIs are called non-STEMIs or non-Q wave MIs (Antman & Braunwald, 2005). Although the immediate prognosis is better in patients with a non-STEMI, their future risk is often higher for death or further cardiac events because of a history of previous heart events or due to the extent of their underlying heart disease (Cannon & Braunwald, 2005).

Blockage in the left main or left anterior descending artery of the heart will cause damage to the front of the left ventricle and is called an anterior MI. When the right coronary artery is involved, the back and bottom of the left ventricle are damaged; this is called an inferior MI. The

circumflex artery feeds the lateral wall of the heart, and blockage in this artery results in a lateral MI (Fig. 47-1).

Open Heart Surgery

Open heart surgery is a procedure that usually involves a **sternotomy** and allows the surgeon to work on the heart. There are several types of open heart surgery.

Coronary artery bypass graft (CABG) is the replacement of occluded coronary arteries with artery or vein grafts. These grafts are attached to the aorta and reconnected below the occlusion in the coronary artery. Sometimes the mammary artery, which comes directly off the aorta, is dissected from its original destination and used as a graft. Another arterial graft is the radial artery. Arteries are preferred as grafts because they stay patent longer than vein grafts. Vein grafts are usually harvested from the legs.

Valve replacement and/or repair may be necessitated by destruction of a heart valve due to disease or congenital malformation. If the surgeon is unable to repair the valve, it is replaced with a prosthetic or tissue valve. If a prosthetic valve is used, patients will have to take thrombolytics for the rest of their lives. The thrombolytics will prevent blood from clotting as it goes through the valve. A tissue or biothesis valve is from humans or pigs. These valves do not require the patient to be on thrombolytic therapy, and they usually last about 10–15 years before they need to be replaced (Gersh, 2000).

Twenty-five percent of the congenital heart defects in adolescents and adults are atrial septal defects (Gersh, 2000). About 30% of people with atrial septal defect will develop symptoms in the third decade of life, but 75% will have symptoms by their fifties (Webb et al., 2005). When the heart has been attempting to compensate for a defect for a long time, it may become enlarged, and the patient may complain of fatigue and shortness of breath. The current standard of practice is to repair these heart defects before the patient has significant symptoms or sustains myocardial damage.

Other Heart Diagnoses and Procedures

Congestive heart failure (CHF) describes the inability of the heart to function as an effective pump. The heart muscle becomes stretched beyond its ability to contract efficiently, resulting in the collection of fluid in the lungs or the extremities. Seventy-five percent of patients with CHF have a previous history of hypertension (AHA, 2005). CHF may also result from a number of other disease processes such as multiple MIs, incompetent valves, cardiomyopathy, and so on. Patients with CHF experience SOB and fatigue and may have an increase in weight and a dry hacking cough. Often they complain of coughing or being SOB in a recumbent position (see Safety

DEFINITION 47-1

de·fin·i·tion

Common Diagnostic Studies for Heart Disease

Blood Tests

Blood tests are usually drawn on patients with symptoms of a probable heart attack. The cells of the heart contain isoenzymes and structural proteins, which are specific to that organ. Death of the heart's cells causes those isoenzymes and structural proteins to be released into the blood stream where an increase in their levels can be measured. CPK MB is an isoenzyme that shows up in the blood within 4–6 hours after a heart attack (Maltas, 2003). Troponin I and troponin T are two structural proteins whose levels rise with heart damage. Troponin is specific to heart muscle. Troponin levels start rising after 3–6 hours and stay elevated for up to 14 days, allowing detection of an MI in patients who wait to seek treatment (Maltas, 2003).

Stress Echocardiogram

A stress echocardiogram is an exercise test usually conducted on a treadmill. Before starting the test, an ultrasound recording is taken of the function of the heart at rest. The patient is then exercised to his or her maximum capacity. After exercising, another ultrasound recording of the heart is done to show how the heart responds to work. It will show whether the heart muscle and valves work normally under pressure or if some parts respond suboptimally. It is also possible to measure how much blood the heart ejects with each beat. This number is the ejection fraction (EF).

A normal EF is $>60\%$. A person is mildly impaired with an EF of 50–59%. A person with an EF of 40–50% has moderate impairment. An EF below 40% is considered significant impairment. The lower the EF, the higher the risk the patient has for further events and complications. If individuals who have a low EF can tolerate mild-to-moderate exercise, they have a better long-term outcome than those who cannot tolerate exercise well (Antman, 2005). The EF does not always accurately reflect an individual patient's ability to work, but the EF is helpful as a starting point for making appropriate exercise and activity recommendations and precautions.

A stress echocardiogram will also reveal the maximum exercise capacity of an individual. Using 60–85% of the maximum heart rate attained during the stress test, the therapist can determine an appropriate level to start exercise and activity.

Stress echocardiography is approximately 88% accurate in predicting coronary ischemia depending on the cohort of the study (Barasch, 2000). When a stress test is given without the echo, the accuracy is reduced to 75% in predicting heart disease, but patient's maximum exercise capacity and their maximum heart rate with exercise is known.

Nuclear Stress Test

A nuclear stress test is conducted with a 12-lead EKG as patients exercise to their maximum capacity on a treadmill. During this test, the patient is injected with a radioactive isotope when the patient feels only able to exercise for one more minute. The patient is then placed under a special instrument called a scintillation camera, which can detect the presence of the radioactive isotope in the heart muscle. This isotope has special properties, which allows it to be readily picked up by healthy myocardium cells, more slowly by cells with poor perfusion, and not at all by infarcted myocardium. The radioactive isotope stays in the blood stream for approximately 72 hours. Those areas with restricted blood flow may eventually "fill in" with the radioactive isotope, and these areas are said to have a reversible defect. Areas that do not "fill in" are infarcted, and the deficit is permanent. Since this process may take several hours, the nuclear test usually has an initial scan, and then another scan is administered 2–3 hours later (Maltas, 2003).

Coronary Angiography

Coronary angiography is currently the most definitive test in the diagnosis of coronary artery disease. A catheter is inserted into a blood vessel in the groin and threaded back into the heart, and a radiopaque dye is injected through it into the coronary blood vessels. The extent of the obstruction in any coronary blood vessel can be visualized. A blockage must be greater than 70–75% of the lumen to be considered significant. A lesion greater than 50% in the left main artery is considered equivalent to two-vessel disease. The length of coronary artery lesion(s) is also taken into consideration. In addition, heart valve function, ventricular wall motion abnormalities, and some heart defects can be detected (Paganda & Paganda, 2001).

Note 47-1 for signs and symptoms). Recent medication treatment options for patients with CHF have increased significantly. Yet even with treatment, 40% of patients will die within 4 years (Yakubov & Bope, 2002).

Cardiomyopathies (CMs) are diseases of cardiac muscle. The three main types of cardiomyopathy are dilated, hypertrophic, and restrictive. Dilated cardiomyopathy is the most common type, comprising over 75% of the

cases. Seventy-five specific diseases can cause dilated cardiomyopathy, but symptoms are an enlarged heart with decreased pumping capacity that usually results in congestive heart failure. Depending on the cohort of the study, 10–50% of people with cardiomyopathy who are hospitalized due to CHF will die within 1 year (Wynne & Braunwauld, 2005); other patients with cardiomyopathy, for unknown reasons, improve over time. An enlarged left

Figure 47-1 Coronary arteries. Location of damage to the heart depends on which coronary arteries are blocked. (From Willis, M. C. [1996]. *Medical terminology: The language of health care* [p. 160]. Baltimore: Williams & Wilkins.)

ventricle and decreased heart function are indicators of a poorer prognosis (Wynne & Braunwald, 2005).

Angina pectoris is heart pain caused by a temporary inadequate supply of blood to the heart muscle. Angina might be described as pain, aching tightness, or pressure. It is usually diffuse and located in the mid chest, but it

may radiate to the mid back, teeth, ear, jaw, or arm. Typically, angina comes on with increased activity and is relieved with rest. Some people, however, may develop angina after a heavy meal or while resting. Nitroglycerin, taken by pill or spray under the tongue, usually relieves angina quickly. Angina is an indication of coronary artery disease; it is not uncommon to have angina after a heart attack. If the frequency or intensity of angina changes, the physician should be notified.

Percutaneous transluminal coronary revascularization (PTCR) or angioplasty is a procedure used to improve the blood flow through an occluded artery and reduce the symptoms of angina. Angioplasty requires the insertion of a catheter into the coronary artery at the site of the occlusion. On the end of the catheter is a balloon that is inflated until the arterial walls at the point of the occlusion are pushed out to allow more blood flow through the area. The initial success rate with angioplasty is 90%, but approximately 30–40% of all angioplasties close within 6 months (Baim, 2005). Sometimes a stent, which resembles a spring in a ballpoint pen, may be used. The stent lies over the balloon, and when the balloon is inflated, the stent opens and

SAFETY NOTE 47-1

Signs and Symptoms of Congestive Heart Failure

- Increase in weight of 2–5 pounds or more over several days
- Inability to sleep
- Persistent dry hacking cough
- Shortness of breath with normal activity
- Swelling in ankles or feet
- Fatigue

Reprinted with permission from Huntley, 1998.

imbeds itself in the artery wall, forming a structure to keep the artery open. Stents without drugs are called bare metal stents. Stents with drugs coating them are called drug-eluting stents. When a bare metal stent is used, the success of the procedure increases to about 70–80% (Lowe et al., 2005). When a drug-eluting stent is used, the restenosis rate with clinical symptoms drops to between 5 and <10% (Baim, 2005). Getting a patient who is having an MI quickly to the catheterization lab for an angioplasty/stent to the involved artery is now considered the standard of care.

For those patients whose lesions are too long or calcified to use the angioplasty balloon, another procedure is available. It is called atherectomy. In atherectomy, the catheter inserted into the coronary artery has a rotating blade that cuts out the plaque. As it cuts the plaque, suction pulls the plaque through a tube and out of the body. The long-term success of this procedure is comparable to angioplasty (Baim, 2005).

CARDIAC REHABILITATION

Cardiac rehabilitation usually involves a multidisciplinary team. Doctors, nurses, occupational and physical therapists, exercise physiologists, dieticians, and social workers may all play a part in the patient's recovery. Doctors, dieticians, and social workers perform their conventional role in treating the cardiac patient. None of the other allied health professionals, however, are trained specifically to work in cardiac rehabilitation, and all need additional training. Geographical tradition and availability of staff seem to determine what role each allied health professional plays. Each discipline uses their own special skills in dealing with patients with heart disease, but their job expectations and responsibilities may essentially be the same. (See Resource 47-1 for information on organizations that dominate policies and certifications in cardiac rehabilitation.)

Occupational therapists are invaluable when treating the patient with heart disease. Therapists are able to evaluate and analyze the patient's activities of daily living. The therapist can then assist patients in modifying activities, if necessary, so they can resume those activities they previously enjoyed. The occupational therapist's expertise in the rehabilitative process and knowledge of comorbid diseases is extremely important when evaluating and adapting treatment for the individual needs of the patient. Patients who have undergone lifestyle changes and experienced life-threatening diseases also benefit from occupational therapy intervention to help with psychosocial adjustment to their new situation.

Risk Factors for Heart Disease

One of the main goals of all phases of cardiac rehabilitation is primary and secondary prevention of heart disease.

Primary prevention refers to efforts to prevent the development of heart disease. Primary prevention efforts are usually limited to health fairs and lecture series because health insurance currently does not cover the cost of primary prevention. Those costs are born either by a sponsor (i.e., a hospital) or by charging admission. Therefore, most of the therapist's efforts are directed toward secondary prevention. Secondary prevention pertains to efforts made to stop or slow the progression of heart disease. Improving an individual's risk factor profile is the method used by therapists for secondary prevention of heart disease.

Ten risk factors increase one's likelihood of developing coronary artery disease. The three risk factors that are not controllable are age, family history, and gender. With advancing age, an individual is at greater risk for heart disease. A family history of a first-degree relative, such as father, mother, brother, or sister, developing heart disease before age 55 for males and before age 65 for females increases one's risk (Maron et al., 2004). The highest risk of developing heart disease for both men and women occurs when another sibling has the disease. Indeed, studies suggest that a sibling with heart disease increases one's risk by three to four times that of a person without a sibling history of the disease (Jairath, 1999). Men are more likely to develop heart disease an average of 10 years earlier than women, but as women approach menopause, they lose the protective effect of estrogen, and their risk of heart disease increases (AHA, 2005). The risk of heart disease in women continues to rise after menopause until they are in their seventies. Then their incidence of heart disease surpasses that in men (AHA, 2005). Although heart disease is commonly considered a male problem, it is an equal opportunity killer. It remains the number one cause of death for both men and women (AHA, 2005).

Controllable Risk Factors

The risk factors one can control are smoking, hyperlipidemia, hypertension, sedentary lifestyle, obesity, diabetes, and psychological stress.

Smoking is a major modifiable risk factor in heart disease that contributes to heart disease in multiple ways. People who smoke have a two to three times greater risk of dying of heart disease (AHA, 2005). Smoking damages the endothelial lining of the coronary arteries, making them more susceptible to plaque formation. Nicotine causes vasoconstriction of the arteries and increases heart rate. Smoking makes the heart more susceptible to lethal ventricular arrhythmias and predisposes it to coronary artery spasm (Ricker & Libby, 2005). Carbon monoxide in cigarette smoke binds with the hemoglobin faster than oxygen, resulting in less oxygen being distributed to the tissues. Nicotine also alters the metabolism of fats, increasing the levels of **atherogenic** LDL cholesterol and decreasing the levels of the heart-protective HDL chole-

terol. Smoking causes the blood to coagulate more quickly and promotes thrombus formation (Ricker & Libby, 2005).

Hyperlipidemia or a high lipid level is a major risk factor among Americans. It has been demonstrated that a total cholesterol level above 200 mg/dL, an LDL cholesterol above 130 mg/dL, and an HDL cholesterol of less than 37 mg/dL for men and 47 mg/dL for women significantly increases the risk of heart disease (AHA, 2005). Fifty-one percent of American adults have cholesterol levels above 200 mg/dL (AHA, 2005). Patients with known coronary artery disease should have an LDL cholesterol below 100 mg/dL. Cholesterol levels may be lowered through a low-fat diet, regular aerobic exercise, and weight loss. If these options are unsuccessful, the physician will put a patient on a lipid-lowering drug. Some individuals inherit an inability to metabolize lipids normally. They have very high lipid levels in their blood because they manufacture their own cholesterol. These patients will never be able to lower their blood lipids sufficiently without medication. When their lipid level is lowered using medication, they have fewer coronary events (Libby, 2005).

Patients with hypertension have two to three times the risk of developing cardiovascular disease (AHA, 2005). The American Heart Association classifies blood pressures greater than 140/90 at rest as being hypertensive. Hypertension causes damage to the arterial walls and causes increased myocardial oxygen consumption due to the need for the heart to do more work against high pressures. High blood pressure may be diagnosed after several elevated blood pressure readings. Other than taking medication, individuals can improve their blood pressure by weight loss, dietary management, regular aerobic exercise, relief of stress, and controlling other risk factors for coronary artery disease (Fisher & Williams, 2005).

Sedentary lifestyle is a risk factor for heart disease. The relative risk of a sedentary lifestyle for heart disease is comparable to the risk associated with smoking, hypercholesterolemia, and high blood pressure (AHA, 2005). People who are physically inactive have twice the rate of heart disease as those who exercise regularly (McArdle, Katch, & Katch, 2001). Regular physical exercise assists with weight control, lowering blood pressure, and improves the lipid profile and glucose tolerance (McArdle, Katch, & Katch, 2001). The Center for Disease Control (CDC) and the American College of Sports Medicine (ACSM) recommend that American adults get 30 minutes or more of moderate physical activity on most and preferably all days of the week (American College of Sports Medicine, 2000). After an MI, those patients who undergo cardiac rehabilitation exercise training have 20–25% fewer MIs than those who do not exercise (Franklin, 2003). Due to the effect of exercise on the heart, circulatory system, and other risk factors, aerobic exercise is an effective weapon against heart disease.

In the United States, seven of every 10 adults are overweight, and three of those are obese. Obesity is now the second leading preventable cause of death (AHA, 2005). Obesity is closely related to and influences negatively a number of risk factors for heart disease such as hypertension, diabetes, hyperlipidemia, and physical activity. The distribution of body fat is important in disease promotion. Central or abdominal obesity is linked to increased risk of coronary artery disease (CAD) (Wallace, 2003). The loss of even 5–10% of one's weight, however, can have a positive influence on risk factors such as hypertension, lipid levels, and sleep apnea (Gaziano, Monson, & Redker, 2005).

Diabetes has long been recognized as a risk factor for heart disease. The incidence of diabetes increased 8.2% from the year 2000 to 2001. Since 1991, the diagnosis of diabetes has increased 61% primarily due to the increase in obesity in the United States (Mokdad et al., 2001). Women who have diabetes lose the protective effect of their hormones against heart disease, and their risk of CAD increases to five times that of non-diabetic women (Foody & Pordon, 2001). Some form of heart or blood vessel disease will kill two thirds to three fourths of persons with diabetes (AHA, 2005). Keeping blood sugar levels in tight control through medication, diet, and exercise reduces macro- and microvascular disease in patients with type I and type II diabetes and thus reduces risk of heart disease (Powers, 2005).

Stress is also considered to be a risk factor for heart disease, but its effect is difficult to quantify. What is stressful for one individual is not for another. Chronic stress, however, negatively affects the cardiovascular system. Stress increases the heart rate, blood pressure, blood lipid levels, and blood clotting. Managing chronic stressors with relaxation techniques or through behavioral change is helpful in eliminating or minimizing the effect of stress on the body.

As part of secondary prevention, the therapist must direct considerable energy toward educating the patient regarding the significance of these risk factors and methods of ameliorating them. Education may take place in one-on-one sessions, such as with the patient while doing a home program, or with groups of patients before, during, or after exercise.

Inpatient Cardiac Rehabilitation or Phase I

The goals of inpatient cardiac rehabilitation are to prevent muscle loss from bedrest, monitor and assess the patient's ability to function, instruct the patient in appropriate home activities, educate the patient about individual risk factors, and teach methods to lessen these risks.

Therapists treat each patient at least once a day and usually twice daily as soon as the patient's medical status has stabilized, often within the first 24–48 hours after admission. Hospital stays for coronary events have declined

significantly in the past 10 years. The average stay for the uncomplicated non-STEMI is 1–2 days; for STEMIs and open heart surgery, it is 3–7 days.

The occupational therapist working in cardiac rehabilitation initiates therapy on a one-on-one basis so that the therapist can interview the patient regarding lifestyle and assess the patient's cardiovascular response to exercise. During exercise, physical measurements of heart rate, blood pressure, EKG response, and symptoms are noted. (Occupational therapists working in cardiac rehabilitation need to take an EKG reading course.) (See Procedures for Practice 47-1 for instructions regarding blood pressure measurement and pulse taking.)

Those patients who are stable are subsequently seen for group treatment. Although programs vary in the type of exercise done, many begin with mild calisthenics for 2-minute bouts with a 1-minute rest. Initially the total time of the calisthenics added together is 4–8 minutes, depending on the

patient's tolerance. As the patient progresses, the amount of time the patient may spend doing calisthenics typically increases to 8–10 minutes. Programs may include other modalities such as stair climbing, treadmill, bicycle ergometer, and/or hall walking (Fig. 47-2). Regardless of the modality used, each is started gradually (i.e., treadmill walking at 1–1.5 mph or less for about 3–5 minutes, with progression based on the patient's tolerance). It is important for the therapist to assess the patient's heart rate, blood pressure, EKG, and symptoms to establish the patient's tolerance for exercise (see Safety Note 47-2).

Clinical Pathways

A clinical pathway is a tool that describes a comprehensive program for a patient with a particular diagnosis such as a myocardial infarction pathway, a coronary artery bypass graft pathway, or a congestive heart failure pathway. The

PROCEDURES FOR PRACTICE 47-1

Measuring Blood Pressure and Pulse

Measuring Blood Pressure

1. Wrap blood pressure cuff 1 to 1 1/2 inches above the antecubital space.
2. The cuff should be wrapped smoothly and firmly around the arm.
3. The bladder of the cuff should cover 80% of the arm circumference.
4. Palpate the brachial pulse on the medial aspect of the arm.
5. Place the stethoscope over the pulse.
6. Close the valve on the inflation ball.
7. Inflate the cuff 20 mm Hg greater than the point where you heard the pulse obliterated.
8. Slowly open the valve on the inflation ball so the mercury or arrow drops at the rate of 2–3 mm per second.
9. The first sound heard is the systolic pressure; make a note of that number.
10. Continue to listen until the pulse starts to muffle and finally disappears.
11. The point at which the pulse disappears is the diastolic pressure; make a note of that number.
12. Be sure to listen for 20 mm Hg longer to make sure you heard the exact last pulsation.
13. Completely deflate the cuff and remove from the patient (Rayman, 2004).

To be considered normal, blood pressure must be under 140/90 at rest. Systolic blood pressure should rise with exercise. Diastolic blood pressure should stay the same or

drop slightly. With exercise, diastolic blood pressure should not increase more than 10 mm of mercury compared with resting. The blood pressure response of patients with a history of high blood pressure is likely to be exaggerated with exercise.

Pulse Taking

1. Locate indentation on lateral side of wrist about 1/2 inch proximal to the wrist crease.
2. Palpate the radial artery with the index and middle finger.
3. Count the number of pulsations for 10 seconds.
4. Multiply that number by 6 to determine the number of beats per minute.
5. Notice if the pulse is regular or irregular.
6. Also note any “skipped” or early beats.

A normal heart rate (HR) range at rest is between 60–100 beats per minute (bpm). Someone who is very fit, such as a runner, may have a heart rate in the 40s or 50s. After open heart surgery, a patient often has a heart rate in the low 100s. During exercise in the first 2 weeks of convalescence, the heart rate should not increase more than 20 bpm above resting for a patient with an MI and about 30 bpm for a patient after surgery (ACSM, 2000). (Note that these are relative guidelines and not absolute.) It is not uncommon for patients who have valve repair or replacement to develop a rapid heart rhythm called atrial fibrillation. This rhythm is usually controlled with medication or by **cardioversion**. If the patient's HR is uncontrolled and is 120 bpm or higher at rest, exercise is contraindicated.

Figure 47-2 Patients exercising in inpatient cardiac rehabilitation to maintain muscle tone and endurance. The exercises also allow the therapist to evaluate the patients' cardiovascular response to light-to-moderate activity while they recuperate from a myocardial infarction, congestive heart failure, or open heart surgery.

treatment plan for a patient with a particular diagnosis is delineated in a grid format. During each day of the hospitalization, the grid lists the treatment that the patient should receive. Areas included in a pathway are IADLs, rehabilitation, nutrition, interventions, patient education, treatments, psychosocial/spiritual counseling, and dis-

SAFETY NOTE 47-2

Signs and Symptoms of Exercise Intolerance

- Chest pain or pain referred to the teeth, jaw, ear, or arm
- Excessive fatigue
- Shortness of breath
- Lightheadedness or dizziness
- Nausea or vomiting
- Unusual weight gain of 3–5 lbs in a 1- to 3-day period

If a Patient Needs to Take Nitroglycerin

A patient with chest pain or angina who has a prescription for nitroglycerin should try a nitroglycerin pill under the tongue. If the chest pain has not disappeared within 3–5 minutes, another nitroglycerin pill should be tried. Continue until a total of three nitroglycerin pills have been taken over a 15-minute period. If the chest pain persists, call 911. The doctor should be notified when the patient first has angina or if there are changes in the frequency or intensity of episodes of angina. Notify the physician if other symptoms of exercise intolerance persist after resting.

charge planning. Daily the various disciplines record, in checklist fashion, the care given. Deviations from the expected routine are recorded as variances in the progress record of the chart. Clinical pathways thus assist in evaluating outcomes and ensure a standard level of care (American Association of Cardiovascular and Pulmonary Rehabilitation [AACVPR], 2004a).

Home Programs

Each patient is given a home program before discharge from the hospital. The type of program given is individualized to the patient and his or her particular diagnosis. The general components of a home program are activity and exercise guidelines, work simplification, pacing, temperature precautions, social activity, sexuality, signs and symptoms of exercise intolerance, and/or a discussion of risk factors. Depending on the diagnosis, certain aspects of the home program are emphasized or minimized. The information should be pertinent to the patient's lifestyle, including favorite activities, work, and/or hobbies with suggestions for resuming these activities.

MI Home Program

The home program of a patient who has had an STEMI will tend to highlight how to evaluate activity/exercise and determine the correct energy expenditure during the patient's recovery. Healing of the heart muscle takes about 4–8 weeks depending on the amount of damage sustained. Patients are usually asked to restrict their activities to the 2–4 MET range during this time (Definition 47-2 and Table 47-1). Pacing and work simplification may also be explained. This is especially important when the patient has had a significant amount of heart damage. (It should be remembered, however, that 88% of those under age 65 eventually will return to work, according to the AHA [1998].) A walking or biking exercise schedule is given. Depression and sexuality are discussed because certain cardiac medications can play a significant role in mood as well as sexual function and desire. Patients should be told that, if

DEFINITION 47-2 *fin·i·tion*

METS

METS are a unit of measure used to describe the amount of oxygen the body needs for a given activity (DeBusk, 2003). One MET is equal to oxygen consumption at rest or 3.5 ml of oxygen/kg of body weight/min. Extensive oxygen consumption tests have been done on a number of activities, and a small sampling of activities is included in Table 47-1. These values are still approximate because they do not take into account environmental factors or skill. The more the body moves and has to work against resistance, the higher the MET level.

Table 47-1. MET Values for Various Activities		
Home	Leisure and Vocational	Exercise and Sports
1.0–2.5 METS		
Sweeping floors Dusting Straightening up Serving food Table setting Knitting and crocheting Putting away groceries Making bed Standing quietly in line Mowing lawn with a riding mower Casino gambling—standing Sexual activity Dressing and undressing Sleeping Watching TV Dish washing	Power boating Fishing from boat Pumping gas Changing light bulbs Typing, computer Sitting for light office work Card playing, sitting Board games Playing piano or organ Driving tractor Sewing with a machine Driving an auto or truck Sitting to study, read, or write	Walking at slow pace Playing catch with a baseball or football Horseback riding, walking
2.6–4.0 METS		
Child care, bathing, and grooming Walk, run, and play with children (moderate) General house cleaning Walking downstairs Sweeping garage or sidewalk Raking lawn Walking and carrying load of 15 lbs	Pitching horseshoes Home auto repair Planting seedlings and shrubs Playing the drums Home wiring or plumbing Feeding small farm animals Standing to pack light to moderate boxes Bartending—standing Walking and picking up yard	Very light stationary biking Weight lifting of light to moderate effort Stretching, yoga Golf using a cart Snowmobiling Walking at moderate speed Water aerobics
>4.0–6.0 METS		
Major house cleaning, such as washing windows, vigorous effort Moving furniture Scrubbing floors on hands and knees Cleaning gutters Painting the outside of house Painting and wallpapering inside of house Weeding or cultivating	Laying carpet or tile Slow wood chopping Farming, feeding cattle Carpentry on outside of house Carpentry, refinishing surfaces Hunting—general Road building, carrying heavy loads Roofing	General calisthenics, moderate effort Shooting hoops Golf, carrying clubs Softball, fast or slow pitch Low-impact or dance aerobics Dodgeball or hopscotch Bicycling at 10–11.9 mph
<6.0–10 METS		
Carrying groceries upstairs Moving household items in boxes Shoveling more than 16 lbs per minute (heavy) Walking or standing with objects weighing 50–74 lbs	Farming, bailing hay Concrete masonry Moving heavy objects such as furniture Firefighter carrying hoses	High-impact aerobics Running 10–12 min/mile Basketball game Jump roping Race walking Swimming laps at a moderate pace Bicycling at moderate pace >12 mph

From Ainsworth et al., 1998.

there is a change in sexual ability or desire after their cardiac event, they should talk to their doctor to explore the role of any new medications in those changes. When a patient can climb two flights of stairs without symptoms of intolerance, they can usually resume sexual relations without cardiovascular symptoms (DeBusk, 2003).

Open Heart Surgery Home Program

Patients who have had open heart surgery are given directions that are more specific. They are in pain and under the influence of analgesics, which may affect retention of information. They are told specifically what to do and what to avoid. They are also given information on stretches and mild exercises to assist in incisional pain management. In these patients, the sternum has been broken and it must be treated like any other broken bone. Surgical patients are to avoid lifting, pushing, or pulling, especially one-sided lifting or pulling, of greater than 10 lbs for 6–12 weeks. Therapists should make recommendations for alternative ways of doing activities to avoid one-sided pulling. For example, when pulling open a heavy door, it is desirable to use two hands, or when picking up a heavy coffeepot, put one hand covered with an oven mitt on the bottom of a coffee pot and the other hand on the handle. Patients who complain of feeling sternal shifting or clicking are told to try to avoid the activity that causes it and to stop any upper extremity exercises. Usually the clicking goes away with just a little care. Be aware that individual surgeons have their own views regarding the exact length of time to avoid lifting and the amount of arm activity they will allow. Walking schedules per patient tolerance are given. Patients are also given information regarding the possible emotional and physical responses they may expect during the healing process, such as easy fatigability or depression. Patients are encouraged to express their affection. If they have sexual intercourse, they may wish to try positions that avoid strain on the sternum, such as side-lying or sitting in a chair facing each other.

CHF Home Program

Patients with CHF and/or cardiomyopathy often have limited endurance. Their home program puts heavy emphasis on pacing and work simplification. It also includes a mild exercise program. Information regarding their diagnosis is given to help these patients understand that overexertion could put them back into heart failure. Signs and symptoms of CHF are included to alert the patient to signs of worsening medical status (see Safety Note 47-1).

Angioplasty Home Program

Patients admitted solely for an angioplasty/stent or atherectomy are usually seen for home instruction. The goal of this home program is to teach risk factor recognition and patient awareness of ways to modify these risks.

An aerobic exercise program positively affects most risk factors for heart disease. Therefore, a variety of ways to exercise are discussed, with the goal of finding one or several modes of aerobic exercise that might interest the patient. For example, if the patient chooses walking, options such as mall walking, treadmill and video walking programs, and outdoor walking are explored. Patients are given instruction in how to start an exercise program and taught how to assess their physical response to exercise using the *Borg Rating of Perceived Exertion Scale (RPE)* (ACSM, 2000) and heart rate monitoring, if appropriate. Again, the therapist reviews signs and symptoms of exercise intolerance. Stress reduction techniques may be covered, and other resources for stress reduction are given. If the patient is a smoker, his or her willingness to quit is assessed. If the patient is in the planning or action phase of quitting, information regarding the effects of nicotine on the body is given, as well as assistance in planning how to beat the urge to smoke and resources for support groups. All information is written so that the patient may refer to it later.

Discharge Planning

Discharge planning begins early due to the shortened hospital stays. The cardiac occupational therapist provides information regarding the level of physical function the patient tolerates at discharge. The therapist also makes recommendations for further therapies and gives input regarding the possible need for home health or extended care facility.

Outpatient Cardiac Rehabilitation or Phase II

Outpatient cardiac rehabilitation is a multifaceted program of EKG-monitored exercise and education for secondary prevention of heart disease. The goals for outpatient cardiac rehabilitation are:

1. Continue medical surveillance and assessment of an individual's cardiovascular response to exercise
2. Limit the physiological and psychological effects of heart disease
3. Instruct on risk factors for heart disease and how to reduce their impact
4. Maximize psychosocial and vocational status

Patients are usually started in outpatient cardiac rehabilitation 1–2 weeks after discharge from the hospital. The program runs 3 days a week for 4–8 weeks. It would be ideal if each patient had a stress test prior to starting rehabilitation so that the results could be used in developing an exercise prescription. Many patients, however, will not have a stress test until 3–6 months after a STEMI or percutaneous transluminal coronary revascularization (PTCT)/stent and a year after a bypass. Often the therapist must take a careful history to determine risk stratification based on the

PROCEDURES FOR PRACTICE 47-2

Determining the Maximum Age-Adjusted Heart Rate (MAHR)

1. Take the number 220.
2. Subtract the patient's age.
3. The difference is that patient's MAHR.
4. To establish his or her exercise heart range, multiply the MAHR by 50–85% to obtain the heart rate for exercise.

For example, a 50-year-old patient's MAHR would be 170 (220–50). To determine the exercise heart rate, multiply 170 by 0.50 and 0.85. The 50-year-old patient's exercise heart rate range is 85–149 bpm.

patient's ejection fraction, hospital course, heart rate and blood pressure response, symptoms, and/or possible EKG changes with exercise. (Risk stratification refers to determination of the patient's risk for further cardiac events based on the past medical history.)

After assessing the patient's risk stratification, the therapist will need to determine the appropriate exercise intensity using one of the following means. The therapist could determine 50–85% of the patient's maximum age-adjusted heart rate (MAHR) (ACSM, 2000) (see Procedures for Practice 47-2 regarding how to calculate MAHR). If, however, the patient is on a beta blocker medication, such as atenolol or metoprolol, his or her heart rate response will be blunted, making the heart rate calculation inaccurate. Using the *Borg RPE Scale* is an additional way to measure the patient's tolerance of exercise. The patient is usually asked to rate the intensity of the exercise on the *Borg RPE Scale*. Initially the patient should try to keep the score between 11 and 13; later in the rehabilitation program, a score between 12 and 15 may be appropriate (ACSM, 2001). The patient's cardiovascular response and/or symptoms all assist in formulating the exercise prescription.

The exercise goal varies per individual depending on the function of his or her heart and physical condition. Usually those with good heart function and physical condition achieve between 5–6 METS. The patient's previous vocational and leisure interests, however, must also be considered in determining the patient's exercise goal.

The elderly, those who are sedentary, or those who have low functional capacity can still benefit by increasing their maximum MET level. For example, a patient with CHF may have a functional capacity of 2.5 METs after a hospitalization. If they can increase their MET level to 3.5–4 METs, they have significantly increased the number of activities or tasks they can do.

The two primary methods of achieving exercise goals are continuous and discontinuous exercise. For some,

continuous exercise works well. For others, short bouts of exercise on various pieces of equipment followed by a short rest of 1–2 minutes are preferable. With continuous exercise, increasing the total duration of the exercise to at least 20–40 minutes is the first goal. Later, intensity is gradually increased. The advantages of continuous exercise are that less equipment and space are needed and the exercise more closely mimics what the patient will be doing at home. The disadvantages are that only certain muscle groups are targeted on one piece of equipment and the patient is exposed to just one form of aerobic exercise.

In discontinuous exercise, the amount of time a patient stays on a piece of equipment remains the same, but the intensity gradually increases. After finishing the allotted time on one piece of equipment, the patient then switches to another; this process is repeated several times. The advantages of discontinuous exercise are that the patient is exposed to a variety of equipment, boredom is minimized, and multiple muscle groups are used. The disadvantages are that discontinuous exercise takes a lot of space and equipment, it is sometimes hard to coordinate patients shifting equipment at the same time, and it does not reflect what the patient will be doing for aerobic exercise at home. With both methods of conditioning, however, the patients achieve the same MET levels.

In outpatient cardiac rehabilitation, a variety of exercise equipment may be used. Treadmills, bicycle ergometers, recumbent bikes, rowing machines, arm ergometers, and so on are used, depending on the patient's preference and to accommodate any existing orthopedic problem the patient may have. Weight training is usually started 2–4 weeks post event. Prior to weight training, patients must meet certain criteria regarding their exercise capacity, blood pressure (BP) control, and ejection fraction (ACSM, 2000).

Risk factor modification is a key focus of outpatient cardiac rehabilitation. Therapists help patients identify their own risk factors and choose which risk factors they would like to try to modify or eliminate. Risk factor education occurs in a variety of ways. Some centers have specific times on various days where health professionals will lecture on a particular topic. Other hospitals have short education sessions before, during, or after exercise sessions. The goal of these educational sessions is to give patients the information they need to modify their risk factors.

Psychosocial issues must be evaluated with the patient who has heart disease because depression, post MI, has been linked to increased mortality (Musselman, 2004). Many centers use standardized questionnaires to determine depression or anxiety such as the *Symptom Checklist-90-Revised*, *Beck Depression Inventory*, or the *Profile of Mood States* (AACVPR, 2004b). The results of testing will indicate if the patient needs referral to a chaplain, social worker, or psychologist based on their circumstance or preference.

Some patients have very physical jobs, which require heavy lifting. Feedback is given to the physician regarding

the patients' exercise capacity and cardiovascular response to aerobic exercise in cardiac rehabilitation. Following the outpatient cardiac rehabilitation program, these individuals may also need to be referred to a work-hardening program to further ready them to return to work.

Community-Based Phase III Cardiac Rehabilitation

Phase III is a community-based cardiac rehabilitation with larger groups of patients and fewer staff members per participant. Phase III programs are often located in community centers, school gyms, or YMCAs. Such programs may follow outpatient or phase II cardiac rehabilitation. Patients may skip phase II, however, and go directly to phase III if they are low risk and have been active in the past. Only a small percentage of patients go to phase III after phase II because it is generally not covered by insurance. Since reimbursement is difficult, it also means that these programs run on a very low budget and usually are lucky to break even.

A physician must refer a participant to a phase III program. Usually a stress test is required, or the physician establishes heart rate guidelines. Trained personnel monitor BP response and assist patients with monitoring their heart rate. EKG monitoring is typically limited to once per month. Goal setting for risk management continues, as does the education component, although the education may be more informal. Participants also enjoy the support and encouragement of others who have a common goal of reducing their incidence of heart disease.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) is a combination of emphysema and bronchitis (MedicineNet, 2005). Emphysema is the progressive and irreversible destruction of the alveoli walls (Etkin, Lenker, & Mills, 2005). The walls of the alveoli have elastic fibers, and when these are destroyed, the lung loses some of its elasticity, resulting in air trapping. This air trapping reduces the ability of the lung to shrink during exhalation; the lung then inhales less air with the next breath (MedicineNet, 2005). Chronic bronchitis is defined as excessive sputum production and cough of at least 3 months in duration occurring 2 years in a row (MedicineNet, 2005). This inflammation also causes the bronchial tubes to increase their production of mucus. The result of these processes is that the patient experiences sudden shortness of breath and may wheeze or cough (MedicineNet, 2005). Patients with COPD have characteristics of all these diseases (see

DEFINITION 47-3

Pulmonary Function Tests

- Patients are asked to exhale forcefully as much air as possible into a spirometer. The amount of air exhaled in 1 second is called the forced expiratory volume (FEV1). Age-related norms for the FEV1 are available (Couch & Ryan, 2000).
- Arterial blood gases are drawn to determine the lungs' ability to oxygenate blood, remove CO₂, and maintain the body's acid-base status (Couch & Ryan, 2000). It is helpful to draw blood gases before and after exercise to see how well oxygenation is maintained during activity.
- A pulse oximeter is a non-invasive test to determine the amount of oxygen in the blood. A probe is wrapped around a fingertip. A light shines through the finger, and the amount of light reaching the other side indicates the amount of oxygen in the blood. Hemoglobin is red, and the more hemoglobin in the blood, the less light is able to penetrate the fingertip (MedicineNet, 2005). The oximeter can occasionally give false readings. If the patient is anemic, wears nail polish, or has poor circulation, the pulse oximetry may be inaccurate. Often the oximetry machine will also determine the patient's pulse. If the palpated pulse and the oximetry machine pulse match, it is likely that the **oxygen saturation (O₂ Sat)** will be accurate.

Definition 47-3 for a description of pulmonary function tests). COPD is a chronic and progressive condition (MedicineNet, 2005). Medications and good health habits can lessen the symptoms and maximize function.

The feeling of breathlessness, called dyspnea, is a key feature of COPD. Damage to the lung results in a flattening of the diaphragm due to hyperinflation. This flattening takes away the ability of the diaphragm to act effectively in assisting with expansion of the lungs during inspiration. To compensate for the lack of inspiratory pressure, patients with COPD tend to use their shoulder girdle muscles to expand their lungs, making it difficult to use those muscles in unsupported upper extremity activities (Coppola & Wood, 2000).

Dyspnea, fatigue, cough, and sputum production are part of the disease process. The effort of breathing takes so much energy that often COPD patients find themselves without enough energy to do their daily tasks, including ADLs and vocational and leisure endeavors. They are unable to increase their ventilation enough to meet physiological demands. Due to the unpleasant sensation of shortness of breath (SOB), patients reduce their physical activities, resulting in muscle weakness and the inability to use oxygen efficiently (Jackson & Horn, 1998). Eating is an

activity made difficult by lack of air. Maintaining adequate nutrition is a problem for 40–60% of patients with COPD, and nutrition problems are independent predictors of mortality (AACVPR, 2004b). Some patients lose weight because of the excessive energy costs of their breathing efforts (AACVPR, 2004b). Others use steroids to reduce lung inflammation, resulting in weight gain that contributes to additional problems. Weight gain exacerbates the problem of not having enough oxygen to metabolize food, and extra weight requires more oxygen to do any activity including eating.

Depression is common with COPD. Between 7 and 42% of patients with moderate to severe COPD experience depression (AACVPR, 2004b). As with any chronic disease process, the changes in lifestyle, the struggle to accomplish normal daily activities, the fear of extreme SOB, and feelings of hopelessness all contribute to the depression that many patients with COPD feel.

PULMONARY REHABILITATION

The American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) sets standards of practice for pulmonary rehabilitation, which are used by insurers and the Joint Commission of Hospital Organizations. The AACVPR has published a book called *Guidelines for Pulmonary Rehabilitation Programs* to guide practice (2004b). It has also instituted a certification for pulmonary rehabilitation programs (see Resources 47-1). A team of health professionals, including doctors, respiratory therapists, dietitians, pharmacists, and occupational and physical therapists, is ideally involved in the pulmonary rehabilitation program. As with other diagnostic categories, the roles may overlap in reinforcing behaviors to enhance function.

The goals of the occupational therapist in pulmonary rehabilitation are (AACVPR, 2004b; O'Dell-Rossi et al., 1999):

1. ADL evaluation and training to increase functional endurance
2. Instruction and training in appropriate breathing techniques with ADLs
3. Evaluation and strengthening of the upper extremity
4. Work simplification and energy conservation
5. Evaluation of the need for adaptive equipment
6. Assistance in adapting leisure activities
7. Education in stress management and relaxation techniques.

ADL Evaluation and Training

Patients with COPD are often limited in their ability to perform their ADLs due to dyspnea. It is common to have

RESOURCE 47-1

Two organizations dominate the administration and policies of cardiac rehabilitation. One is the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR), which published the book *Guidelines for Cardiac Rehabilitation and Secondary Prevention Programs*. Government agencies and third-party payers use this publication to determine appropriate cardiac rehabilitation policies and procedures. The second is the American College of Sports Medicine (ACSM), which has several nationally recognized certifications for health professionals who wish to work in

cardiac rehabilitation. Both organizations offer continuing education courses in cardiac rehabilitation. Together these two organizations shape the practice of cardiac rehabilitation.

significant muscle wasting from disuse. The therapist should note during the ADL evaluation the patient's breathing pattern. Often patients with COPD hold their breath, breathe shallowly and fast, or elevate their shoulders as they breathe. The amount of oxygen in the blood or oxygen saturation (O_2 Sat) with activity should also be measured by pulse oximetry (Procedures for Practice 47-3). If the O_2 Sat falls below 90% with a patient's ADLs, the use of oxygen with activity should be considered. If the patient does not have home oxygen, the physician should be informed of the patient's low oxygen saturation. Currently the O_2 Sat must be below 88% to qualify for reimbursement for home oxygen from Medicare or other supplemental insurances (Couch & Ryan, 2000). As part of the functional assessment, measurements of heart rate and blood pressure should also be taken.

Breathing Techniques

It is important that the patient practice use of breathing techniques with ADLs. After becoming familiar with diaphragmatic and pursed lip breathing, the patient should attempt tasks using these breathing techniques that previously caused them to be breathless. The pulse oximeter helps to reinforce the improvement in the O_2 Sat with use of a breathing technique. Timing the breath with work is also helpful. For example, the patient should breathe out with pushing the vacuum cleaner, and breathe in while pulling the vacuum cleaner. Exhaling with the exertion of lifting is less taxing not only on the lungs but also on the cardiovascular system because it prevents the Valsalva

PROCEDURES FOR PRACTICE 47-3

Breathing Techniques

Patients are instructed to practice these techniques while sitting in a relaxed position preferably with feet elevated. After they become proficient using these breathing methods at rest, patients should try using them while doing pleasant activities such as reading or watching television. Finally, patients should try using one of these techniques while doing a task that is difficult, such as stair climbing (Coppola & Wood, 2000).

Pursed Lip Breathing

- Breathe in through your nose.
- With lips pursed, exhale air slowly.
- Try to take twice as much time to exhale as it did to inhale.

Diaphragmatic Breathing

- Sit in a relaxed position preferably with feet elevated.
- Place your hand on your abdomen.
- As you inhale through your nose, try to feel your stomach push out as your lungs fill with oxygen.
- Next, feel your stomach go down as you slowly breathe out through pursed lips.
- Continue to repeat this process until you become comfortable doing it.
- Stop the diaphragmatic breathing if you become lightheaded or fatigued.

maneuver (see Procedures for Practice 47-3 for breathing techniques).

Upper Extremity Function

Muscle strength of the upper extremity must be evaluated. Since pulmonary patients are often on steroids, their shoulder girdle, trunk, and hip muscles are usually weak (Coppola & Wood, 2000). Patients with COPD commonly use the accessory muscles of the shoulder girdle to help them breathe, which makes it difficult for them to use these muscles in unsupported upper extremity activity. Upper extremity (UE) strengthening has been found to improve the quality of life by increasing the capacity to work and reducing the oxygen requirement of upper extremity activity (Couch & Ryan, 2000). Use of free weights, Theraband, an arm ergometer, and other upper body strengthening techniques are all helpful in increasing upper body strength. Additional improvement in functional status is seen when leg training is added (Couch & Ryan, 2000).

Work Simplification and Energy Conservation

Since their work capacity is significantly reduced, patients with COPD will benefit from instruction in work simplification and energy conservation. Bathing is a particularly strenuous activity because the hot humid air makes breathing difficult. Therapists encourage patients to use the ventilation fan or leave the door open while bathing to keep the humidity level down. Recommending the use of a chair in the shower and using a thick terry robe after showering instead of toweling off are two suggestions that are helpful in reducing energy expenditure. Unsupported upper extremity activity is very fatiguing for patients with COPD. It is important to teach these patients to support their arms during upper extremity activities such as hair combing or shaving. Sometimes a machine like an electric toothbrush can be of assistance. Scheduling of activities that require more energy expenditure for the time following the use of an inhaler will also allow patients to accomplish more (Couch & Ryan, 2000).

Not all patients with COPD will need adaptive equipment. As the disease progresses in severity, however, some adaptive equipment is useful (Fig. 47-3). Since bending over to tie shoes or put on pants may cause significant SOB, elastic shoe laces, a long-handled shoe horn, or a reacher to assist with putting on slacks may be helpful.

Promoting Self-Enhancement Roles

Having COPD tends to isolate those who have it. Just completing daily necessities takes so much energy that little, if any, is left for leisure activities. Many patients fear becoming very SOB in front of others or are embarrassed using

Figure 47-3 Using adaptive aids for self-care activities can be an effective way to conserve energy and maintain independence for those with cardiac or respiratory conditions.

oxygen. The occupational therapist can help the patient evaluate previously enjoyed activities and see if those activities can be adapted to fit the current health status. Providing patients with information regarding programs or activities available in their community is also helpful. Sometimes involving a helper or companion may make an activity more feasible.

Stress Management

The feeling of being unable to get enough air is truly frightening. Patients with COPD often experience a sense of panic with breathlessness. Teaching patients methods to cope with extreme SOB can lessen their fear. Leaning forward and resting their arms on the table releases the diaphragm and makes breathing easier. Using pursed lip and/or diaphragmatic breathing helps to slow the pace

of breathing so that the patient is not breathing so shallowly and rapidly. A stress management technique such as visualization may help patients calm themselves by mentally transporting them out of the stressful situation. It is important that the patient practice these options prior to actually needing them. Having a well-practiced plan of action for the panic associated with breathlessness will give patients confidence in their ability to control the situation.

Heart disease and pulmonary disease, as the first and fourth leading causes of death, respectively, pose a major health problem. As either a primary or a secondary diagnosis, both heart disease and COPD require specialized attention in planning occupational therapy intervention. If a patient has a history of heart disease or COPD, the occupational therapy practitioner must assess the patient’s cardiovascular response to activity or exercise. Precautions for the patient’s cardiac or pulmonary problem must be incorporated into the treatment program.

CASE

EXAMPLE # 1

K. M.: Cardiac Rehabilitation

Occupational Therapy Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information K.M. is a married, 32-year-old mother of a 3-year-old child and a full-time health worker. The day after the delivery of her second child, she suddenly developed a migraine headache. Her condition deteriorated quickly. She became very short of breath (SOB) and needed a rebreather mask with 10 L of oxygen to maintain her O₂ saturation. Her heart rate was 135–140 bpm. The next day, she was diagnosed as having an anterior wall myocardial infarction (MI). Several days later, her pulmonary edema had resolved, and she had a coronary angiogram. The angiogram showed normal coronary arteries and an ejection fraction (EF) of 25–30%. She was subsequently diagnosed with a cardiomyopathy.</p> <p>Initially, she was referred to inpatient cardiac rehab for general conditioning and instructions for appropriate activities at home. She had very limited endurance. She had a 10-pound lifting restriction, which, with a newborn, made her dependent on family and friends.</p>	<p>Understand the patient’s diagnosis or condition</p> <p>Know the person</p>	<p>“Cardiomyopathy after pregnancy is rare. If she improves within the 6 months after diagnosis, she will probably be able to lead a normal life.”</p> <p>“K.M. will be a busy lady, working and taking care of two children under 3 years old. She works in the health care system and has some knowledge of health issues. K.M. is used to a full-time income and taking care of herself, her home, and family. It must be stressful to have to rely on others to take care of something she normally did herself.”</p>

She was seen by home health occupational therapy for several weeks. She was given exercises to increase her endurance and instructed in energy conservation techniques. Although she became somewhat stronger, she was still dependent on volunteers around the clock to do the majority of household tasks and take care of the children. This caused her a great deal of stress. Her therapist instructed her in stress management techniques and practiced them with K.M.

Reason for Referral to Cardiac Occupational Therapy Phase II

K.M. was referred to outpatient cardiac rehabilitation for physical conditioning and education.

Appreciate the context

“I will talk with the husband to get his view of how things are going at home and get a feel of how supportive he is to K.M. I will also need to consider if K.M. is getting secondary gain from all the attention.”

Develop provisional hypotheses

Assessment Process and Results

K.M. arrived in outpatient cardiac rehabilitation via wheelchair because she felt she was too weak to walk from the car and exercise. She was now doing her own self-care but still relied on volunteers for most of her household chores and caring for her children. She admitted she was stressed by her diagnosis, the number of volunteers in her home, and financial worries. She reported that she slept excessively and was exhausted with exercise. She also reported that she had a history of depression and complained of being somewhat depressed. She was able to walk slowly on the treadmill at 2.0 mph for 20 minutes with normal cardiovascular response. A recent echocardiogram revealed her EF to now be up to 50%.

Consider evaluation approach and methods

“Initially, K.M. is allowed to demonstrate what she can comfortably do physically. After 20 minutes of walking, she still is tolerating the exercise well.”

Interpret observations

“K.M. doesn’t seem to correlate her ability to easily walk 20 minutes at a strolling pace as indicative of her ability to do many household chores, such as dish-washing, folding clothes, making beds, etc. I will continue to assess K.M. to see if she may need referral for psychiatric help.”

Occupational Therapy Problem List

- Low physical capacity for work less than 3 METS.
- Inability to engage in previous work and leisure pursuits due to decreased endurance.
- Depression over feelings of dependency and concern over cardiac diagnosis.
- Dependence on volunteers for most IADLs.

Synthesize results

“K.M. seems to be overwhelmed with her diagnosis and has not assimilated that her heart function has now improved to near normal. With an exercise program to increase her physical capacity, she should be able to return to her job and all her IADLs. Stress management technique training will assist her to cope with difficulties caused by illness.”

Occupational Therapy Goal List

- Learn to monitor physical response to exercise and activity through use of *Borg RPE Scale* and pulse monitoring.
- Gradually increasing capacity for work through aerobic exercise and strengthening exercises (2–5 METS).
- Gradually resume household and leisure pursuits (1.5–5 METS).
- Learn to pace household activities.
- Learn stress management techniques to cope with difficulties caused by illness.
- Instruct patient in risk factors for heart disease.
- Identify patient’s personal risk factors and ways to ameliorate their effects.
- Start a regular home aerobic exercise program.

Develop intervention hypotheses

“As K.M. increases her endurance, we can gradually shift her back to some of her household responsibilities of the same energy or MET level. In the meantime, learning stress techniques will help her handle her current situation. Education about her current health problem will help her understand that she is truly getting better.”

Select an intervention approach

“Cardiac rehabilitation will concentrate on an aerobic exercise and strengthening program. Brief educational sessions will be conducted as she exercises or after the exercise session.”

Consider what will occur in therapy, how often, and for how long

“K.M. is highly motivated to improve, but conditioning takes time. I will see her three times a week for 6 weeks. During that time, I will help her understand the connection between workload on treadmill or exercise cycle and home activities. Together we can develop a plan on how she will start resuming household tasks. I will also instruct her in a home exercise program to assist in improving her conditioning. After exercising, we will practice some stress management techniques.”

Intervention

As she regained physical strength through exercise, K.M. could start resuming more of her usual activities and reduce her dependence on volunteers. Instructing K.M. in how to assess her own physical response to exercise and activity gave her confidence that she was in control. Since K.M. had difficulty with pacing, the therapist had her keep a diary of her daily routine. Later, they reviewed it, and the occupational therapist reviewed work simplification techniques and methods of pacing. The therapist also assigned her tasks within her current aerobic capacity to assist her in resuming her home responsibilities. K.M. was also instructed in stress management techniques to help her deal with the stresses of her illness. Due to her previous history of depression, the therapist reviewed information about the relationship of depression and fatigue. The occupational therapist explored with K.M. the possibility of seeking professional help and/or medication to deal with her depression. Additionally, K.M. was instructed in the risk factors for heart disease. Her individual risk factors were identified, and information was provided on how to ameliorate their effects. As part of her risk factor reduction, K.M. initiated a walking program.

- Assess the patient’s comprehension
- Understand what she is doing
- Compare actual to expected performance
- Know the person
- Appreciate the context

“K.M. was a quick learner. As she fully understood that her heart function was near normal, she really started to gain confidence that her life could return to normal. However, she needed some concrete direction to translate what she was learning into action. Adding the additional home exercise program helped to increase her capacity more quickly, but depression was holding her back from making a complete recovery. Even with her health care background, she did not realize the effect of depression on her physically. With more information about depression, she was more willing to seek professional help.”

Next Steps

Discharge from outpatient cardiac rehabilitation.

- Anticipate present and future patient concerns
- Analyze patient’s comprehension
- Decide if the patient should continue or discontinue therapy and/or return in the future

“K.M. was making significant strides in returning to her previous activity level. She seemed to benefit significantly from activity modification, education, and information on heart disease. She had initiated a home walking program, and she planned to return to work within a month.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Implications of a Diagnosis

K.M. was initially diagnosed as having an anterior MI and, later, was also given a diagnosis of cardiomyopathy. If a patient has had an MI, what symptoms or signs would you look for to determine if he or she is tolerating an activity or exercise? Would those signs and symptoms be different if the patient has a diagnosis of cardiomyopathy without an STEMI?

CASE

EXAMPLE # 2

Pulmonary Rehabilitation

Occupational Therapy Process

Patient Information

Mr. M. is an 85-year-old male with a medical history of congestive heart failure, chronic obstructive pulmonary disease (COPD), and diabetes. He also has a history of coronary artery disease and has had a myocardial infarction in the past. He has been on home oxygen but reports he was not always using it despite it being prescribed. He lives alone in an apartment building with an elevator. Prior to this hospitalization, he had recently begun receiving home visits from an RN and was getting meals-on-wheels. Up until this point, he has been independent with dressing, toileting, bathing, laundry, and finances. He is ambulating without an assistive device but owns a front-wheeled walker and a wheelchair. He also stated that he owns a shower chair and has a hand-held shower but has not needed to use the shower chair for bathing. He does not drive and is provided with transportation by various family members. He is currently on 6 L of oxygen and is receiving steroids and inhalers to improve breathing. He states that he has had “a little” education for COPD/congestive heart failure (CHF) management in the past.

His goal was to return to his apartment at discharge from the hospital, to which he was admitted for increased shortness of breath. He was open to receiving more assistance from family or outside agencies if necessary.

Reason for Referral to Occupational Therapy

Mr. M. was admitted to the hospital due to increased shortness of breath. He was referred to occupational therapy for an evaluation and further treatment to improve efficiency with functional activities. Because Mr. M. lives alone, it is especially important that he be as independent as possible to allow him to reach his goal of returning to his apartment.

Clinical Reasoning Process

Objectives

Understand the patient’s diagnosis or condition

Know the person

Examples of Therapist’s Internal Dialogue

“Mr. M. has been on 6 L of oxygen chronically at home and has other medical conditions that indicate to me that he likely has poor endurance and may have had some difficulty managing ADLs at home.”

“The lack of Mr. M.’s use of energy conservation techniques and his prescription for oxygen during daily activities suggests that he would benefit from education in these areas. His daughter reports some forgetfulness in the patient, and therefore, I need to keep in mind that he may need to have education repeated and in written form, as well as hands-on practice and demonstration, for the most success in learning new information.”

Appreciate the context

Develop provisional hypotheses

“I feel that Mr. M. will benefit from the combination of education and adaptive equipment use, as well as exercise to improve his activity tolerance at home. I am hoping that, as Mr. M. gets more fluent with using breathing techniques, he will be more inspired to combine them with the adaptive equipment use to improve his efficiency. I am glad that he has a supportive family that is working to keep Mr. M. as independent as possible.”

Assessment Process and Results

Mr. M.’s assessment took place in his hospital room. He was on 6 L of oxygen via nasal cannula. He appeared to be comfortable at rest, but following activity, his oxygen saturations decreased to 85%. He was able to complete pursed lip breathing with cues, and his saturations increased to 93% after 90 seconds of rest and pursed lip breathing. His upper body strength and range of motion were within functional limits. He was able to demonstrate ability to physically complete grooming, dressing, and toileting independently but was limited by decreased endurance and rapid shortness of breath. He frequently had to stop what he was doing to rest and, for that reason, took extra time or chose not to complete some tasks. He was able to complete basic transfers and ambulate in his room with stand-by assistance and no assistive device. Basic cognitive screen indicated that Mr. M.’s cognition was intact. His daughter did report that he has been more forgetful lately.

Consider evaluation approach and methods

“My focus was primarily on Mr. M.’s functional status and assessing his level of fatigue during functional tasks. I did spend some time observing him completing ADLs as well as interviewing him about his perceived level of fatigue and level of difficulty completing tasks. I monitored his oxygen saturations throughout our treatment sessions and observed his levels of dyspnea.”

Interpret observations

“We discussed what ADLs were a priority to him versus less important tasks, and we were able to narrow our focus and set specific goals.”

Occupational Therapy Problem List

- Limited endurance affecting ADL performance
- Limited education of energy conservation and work simplification techniques and pursed lip and diaphragmatic breathing
- Decreased awareness of adaptive equipment resources and oxygen utilization
- Mild memory impairments

Synthesize results

“It was apparent to me that Mr. M. was not conserving the maximum amount of his energy during certain functional tasks. Occasionally when he was fatigued, he would not complete grooming or hygiene tasks at all. I feel that, because he lives alone, we needed to focus on being able to complete his basic self-care activities efficiently and independently. At this point, he was not able to complete all self-care activities due to fatigue and shortness of breath.”

Occupational Therapy Goal List

(anticipated length of treatment: 4–5 sessions)

- Patient will be able to verbalize and demonstrate understanding of pursed lip breathing and diaphragmatic breathing during functional activities by discharge.
- Patient will verbalize or demonstrate understanding of 2–3 work simplification and energy conservation techniques during self-care activities, community activities, and laundry and other homemaking tasks by discharge.
- Patient will complete tub transfer independently using adaptive equipment to increase activity tolerance by discharge.
- Patient will have all recommended adaptive equipment or resources for pursuing purchase of equipment by discharge.
- Patient will be independent with a 10- to 15-minute upper extremity exercise program while using pursed lip breathing to improve overall endurance and ability to tolerate ADLs.

Develop intervention hypotheses

“I plan on providing Mr. M. with instruction on breathing techniques, energy conservation, adaptive equipment recommendations, and resources. This education will provide him with improved activity tolerance and give him a greater sense of independence. I believe that it is important to provide him with the opportunity to prioritize the importance of completing certain tasks and allowing him to participate in the goal-setting process.

Select an intervention approach

“My intervention will primarily focus on an adaptive approach with a focus on patient education.”

Consider what will occur in therapy, how often, and for how long

“Mr. M. will likely only be hospitalized for 5 to 6 days, and therefore, we will need to strive to meet our goals in that timeframe. I will focus mostly on completing functional tasks while providing education throughout the sessions. Written materials will also be provided, as well as family education when possible.”

Intervention

Mr. M.'s treatment plan consisted of education for specific breathing techniques (pursed lip and diaphragmatic). He was instructed on how to incorporate these breathing techniques into his daily routine. He was then provided with more education in energy conservation and work simplification to allow him to be more efficient. Discussion about adaptive equipment needs took place, and recommendations were made. He was instructed in an upper extremity exercise program to increase endurance, and he was provided with a handout to encourage him to continue with the exercises after he was discharged. Mr. M. was provided with written instruction for all education due to memory impairments. Repetition and hands-on training were also provided whenever possible.

Providing education was key to allow Mr. M. to understand how to manage his COPD symptoms better. He was better able to manage his shortness of breath and fatigue during activities by using pursed lip breathing combined with work simplification and energy conservation techniques. Discussion about the benefits of adaptive equipment use and incorporation into Mr. M.'s daily routine has allowed him to complete more tasks independently and with less fatigue. He was in agreement with using a shower chair, hand-held showerhead, and long-handled bath sponge to ease the burden that bathing once had been. Mr. M. elected to purchase a long-handled bath sponge from the hospital before discharge, and he already had a shower chair and hand-held showerhead at his apartment. He was encouraged to use his oxygen for all activities, including showering, to maintain a desirable oxygen saturation level for his safety. By participating in a daily exercise program, Mr. M.'s endurance improved, which allowed him to complete his ADLs with much less shortness of breath and fewer rest breaks. Mr. M. was seen for six sessions by occupational therapy. He met all of his established goals and was discharged back to his apartment.

Assess the patient's comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

"I could see the initial frustration that Mr. M. had when he was not fully able to complete tasks due to dyspnea. He was hesitant to try pursed lip breathing initially due to thinking it was 'too confusing' and that he would 'forget how to do it.' But with repetition and encouragement, he was able to quickly learn the technique and feel the benefits. Once we started to incorporate the use of adaptive equipment (such as a shower chair, hand-held showerhead, and long-handled bath sponge), Mr. M. was appearing more positive and confident in his abilities. He really was a rewarding patient to work with because he dramatically improved with simple modifications to his routine."

Next Steps

Discharge to his apartment with recommendation of home occupational therapy evaluation and to resume meals-on-wheels as was established previously.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

"I am recommending a home occupational therapy evaluation to reinforce the use of adaptive equipment and oxygen in Mr. M.'s home setting. I feel that Mr. M. was able to fully appreciate the benefits of using pursed lip breathing and oxygen to extend his endurance. He was comfortable with the idea of using adaptive equipment and work simplification techniques incorporated into his everyday routine. He is confident in his abilities to complete his daily activities and to return to his apartment independently. His family is comfortable with his abilities to care for himself, and they feel he has the resources he needs to be successful."

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Implications of a Diagnosis**

Mr. M. has COPD, but he also has several other comorbid diseases. How would these other conditions potentially affect your treatment?

Evidence Table 47-1 Best Evidence for Occupational Therapy Practice Regarding Cardiac Rehabilitation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Any form of supervised or unsupervised structured exercise program (compared with usual care)	Inpatient, outpatient, or community- or home-based setting exercise program either with or without psychosocial and educational interventions.	8,940 patients.	Varied from study to study. Median intervention time was 3 months.	Meta-analysis of 48 trials.	Yes, significant reduction in all-cause mortality and total cardiac mortality, a significant reduction in total cholesterol and triglycerides and systolic blood pressure, and lower self-reports of smoking.	Reduction in all-cause mortality (odds ratio [OR] = 0.80; 95% confidence interval [CI]: 0.68 to 0.93). Reduction in cardiac mortality (OR = 0.74; 95% CI: 0.61 to 0.96). Reduction in total cholesterol level (weighted mean difference, -0.37 mmol/L; 95% CI: -0.63 to -0.11 mmol/L). Reduction in total triglyceride level (weighted mean difference, -0.23 mmol/L; 95% CI: -0.39 to -0.07 mmol/L).	Taylor et al., 2004

	<p>Reduction in systolic blood pressure (weighted mean difference, -3.2 mm Hg; 95% CI: -5.4 to -0.9 mm Hg). Reduction in smoking (OR = 0.64; 95% CI: 0.50 to 0.83).</p>						<p>Inpatient and extended cardiac counseling and rehabilitation</p>
<p>Inpatient rehabilitation: knowledge, $p < 0.005$; depression, $p = 0.009$; anxiety, $p = 0.001$; and disability, $p < 0.009$. Extended treatment: knowledge, $p = 0.002$; depression, $p = 0.001$; anxiety, $p = 0.013$; and disability, $p < 0.005$.</p>	<p>Yes. The cardiac rehabilitation groups (inpatient and extended) did better than the control group in knowledge, less depression, less physical disability, and less anxiety (persons in the control did not receive any formal programming).</p>	<p>Randomized, controlled study. IA2a. Therapists and subjects unblinded.</p>	<p>Inpatient group received 5.5 sessions and extended group received 9.55 sessions over 6 weeks.</p>	<p>100 patients post myocardial infarction (MI) and < 70 years old.</p>	<p>Inpatient rehabilitation and extended cardiac rehabilitation consisting of exercise and education on resumption of activities, emotional effects of heart disease, risk factors, and coronary anatomy and physiology.</p>	<p>Inpatient and extended cardiac counseling and rehabilitation</p>	
						<p>Johnston et al, 1999</p>	

Evidence Table 47-2 Best Evidence for Occupational Therapy Practice Regarding Pulmonary Rehabilitation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Patients seen in hospital-based program	Rehabilitation group was seen repeatedly for exercise and education. Brief advice group was given written educational materials and advice.	103 patients with severe chronic obstructive pulmonary disease (COPD) having a forced expiratory volume in 1 second (FEV1) <40% predicted value; 54 in exercise group; 49 in advice group.	Rehabilitation group was seen 2 times a week for 6 weeks. Brief advice group was seen once for 1 hour.	Randomized controlled study. IA2a (lacked blinded subjects and instructors)	Yes, the rehabilitation group did significantly better on the shuttle walk test. Improvements in quality of life were not significant.	$p < 0.001$	White et al., 2002
Exercise for pulmonary rehabilitation	Studies included in meta-analysis involved exercise (upper extremity, lower extremity, or respiratory muscle).	979 patients having COPD with an FEV1 <70% predicted in exercise trials. 723 patients meeting the above criteria participated in trials in which shortness of breath (SOB) was an outcome measure.	Experimental groups participated in exercise 3 times per week for at least 4 weeks.	Meta-analysis of 20 trials.	Yes, the rehabilitation group did significantly better in exercise capacity (walking test) and improvement in SOB than the control group.	Effect size for walking test = 0.71; 95% confidence interval (CI): 0.43 to 0.99. Effect size for SOB (12 trials) = 0.62; 95% CI: 0.35 to 0.89.	Salman et al., 2003

SUMMARY REVIEW QUESTIONS

1. A person is admitted to the hospital with an acute STEMI. He is given thrombolytics to reverse clot formation in his coronary arteries, but the thrombolytics cause a cerebral bleed. In evaluating and treating for stroke-related deficits, what physiological parameters should the therapist take to measure the workload on the patient's heart? What factors might increase these parameters?
2. What cardiac symptoms might a patient who has a previous heart history exhibit if he or she were not tolerating the treatment you prescribed for the patient's current shoulder injury?
3. What symptoms would a person going into CHF exacerbation exhibit?
4. In reviewing a patient's medical record after hip replacement surgery, what cardiac diagnoses might impinge on your treatment? What cardiac diagnostic tests might provide information to help you make decisions about the severity of his or her heart disease?
5. Describe in detail the differences between a home program for a patient with an STEMI, a coronary artery bypass graft, and an angioplasty. How would you customize the program for the individual?
6. Describe the different ways of conditioning an outpatient in cardiac rehabilitation. What are the advantages and disadvantages of each method?
7. List the risk factors for heart disease. What methods might an occupational therapist use to decrease a patient's risk for coronary artery disease?
8. Develop a treatment plan for a patient with COPD who is having problems with SOB while doing her ADLs.
9. Describe pursed lip and diaphragmatic breathing. How would you teach it to a patient with COPD?
10. If you were the only occupational therapist in a small rural hospital, where could you find information pertaining to the treatment of the patient with cardiac or pulmonary disease?

ACKNOWLEDGMENT

Thanks to Stacey Larson, MA, OTR/L, staff therapist from Fairview Southdale Hospital in Edina, Minnesota, for submitting the case study on COPD.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Discuss normal swallowing.
2. Identify types of dysphagia and their presentation.
3. Describe how to perform a clinical dysphagia assessment.
4. Employ basic compensatory and rehabilitative strategies to treat dysphagia.
5. Describe instrumental evaluation procedures for dysphagia.

CHAPTER 48

Dysphagia

Wendy Avery

Glossary

Aspiration—Entrance of food or secretions into the larynx below the level of the vocal cords.

Bolus—Food or liquid in the mouth.

Deglutition—The act of swallowing.

Direct therapy—Therapeutic techniques involving ingestion of food or liquids.

Dysphagia—Difficulty with any stage of swallowing.

Eating—Ingestion of food and liquid, including the pre-oral, oral preparatory, oral, pharyngeal, and esophageal stages.

Feeding—Taking or giving nourishment.

Fiberoptic endoscopic evaluation of swallowing (FEES)—Direct visualization of the swallow using a small illuminated camera at the end of a flexible tube (endoscope), which is introduced into the pharynx through the nose

Indirect therapy—Therapy addressing the prerequisite capacities associated with swallowing without ingestion of food or liquid.

Instrumental evaluation—Use of technology to assess aspects of swallowing.

Laryngeal penetration—Entrance of food or secretions into the larynx above the level of the vocal cords.

NPO (nil per os)—Latin for “nothing by mouth”: no food or medication to be administered orally.

Swallowing—Ingestion of nourishment, beginning with introduction of food into the mouth and ending with reception of food into the stomach; includes the pre-oral, oral preparatory, oral, pharyngeal, and esophageal stages.

Videofluoroscopy—Moving radiographic images of swallowing structure and physiology, also known as “modified barium swallow study,” recorded on videotape or DVD.

Dysphagia, or difficulty with any stage of **swallowing**, interferes with functional independence for many recipients of occupational therapy services; 33% of acute-care hospital inpatients (Groher & Bukatman, 1986), 32% of rehabilitation hospital inpatients (Cherney, 1994), and 59% of nursing home residents (Siebens, Trupe, & Siebens, 1986) may be dysphagic. Dysphagia care is a rapidly evolving science. Safe swallowing is a critical and life-supporting activity of daily living that is addressed by occupational therapists in many environments, including acute-care and psychiatric hospitals, rehabilitation centers, outpatient clinics, nursing homes, and schools.

Occupational therapists assist patients with dysphagia in rehabilitation of abilities that affect swallowing, including self-feeding, cognition, perception, sensory and motor skills, and postural control. Patients with acute, chronic, congenital, and acquired dysphagias may all benefit from intervention. In some settings, occupational therapists serve as the primary swallowing therapist (Avery-Smith, 1998); in other settings, speech and language pathologists serve as the primary swallowing therapist. Dysphagia care may be provided by a multidisciplinary dysphagia team.

This chapter introduces the entry-level skills required for the evaluation and treatment of dysphagia in adults. Independent intervention with the dysphagic patient requires advanced knowledge and skills on the part of the occupational therapy clinician. The American Occupational Therapy Association (2000) delineates entry-level and advanced-level skills in dysphagia care for occupational therapists and assistants. Further

information about dysphagia can be acquired by seeking basic and advanced learning opportunities, researching new developments, attending workshops and conferences, and receiving mentoring.

NORMAL SWALLOWING

Deglutition is a complex process involving both volitional and non-volitional behaviors. The cranial nerves execute the sensory and motor processes that constitute swallowing. Cortically mediated factors, including appetite, attitude, attention span, appreciation of food, and body position, influence swallowing and must be considered in evaluation and treatment. Oral, pharyngeal, and esophageal structures involved in swallowing are shown in Figure 48-1.

The stages of swallowing include the pre-oral, oral preparatory, oral, pharyngeal, and esophageal stages (Definition 48-1). The pre-oral, oral preparatory, and oral stages are voluntary. The length of the oral preparatory stage varies considerably with the type of **bolus** (Hiemae et al., 1996) and age (Logemann, 1998). Oral transit time, the length of time to accomplish the oral stage, is normally 1–1.5 seconds (Tracy et al., 1989). The pharyngeal stage is involuntary, although volitional movements can alter it. Normal pharyngeal transit time is 1 second (Tracy et al., 1989). Although the patient’s position may affect the esophageal stage because of the effects of gravity, this stage is involuntary.

Figure 48-1 The oral, pharyngeal, and esophageal structures involved in swallowing. 1. The hard palate. 2. The base of the tongue. 3. The soft palate and uvula. 4. The vocal cords. 5. The laryngeal vestibule. 6. The hyoid bone. 7. The upper esophageal sphincter. (Adapted with permission from Groher, M. E. [1997]. *Dysphagia: Diagnosis and management* [3rd ed.]. Boston: Butterworth-Heinemann.)

IMPAIRED SWALLOWING

Many disease processes cause dysphagia, including those that affect the central nervous system, peripheral nervous system, motor end plate, muscles, and other anatomical structures. Trauma may affect anatomy and physiology, resulting in dysphagia. Dysphagia can lead to dehydration (Musson et al., 1990), malnutrition (Finestone et al., 1995), and pulmonary complications due to aspiration, including aspiration pneumonia (Schmidt et al., 1994), airway obstruction (Eckberg & Feinberg, 1992), adult respiratory distress syndrome (Garber et al., 1996), and death (Schmidt et al., 1994). The limited ability to participate in social and cultural activities because of chronic dysphagia can profoundly affect an individual.

Types of Dysphagia

Dysphagia occurs in three types: paralytic, pseudobulbar, and mechanical. Paralytic dysphagia results from lower motor neuron involvement that causes weakness and sensory impairment of oral and pharyngeal structures, including weakness or absence of the swallowing reflex. Pseudobulbar dysphagia results from upper motor neuron

DEFINITION 48-1

The Stages of Swallowing

Pre-Oral Stage

The food is visually and olfactorily appreciated. This stimulates salivation, and there are preparatory movements of the mouth to ready the oral cavity to receive and mobilize the food or liquid. Spontaneous upper extremity movements occur as the person reaches for and grasps the utensil, cup, or finger food and brings it to the mouth.

Oral Preparatory Stage

The food is received and contained by the mouth. It is then formed into a bolus of food and mixed with saliva. Pureed or liquid boluses require little mastication and may briefly be held centrally in the mouth by the tongue and cheek musculature. If solid, the food may need to be bitten off to be contained in the mouth. The bolus is chewed in a rotary motion by the molars and is moved between the left and right molars. The buccal muscles contract to prevent food from pocketing between the cheeks and the teeth. Once masticated or formed, the bolus is brought to the center of the tongue.

Oral Stage

As the cheek and tongue muscles retain the bolus centrally in the mouth, the tongue squeezes it against the hard palate, moving it posteriorly to the level of the faucial arches.

Pharyngeal Stage

The soft palate elevates to close off the nasopharynx. The larynx and hyoid elevate and protract, minimizing the size of the laryngeal vestibule (its opening) as the epiglottis tips to cover the vestibule. Breathing stops (termed “swallowing apnea”), which reduces the possibility of **aspiration** or laryngeal penetration of food or liquid. The vocal cords close. Simultaneously, the pharyngeal constrictor muscles sequentially contract to propel the bolus through the pharynx. The elevation of the larynx causes the upper esophageal sphincter (UES) to relax, allowing the bolus to pass through it.

Esophageal Stage

The UES returns to its normal tonic state, and the bolus is transported through the esophagus via esophageal peristalsis and gravity. The lower esophageal sphincter relaxes, allowing the bolus to pass through into the stomach.

involvement, causing hypotonicity or hypertonicity of oral and pharyngeal structures and a slow or poorly coordinated swallowing reflex. Paralytic and pseudobulbar dysphagia are neurological dysphagias. Mechanical dysphagia is caused by loss of oral, pharyngeal, or esophageal structures; weakness; and/or sensory deficits due to trauma or

surgery. Secondary disorders in addition to the primary cause of a particular type of dysphagia may complicate the presentation. Debilitation, lack of appetite, and overall nutritional status can affect a client's stamina and ability to participate in dysphagia rehabilitation (Safety Note 48-1 and Definition 48-2).

SAFETY NOTE 48-1

Pulmonary Concerns

Respiratory problems may contribute to dysphagia and vice versa because the respiratory and swallowing mechanisms share anatomy and physiology,

Secretion Management

The patient's airway must be clear of excessive secretions. Intermittent suctioning through the nose or tracheostomy may be needed to clear the airway. The swallowing therapist should work closely with nursing and respiratory staff to assess whether airway protection and the ability to maintain oxygenation are adequate. Personnel should be available to suction the airway as necessary.

Tracheostomy

A tracheostomy tube reroutes breathing through a stoma in the neck. Tracheostomy tubes may be temporary or permanent and are used to keep the airway open (Fig. 48-2). Tracheostomies provide easy access for suctioning or ventilator use but can cause or exacerbate dysphagia. They cause reduced smell and taste sensation because the patient is not breathing through the nose. Tracheostomy reduces the ability to clear the upper airway if laryngeal penetration occurs. It increases the risk of aspiration due to pooling in the pharynx, delays trigger of the swallow reflex (Devita & Spierer-Rundback, 1990), decreases duration of vocal cord closure (Shaker et al., 1995), and reduces laryngeal movement. An "open" tracheostomy in which the tube is not covered or "capped" eliminates the subglottic pressure, reducing the force of the swallow response (Gross, Mahlmann, & Grayhack, 2003).

Mechanical Ventilators

Ventilators are machines that assist patients to breathe if they cannot do so on their own. Positive pressure ventilators may be used temporarily, to assist a patient through an acute illness, or chronically, for a patient with a long-term respiratory deficit. Positive pressure ventilators deliver breaths to patients through a tube in the nose or mouth or through a tracheostomy. Patients who use a ventilator to breathe via a tracheostomy may be able to eat by mouth. Breathing and swallowing alternate (Logemann, 1998). A well-coordinated swallow is needed to interpose the swallow between inhalation and exhalation. Patients

Figure 48-2 A tracheostomy tube. Tubes come in different sizes and may come with or without the cuff as pictured. The pilot balloon is used to inflate the cuff with a syringe and indicates relative inflation of the cuff. The inflated cuff prevents food or secretions from falling further into the airway.

who have had mechanical ventilation for more than a week have been shown to have multiple swallowing deficits once the ventilator is removed (Tolep, Getch, & Criner, 1996). Patients who are ventilator dependent via tracheostomy are prone to aspiration during eating (Elpern et al., 1994).

DEFINITION 48-2

de·fin·i·tion

Clinical Dysphagia Presentation for Various Diagnostic Groups

Alzheimer's Disease: Pseudobulbar Dysphagia

- Decreased attention span and apraxia for swallowing and self-feeding may be seen.
- Oral and pharyngeal responses slow and a need for physical and verbal cues to self-feed are needed (Priefer & Robbins, 1997).
- Difficulty with self-feeding is common.
- Clients prefer sweet flavored and pureed foods.
- Clients are prone to aspiration in later stages of the disease (Horner et al., 1994).

Brain Injury: Pseudobulbar, Paralytic Dysphagia

- Type and severity of dysphagia in brain injury depends on the cause of the injury and location and size of brain lesions.
- Behavioral and cognitive problems affect self-feeding and swallowing.
- Abnormal pathological reflexes can affect oral and pharyngeal control (Logemann, Pepe, & Mackay, 1994).
- Increased or reduced muscle tone may cause decreased mouth opening, decreased lip closure, drooling, decreased tongue control, and pocketing of the bolus in the cheek (Logemann, Pepe, & Mackay, 1994; Mackay, Morgan, & Bernstein, 1999).
- Delayed pharyngeal swallow trigger, nasal regurgitation, decreased base of tongue movement, and decreased laryngeal elevation with resulting pharyngeal residue may be seen (Logemann, Pepe, & Mackay, 1994).
- Overall mealtime may be slow (Mackay, Morgan, & Bernstein, 1999).

Cerebrovascular Accident: Pseudobulbar and Paralytic

- Pharyngeal and laryngeal sensory deficits may occur in right and left hemispheric as well as subcortical strokes (Aviv et al., 1996).
- Symptoms vary with lesion location and size.
- Patients with right hemispheric stroke (pseudobulbar dysphagia) display mild oral transit delays and some delay in pharyngeal trigger and laryngeal elevation (Lazarus, 1995). The pharyngeal stage lasts longer, and there may be penetration of the larynx and aspiration (Robbins et al., 1993). There may be neglect or denial of swallowing problems.
- Patients with left hemispheric stroke (pseudobulbar dysphagia) display delays in initiating the oral stage and in triggering the pharyngeal stage (Lazarus, 1995). The

pharyngeal stage takes longer (Robbins et al., 1993). There may be apraxia for **eating** and swallowing.

- Patients with subcortical stroke (paralytic dysphagia) demonstrate mild oral transit delays and a delay in triggering the swallow. There is general weakness of pharyngeal swallow, as seen in reduced laryngeal elevation, reduced tongue base retraction, and unilateral pharyngeal weakness (Horner et al., 1991; Robbins et al., 1993). There may also be reduced upper esophageal sphincter (UES) opening (Horner et al., 1991).

Developmental Disabilities: Pseudobulbar, Paralytic Dysphagia

- Cerebral palsy (CP) and mental retardation, together or in isolation, may present deficits of bolus formation and transit, delayed swallow reflex, pharyngeal dysmotility, esophageal disease, and aspiration (Rogers et al., 1994).
- Abnormal oral reflexes, oral hyposensitivity or hypersensitivity, pharyngeal stage delay, decreased laryngeal elevation, and aspiration may be observed (Logemann, 1998).
- Poor postural, head, neck, and limb control can affect swallowing.

Head and Neck Cancer: Mechanical Dysphagia

- Swallowing problems with head and neck cancer vary with tumor type, size, and location.
- Bolus control and containment problems result from surgery to the lip (McConnel & O'Connor, 1994).
- Resection of tumor from the floor of the mouth causes difficulty with bolus control, reduced laryngeal elevation, and its accompanying reduction in UES opening (McConnel & O'Connor, 1994).
- Glossectomy, or removal of some or all of the tongue, causes difficult or absent bolus mobilization; a resection of the tongue base limits the elevation needed to initiate the pharyngeal swallow (McConnel & O'Connor, 1994).
- Unilateral laryngeal cancer may require a vertical laryngectomy or hemilaryngectomy; this may cause reduced vocal cord closure, reduced posterior tongue movement, and reduced UES opening (McConnel & O'Connor, 1994).
- Supraglottic laryngectomy reduces glottic closure, laryngeal elevation, and opening of the UES (McConnel & O'Connor, 1994).
- Extensive cancer of the larynx necessitates a total laryngectomy, which separates the foodway and airway tracts and creates a permanent anatomical tracheostomy. Although aspiration is no longer a threat, there is no laryngeal elevation, hence there is a reduced movement and force of the UES (McConnel & O'Connor, 1994).

(continued)

DEFINITION 48-2 (continued)

de·fin·i·tion

- Adjunctive radiation therapy causes edema in areas adjacent to the radiation field, fibrosis, and reduced salivary flow, causing dry mouth or xerostomia.
- Radiation therapy combined with chemotherapy without surgery can reduce tongue base movement, laryngeal elevation, and pharyngeal range of motion and speed (Lazarus et al., 1996).
- Radiation therapy combined with surgery can cause longer oral transit time, increased pharyngeal residue, and reduced UES opening (Pauloski et al., 1998).

Multiple Sclerosis: Pseudobulbar, Paralytic Dysphagia

- Dysphagia symptoms vary with location of plaques in the central and peripheral nervous systems.
- Weakness of the oral structures and the neck muscles may be seen (Thomas & Wiles, 1999).
- Delayed pharyngeal swallow and weakness of pharyngeal contractions may be seen (Logemann, 1998).

Neoplasms of the Brain: Pseudobulbar, Paralytic Dysphagia

- Dysphagia may be due either to a tumor or to metastasis in the brain or to medical or surgical interventions (Newton et al., 1994).
- Symptoms vary with the location and extent of the client's neoplasm and interventions, and symptoms may

be similar to those found in clients with stroke (Wesling et al., 2003).

Parkinson's Disease: Pseudobulbar Dysphagia

- Impulsiveness and poor judgment can affect swallowing (Leopold & Kagel, 1996).
- Jaw rigidity, abnormal head and neck posture, impaired coordination of tongue movements and mastication, and difficulty with coordination of upper extremity movements for self-feeding are seen (Leopold & Kagel, 1996).
- **Feeding** and swallowing may be too slow and laborious to allow sufficient nutritional intake.
- There may be oral residue, poor oral bolus manipulation, residue in the pharynx, delayed laryngeal elevation, and delayed oral and pharyngeal transit times (Nagaya et al., 1998).
- Impaired pharyngeal motility and aspiration may be seen (Leopold & Kagel, 1997).

Psychiatric Disorders: Pseudobulbar Dysphagia

- Tardive dyskinesia caused by long-term use of neuroleptic agents causes dystonia of the tongue and larynx and hyperkinesis of the face, jaw, tongue, and UES (Groher, 1997; Sokoloff & Pavlakovic, 1997).
- There can be choking due to eating too quickly (Fioretti, Giacotto, & Melega, 1997).

DYSPHAGIA ASSESSMENT

A dysphagia assessment involves two components, a clinical assessment and an **instrumental evaluation**.

Clinical Assessment

Clinical assessment of dysphagia must be thorough, with examination of all areas relevant to swallowing. It is best done using a reliable and valid tool (Avery-Smith, Rosen, & Dellarosa, 1997). A reliable and valid tool allows for accurate assessment and reassessment by different test administrators and ensures that each test item provides accurate assessment of performance components. Figure 48-3 illustrates the use of a chartable form to document evaluation results.

History, Nutrition, and Respiratory Considerations

The clinician reviews the patient's medical and surgical history, with special attention to any diagnoses and procedures that are relevant to dysphagia. The patient and caregiver also provide information about any history of

swallowing disorders. Specific signs and symptoms and modifications in behaviors relevant to mealtimes are noted, as are changes in food intake and weight loss. The current nutritional sources are recorded, including the length of time the patient has been **NPO**, or not eating by mouth, if applicable. The therapist also documents any cultural and religious dietary preferences and practices. Information regarding respiratory status is gathered from the hospital chart and staff, especially any tracheostomy and/or mechanical ventilation and the level of independence with secretion management.

Assessment of Cognitive, Perceptual, and Physical Abilities

Important cognitive and perceptual considerations include the level of alertness and arousal, orientation, ability to attend to a feeding session or meal, ability to follow multistep commands, and any visual deficits or neglect. The clinician notes the patient's insight into his or her dysphagia and observes head, neck, trunk, and limb control and endurance for being out of bed at mealtimes. The ability to self-position and self-feed and need for or use of adaptive eating equipment are assessed.

DYSPHAGIA

Evaluation Protocol
RECORD FORM

Client name: DOE, John DOB: 11/1/20 Age: 80 Date: 11/1/00
 Physician: Dr. Physician Location: bedside Type of service: Neuro
 Type of eval: Initial Re-eval Assistive or postural devices used: wheelchair
 Diagnosis: CVA, hemi Date of onset: 12/25/99 Reason for referral: SLD dysphagia
 Last oral feeding: breakfast Clinician/Title: Wendy Avery-Smith, OTT

HISTORY AND OBSERVATIONS

Feeding History

Normal preexisting function? No Yes
 When did change occur? Describe change.
Coughing with all textures, p CVA
 Has consistency of food changed? No Yes
 When, and how did client compensate? MD ordered Level I Aspiration Prevention Diet
 Has food intake changed? No Yes
 When, and how? Reduced, p CVA
 Weight loss? No Yes
 Number of lbs: _____ When? _____
 Other changes: _____

Nutritional Status

Nutritional Route:

Mastication				Not tested

Pharyngeal Stage

- Laryngeal elevation Normal Impaired Absent
- Voice quality after swallow Normal Impaired Absent (was not present pre-swallow)
- Auscultation:
 - Audibility of upper esophageal sphincter: No Yes
 - Pooling No Yes
- Comments: Delay in trigger of pharyngeal swallow response.

- Repetitive swallows No Yes Number of swallows: 1
- Cough reflex No Yes
 - Before swallow During swallow After swallow

Other Observations:

O₂ saturation level remained at 96 % before, during and immediately after feeding trial

During the feeding trial, record the patient's recognition of swallowing problems and upper extremity control for self-feeding.

Comments:

It is aware of inability to swallow fluids and chewable solids. He required hand over hand assistance to load spoon and bring to mouth. Able to hold a plastic cup with two hands, and bring to mouth.

Figure 48-3 (continued)

IMPRESSIONS

Summary

This 80 yo gentleman is SLP CVA & R hemiplegia and aphasia. He shows reduced oral tone and control in the R tongue and cheek. He is managing soft formed boluses with extra time for oral manipulation and a slowed swallow response. No pooling or coughing was noted after swallowing. There were no clinical signs of laryngeal penetration or aspiration.

Functional Level (Physical and verbal assistance needed for positioning, hand-to-mouth movements, and swallowing):

It was able to self-feed & hand over hand guidance to use utensil, but was able to use cup & 2 hands. He needed supervision to transfer to the wheelchair to eat and verbal cues to prepare his tray to eat.

Intermittent supervision at meals and snacks, as well as assistance to self-feed & R hand is recommended.

Recommendations/Plan:

- NPO (No food by mouth)
- Nutrition consultation: _____
- Videofluoroscopy To assess laryngeal protection & fluids.
- Prefeeding program
- Special positioning, Adaptive equipment: Seated to eat
- Mealtime supervision Constant Intermittent Set-up
- Diet recommendation: Continue & Level I, Aspiration Prevention
- Other: Short-term goals:
 - ① Advance diet to level II, including cooked fruit and pasta.
 - ② Tolerate soft chewables without s/s aspiration
 - ③ Use of techniques to maintain lip closure and prevent food pocketing
 - ④ Vocal cord adduction exercises
 - ⑤ Modified self-feeding & equipment and adapted seat.

Assessment of Oral and Pharyngeal Abilities

Once direct physical assessment begins, the clinician must observe universal precautions to prevent exposure to pathogens for both the clinician and the patient (Safety Note 48-2). The occupational therapist begins by assessing oral and pharyngeal control, including tone, range of motion, strength, and sensation of the lips, tongue, jaw, and cheeks and any abnormal oral reflexes. To assess pharyngeal control, the therapist observes soft palate movement, gag reflex, vocal quality, and volitional cough. A stethoscope may be used to listen for pooling of fluid above the level of the vocal cords, as pooled liquids resonate during breathing. The therapist rates the patient's hunger and level of enthusiasm for a snack or meal.

The Feeding Trial

Interventions that maximize performance can be initiated before the feeding trial begins (Procedures for Practice 48-1). The safest food textures are chosen for the trial. Easy-to-manage foods and thick fluids are attempted first, especially if the patient has been NPO and/or has a diagnosis or clinical picture that suggests a high risk of aspiration. During the oral stage, the clinician observes bolus containment, formation, propulsion, and mastication. During the pharyngeal stage, the clinician assesses laryngeal elevation, voice quality after swallow, repetitive swallows, and cough

reflex. The therapist should observe for signs and symptoms of **laryngeal penetration** or aspiration, especially during the first feeding trial (Safety Note 48-2). The evaluation concludes with a summary, recommendations, and a plan (Avery-Smith, Rosen, & Dellarosa, 1992).

Specific techniques are helpful during the feeding trial. Auscultation of the swallow with a stethoscope (Fig. 48-5) can reveal the efficiency and safety of the oral and pharyngeal stages (Zenner, Losinski, & Mills, 1995). Gentle palpation of the neck (Fig. 48-6) during the swallow reveals symmetry, strength, and speed of oral pharyngeal movement and may be done simultaneous to auscultation. Use of a pulse oximeter, a non-invasive monitoring device that measures the patient's oxygen saturation in the bloodstream, may be effective in assessing whether aspiration or respiratory difficulties are occurring (Sherman et al., 1999). Normal oxygen saturation in the bloodstream falls in between 93 and 98%; a level below 92% after swallowing suggests aspiration. If the patient can self-feed, palpation and auscultation may be done simultaneously. If the patient needs help to self-feed, auscultation and guiding with hand-to-mouth efforts may be done simultaneously.

Recommendations and Plan

Once the clinical evaluation is complete, recommendations and a plan are formulated. As seen in Figure 48-4, recommendations may include: whether eating by mouth is

SAFETY NOTE 48-2

Precautions for the Therapist and Patient

The swallowing therapist stays close to the patient during eating and is exposed to oral secretions and respirations. Likewise, the patient is exposed to pathogens on the therapist's clothing and hands and in the therapist's respiratory tract. Universal (also called standard) precautions should be used. The use of gloves is mandatory anytime the therapist touches the face or inside the oral cavity.

Dysphagia patients are prone to difficulty with airway obstruction and aspiration during eating. For the safety of the patient, the swallowing therapist should be trained in suctioning of the airway, the Heimlich maneuver, and cardiopulmonary resuscitation.

Signs and Symptoms of Potential or Actual Aspiration

Although laryngeal penetration or aspiration may be silent, occurring without overt warning signs and symptoms, the following indicate that it may occur or be occurring. If observed during a dysphagia evaluation, these signs or symptoms can indicate that a feeding trial should not be initiated or should be discontinued. Specific items

of concern are as follows (Avery-Smith, Rosen, & Dellarosa, 1997):

1. The patient cannot remain awake for the clinical evaluation.
2. The oral and/or pharyngeal sensation and motion assessment reveal poor ability to manipulate and contain the bolus.
3. The bolus remains in the mouth, and the patient cannot initiate or complete the oral preparatory stage within a reasonable time.
4. There is excessive coughing or choking before, during, or after swallowing.
5. There is no swallow response once the oral stage is completed.
6. There is a change in voice quality, often wet, or no voice after swallowing.
7. Severe pooling or wetness is heard on auscultation or by the naked ear; secretions are poorly managed.
8. Silent aspiration is suggested by a change in the patient's color and/or respiratory rate, increased congestion on auscultation of the chest, and/or a reduction in oxygen level in the blood as recorded by pulse oximetry.

PROCEDURES FOR PRACTICE 48-1

Preparation for Eating

Prior to the feeding trial portion of an evaluation and snacks or meals, measures must be taken to optimize the patient's swallowing performance. As these strategies do not involve ingestion of food, they are **indirect therapy** techniques.

- Provide a quiet environment to encourage concentration.
- Position the patient upright in a chair to minimize the risk of aspiration. The feet should be supported, and the arms should be free for self-feeding. Patients with pseudobulbar dysphagia may need special attention to positioning before eating and special positioning devices; they may need assistance to maintain head and neck alignment and facilitation to stimulate oral and pharyngeal motions prior to and during eating (Fig. 48-4).
- Complete oral hygiene activities before the trial because this stimulates sensation and range of motion in oral structures.
- Present a simplified visual array of food and utensils for the patient with visual neglect and/or other visual deficits. Anchors, colorful cues to call attention to the side of the plate, are helpful for patients with neglect.
- Present appetizing, culture-specific foods, utensils, and tableware.
- Provide adaptive equipment and/or use hand-over-hand guiding to facilitate self-feeding.
- Provide simple explanations and one-step verbal directions if necessary.
- If the patient eats too quickly or is confused by multiple food choices, present one food at a time.
- Use small-bowled utensils and verbal or manual assistance to load just a teaspoon-sized bolus. Pinch the straw to limit the amount of liquid consumed or use a covered cup with a small opening.

Figure 48-4 Using the half-nelson position to assist with head and neck control. The therapist can also assist with jaw, cheek, and lip control at the same time.

advisable; whether an instrumental evaluation is advised; whether a nutritional consultation with a dietitian is needed; recommended diet type; mealtime positioning and supervision; adaptive equipment; and type and amount of assistance. Evaluation of the patient is ongoing, and with additional information from clinical observations, instrumental evaluations, and input from other dysphagia team members, the treatment plan and goals change.

Instrumental Evaluation

Clinical assessment goes hand in hand with instrumental evaluation, which uses imaging and diagnostic studies to provide critical information about the unseen parts of the

oral, pharyngeal, and esophageal stages of swallowing. Various types of instrumental evaluations for dysphagia are discussed in Definition 48-3. These evaluations are usually performed by physicians, often together with a swallowing therapist. Aspiration of food or fluid may be silent (Linden, Kuhlemeier, & Patterson, 1993). Imaging studies, such as **videofluoroscopy**, are needed to identify aspiration (Splaingard et al., 1988), but they may not identify aspiration in all instances, as client skills can vary, and the testing situation in the radiology suite may not approximate an actual eating situation very closely. However, these studies do provide important information about the quality of the swallow and the efficacy of compensatory therapy techniques used during swallowing.

Figure 48-5 Auscultation of the swallow using a stethoscope. The therapist may be able to facilitate head position and guide self-feeding while listening to the sounds of the swallow.

Figure 48-6 Palpation of the neck during swallowing. The first finger is under the chin; the second finger is at the base of the tongue; the third finger is over the thyroid cartilage; and the fourth finger is at the base of the throat. A very light touch should be used so as not to inhibit motion.

DEFINITION 48-3

de·fin·i·tion

Instrumental Evaluation of Swallowing

Instrumental evaluation uses technology, including the following.

Electromyography

Electrodes are placed either into the muscle via a small needle or on the skin over a muscle to record contractions of the muscle. Surface electrodes have been used to assess aspects of oral bolus management in neurological dysphagia patients and pharyngeal, laryngeal, and esophageal activity (Ertekin et al., 1998).

Fiberoptic Endoscopic Swallowing Study

A fiberoptic laryngoscope, a narrow flexible tube with a small camera on its tip, is introduced through the nose into the

nasopharynx, where structures including the palate, pharynx, and larynx are viewed for assessment of anatomy and movement. Food is administered in different consistencies to observe posterior oral and pharyngeal function and airway protection during eating.

Manometry

A catheter with transducers to measure pressure is introduced into the esophagus. The force, timing, and sequence of the esophageal contractions are measured.

Scintigraphy

A radioactive isotope is mixed with food. As the bolus is swallowed, a gamma camera tracks the radioactive particles. This test measures the speed of bolus transit and can accurately measure the amount of bolus that is aspirated.

(continued)

DEFINITION 48-3 (continued)

de·fin·i·tion
Ultrasonography

An ultrasound transducer held under the chin produces images of oral and pharyngeal stages of swallow, revealing the mobility of structures and boluses swallowed.

Videofluoroscopy

The patient is seated between a movable camera and a fluorescent screen. Radiographic images of oral, pharyngeal, and esophageal structures are delivered to a screen from the camera as barium or barium-impregnated fluids and foods are swallowed. The images are recorded on videotape or DVD. Figure 48-7 illustrates a videofluoroscopic image of the oral, pharyngeal, and upper esophageal structures. Swallowing pathology and the effectiveness of compensatory

swallowing techniques and positions can be observed. The patient may be positioned in a lateral and/or anteroposterior position to view structure and function from both perspectives. Videofluoroscopies are often repeated to assess progress. A swallowing therapist is usually present to ensure that the test reproduces compensatory maneuvers and food textures being used and to ensure that it mimics real eating as accurately as possible. In some instances, the swallowing therapist may perform the videofluoroscopy. Therapists assisting with or performing videofluoroscopies must be expert swallowing clinicians; they must be fully trained in use of the equipment and procedures used in videofluoroscopy. Videofluoroscopy of swallowing may also be known as “MBS” or “modified barium swallow.”

Figure 48-7 A videofluoroscopic image of the oral, pharyngeal, and esophageal structures. (Videoprint image courtesy of Bette Pomerleau, MS, SLP, and Ray Autiello, LPN, RT, of Universal Mobile Services, Haverhill, MA.)

DYSPHAGIA INTERVENTION

One consideration in treatment is remedial versus compensatory goals. Remedial treatment focuses on restoring a normal level of swallowing function. Potential for partial or full recovery is anticipated when goals are remedial. Compensatory treatment circumvents a problem with the use of alternative strategies and techniques. Use of these techniques implies either that full recovery is not anticipated or that these techniques are necessary for a safe, functional swallow prior to recovery of normal swallowing. Table 48-1 discusses compensatory and remedial interventions for specific swallowing deficits. Compensatory swallowing maneuvers and their indications are discussed in Definition 48-3. Goals may be remedial and then change to compensatory once a plateau in function is reached.

Another consideration is the type of therapeutic techniques used. **Indirect** therapy addresses the prerequisite abilities or the capacity to swallow without ingestion of food or liquid. Patients who are at high risk for aspiration often begin with indirect therapy only. Indirect therapy can include range of motion, strengthening, and coordination exercises for weak or hypotonic oral and pharyngeal musculature; strengthening of pharyngeal and laryngeal structures; techniques to reduce or stimulate sensitivity of oral musculature; and techniques to improve the pharyngeal swallowing response. Indirect therapy also involves manipulating the environment to optimize behaviors that affect swallowing (see Procedures for Practice 48-1).

Direct therapy rehabilitates prerequisite abilities or the capacity to swallow during therapeutic snacks or meals. This entails exercises and/or the use of compensatory swallowing maneuvers that include ingestion of food. Indirect therapy may continue once direct therapy has begun. An individualized treatment plan usually includes a selection of direct and indirect techniques. The complexity of a treatment plan depends on the ability of the patient and/or caregiver to process complex information. Treatment techniques, especially in the pharyngeal stage, where the effect of techniques are unseen, should be evaluated by videofluoroscopy or fiberoptic endoscopy to assess their efficacy. Although not discussed in depth here, for many patients, optimizing self-feeding skills is an important goal to address hand-in-hand with swallowing goals. Although not yet proven in the literature, the sensory inputs and motor patterns used for self-feeding are probably related to those used in the partly voluntary swallow, and facilitating both skills enhances each.

Progression of Diet with Swallowing Therapy

As indirect therapy begins, some patients may receive all nutrition, hydration, and medication via a non-oral source,

such as intravenous or gastrostomy tube feedings. As the patient recovers the ability to swallow without laryngeal penetration or aspiration, direct therapy with the therapist present begins during snacks and progresses to meals. As improvement continues and the patient learns compensatory techniques, he or she may progress to eating under the supervision of nursing personnel and trained significant others and then progress to eating independently. Calorie counts are initiated by the dietitian to assess the adequacy of oral intake. Once food intake improves and calories are consistently sufficient, non-oral feeding sources may be used only for hydration and/or medication. Finally, as the patient improves and fluids and medications are safely ingested by mouth, the use of non-oral feeding sources can be discontinued. Diet textures are upgraded as skills develop. Depending on the diagnosis and potential for recovery, patients may level off at any point in the described progression (Procedures for Practice 48-2).

Dysphagia Diets

Dysphagia diets are designed to provide stepwise gradation of food and fluid textures that are matched to the patient's improving oral and pharyngeal skills. Groher (1987) found that a diet of mechanical soft foods that form a cohesive bolus and thickened fluids significantly reduced the incidence of aspiration in a group of patients with pseudobulbar dysphagia compared with pureed food and thin fluids. Specific textures and flavors can stimulate optimal oral and pharyngeal motion; for example, sour flavors may stimulate movement responses (Pelletier & Lawless, 2003). Patients may have strong preferences; those with dementias may prefer sweet flavors and reject foods that require chewing. Dysphagia diets for most patients follow this general progression:

1. Thick purees, such as pudding and applesauce
2. Very soft moist chewables, such as soft cooked vegetables, fruits, and soft pastas
3. Drier chewables, such as cookies and breads
4. Foods requiring biting, firmer chewables such as meats, and mixed textures like cereals and milk or pills and water.

The progression of fluids advances thus:

1. No fluids at all
2. Honey-thick fluids
3. Nectar-thick fluids
4. Thin, flavored fluids
5. Water

Fluids are easily thickened with commercial thickeners, which can be mixed with hot or cold beverages. Unthickened or "free" water is sometimes provided to dysphagia clients on the assumption that consuming small amounts of water creates little risk of pneumonia and can improve

Table 48-1. Compensatory and Remedial Interventions for Specific Problems

Patient Problem	Compensatory Intervention	Remedial Intervention
Swallowing apraxia		Provide a natural mealtime setting; enhance self-feeding skills to facilitate oral skills. Provide a variety of boluses to stimulate oral movements (Logemann, 1998).
Weakness of cheeks, lips	Provide soft solids and thick fluids for easy oral manipulation; place food at back and stronger side of mouth; tilt head toward stronger side; massage cheek to prevent pocketing; hold lips closed; inspect mouth after meals to check for residue.	Use tapping, vibration, and quick stretch to stimulate movement; provide range-of-motion and stretching exercises progressing to resistive sucking and blowing exercises.
Abnormal oral reflexes	Avoid stimuli that provoke rooting, bite, tongue thrust, sucking, and hyperactive gag. Elicit movements antagonistic to undesirable reflex; for example, encourage mouth opening to weaken bite reflex. Seat patient with body well supported to minimize proximal extensor tone, which can provoke abnormal distal movements and reflexes.	
Facial, intra-oral hypersensitivity		Provide systematic desensitization to face and intra-oral area. If sensory defensiveness affects whole body, a program of sensory diet and graded sensory stimulation to body should precede stimulation to oral area, followed by careful introduction of food. Use systematic desensitization with guided imagery to reduce muscle tone and anxiety regarding eating and mouth.
Oral hyposensitivity	Place bolus on more sensitive areas of mouth; use warmer or colder bolus and flavorful food to stimulate sensation (Logemann, 1998). Use heavy or viscous boluses.	Sensory diet providing heightened tactile and proprioceptive input to intra-oral structures may stimulate sensation and movement before and during a meal or snack.
Reduced lingual control	Introduce diet requiring little oral manipulation, including soft solids and thick fluids; use posterior and/or lateral placement of food on stronger side; inspect mouth for residue after meals.	Introduce active and passive tongue range-of-motion exercises, activities; provide quick stretch to tongue with tongue depressor or gloved fingers; provide articulation and tongue-strengthening exercises (Robbins et al., 2005)
Slow oral transit time	Use cold boluses to hasten oral transit time; take care in case they melt into a difficult-to-manage liquid. Sour boluses, such as those infused with lemon juice, can speed oral manipulation.	
Delayed swallow	Use a sour bolus to reduce swallow delay (Logemann et al., 1995). Try chin tuck to enhance airway protection; increase bolus volume and viscosity to reduce pharyngeal delay time (Bisch et al., 1994).	Try thermal-tactile stimulation: stroke anterior faucial arches with iced laryngeal mirror (Fig. 48-8); hastens initiation and overall speed of swallow immediately after application (Rosenbek et al., 1996).
Reduced laryngeal elevation	Use Mendelsohn maneuver to prolong laryngeal elevation or chin tuck to elevate larynx; use supraglottic or supersupraglottic swallow to clear or minimize any material in airway (Logemann, 1998).	Use “Shaker” exercises (a program of head raising exercises) to strengthen suprahyoid musculature and prolong opening of the UES (Shaker et al., 2002).
Reduced laryngeal closure	Use supraglottic or super supraglottic swallow to enhance airway protection (Logemann, 1998) or chin tuck to elevate and close off larynx.	Introduce vocal cord adduction exercises (Logemann, 1998).
Tracheostomy	Occlusion of tracheostomy tube minimizes aspiration and improves swallow biomechanics (Logemann, Pauloski, & Colangelo, 1998); use of one-way speaking valve can decrease frequency of aspiration (Dettelbach et al., 1995). Chin tuck may be useful.	

The swallowing therapist typically has to try several interventions, preferably with the assistance of videofluoroscopy, to assess which techniques work most effectively. Clinicians should work under the guidance of an experienced therapist when using a technique that is new to them.

Figure 48-8 Thermal-tactile stimulation of the swallow. An iced laryngeal mirror is used to stroke the faucial arches to elicit or improve strength of the swallowing reflex.

hydration (Garon, Engle, & Ormiston, 1997). As bacterial pathogens in the mouth may be aspirated into the lungs, meticulous oral hygiene is needed with any diet and free water to reduce the risk of pneumonia (Yamaya et al., 2001).

Patient and Caregiver Training

Although the occupational therapist alone may carry out treatment, the plan for intervention also includes education of the patient, nursing staff, and caregivers (Definition 48-4). The patient and family should understand the cause of and prognosis for the patient's

dysphagia and the importance of strategies to be carried out at home. It may be helpful to have the patient view the videofluoroscopy or fiberoptic endoscopy to clarify his or her condition and the benefits of compensatory techniques. Mealtime positioning, adaptive equipment, and the type and amount of assistance must be taught to caregivers. Meal preparation practice and community outings can reinforce diet modifications, enhance patient and family education in various settings, and motivate the patient.

Efficacy of Dysphagia Intervention

Numerous studies cite the efficacy of dysphagia intervention in both acute and chronic populations with a variety of diagnostic cohorts. Odderson, Keaton, and McKenna (1995) found that early management of dysphagia in the acute-care setting prevents incidents of aspiration and is cost effective. Dysphagia intervention has been shown to be effective for patients with traumatic brain injury (Shurr et al., 1999), acute neurogenic dysphagia (Bartolome, Prosiegal, & Yassouridis, 1997), stroke (Elmstahl et al., 1999), chronic dysphagia following brainstem lesions (Huckabee & Cannito, 1999), and head and neck cancer (Dejonckere & Hordijk, 1998) and for the profoundly mentally retarded cerebral palsy population (Helfrich-Miller, Rector, & Straka, 1986). Examples of proven therapeutic techniques to manage dysphagia are presented earlier in the chapter.

As the emphasis on evidence-based medicine and rehabilitation advances, clinicians must keep abreast of new knowledge. Useful resources on dysphagia care for both beginning and advanced-level swallowing therapists are noted under Resource 48-1. The author encourages the reader to explore further learning and expertise in dysphagia care. In many facilities, problem-oriented rehabilitation team goals are supplanting discipline-specific goals to target improvement of specific abilities that pose barriers to discharge, creating a need for occupational therapists versed in dysphagia management. Early discharge from acute care and rehabilitation hospitals and minimized staffing in health care facilities create situations in which competence in dysphagia intervention has become a mandatory skill for occupational therapy practitioners. Occupational therapists, with their background in the many abilities and capacities that influence eating and swallowing, make logical primary swallowing therapists.

PROCEDURES FOR PRACTICE 48-2

Compensatory Swallowing Maneuvers: Their Purpose and Execution

The following techniques are ways to use volitional movement to improve the quality of the pharyngeal swallow. Most of them are complex and require a good attention span and the ability to follow complex directions on the part of the patient.

Maneuver	Purpose	Execution
Chin tuck	Moves base of tongue back; narrows opening to larynx, protecting airway; helps protect airway when larynx is low and swallow is delayed (Ohmae et al., 1996; Welch et al., 1993).	Tuck chin down toward chest while swallowing.
Effortful swallow	Helps to elevate base of tongue (Pouderoux & Kahrilas, 1995).	Squeeze hard with throat muscles while swallowing.
Mendelsohn maneuver	Prolongs opening of UES when larynx is low (Logemann, 1998).	Push tongue into roof of mouth; try to keep Adam's apple up while swallowing.
Neck rotation	Closes weaker side of pharynx; uses stronger intact musculature in cases of unilateral weakness of pharynx and/or vocal folds (Logemann et al., 1989).	Turn head to the weaker side while swallowing.
Supraglottic swallow	Compensates for weak vocal cord closure, reduces penetration of food into larynx during swallow by closing vocal cords (Ohmae et al., 1996).	Swallow while holding breath; then cough. Volitional cough after swallow helps to ensure that anything in airway returns to pharynx to be reswallowed.
Super supraglottic swallow	Reduces penetration of food into larynx during swallow by narrowing opening to airway (Ohmae et al., 1996).	Hold breath and bear down; maintain breath-hold, keep bearing down while swallowing; cough after swallowing.

DEFINITION 48-4

de·fin·i·tion

Instrumental Intervention

Surface electromyography provides patients with improved awareness of swallowing function, providing for better swallowing. This intervention has been shown to be useful in populations with stroke (Crary et al., 2004; Freed et al., 2001). One example of this is VitalStim Therapy, which uses a specially designed electrical stimulation unit with surface electrodes placed on the neck (Fig. 48-9).

Figure 48-9 VitalStim, a specially developed neuromuscular stimulation unit that facilitates contraction of the muscles used in swallowing, in place on a dysphagic patient's neck. (©2005 Encore Medical, L.P. VitalStim is a registered trademark of VitalStim, LLC.)

CASE EXAMPLE

Mr. D.: Dysphagia Evaluation and Treatment for a Patient with Left Cerebrovascular Accident (CVA)

Occupational Therapy Process

Clinical Reasoning Process

Objective

Examples of Therapist's Internal Dialogue

Patient Information

Mr. D. is an 86-year-old man with a left hemispheric CVA. He was admitted to an acute-care hospital with aphasia and right upper extremity weakness, with a prior history of hypertension and transient ischemic attacks (TIAs) with aphasia.

Understand the patient's diagnosis or condition

"According to my experience and the literature, patients with dysphagia due to an acute single stroke eventually swallow safely without compensatory techniques. However, Mr. D. has had prior TIAs (possible permanent damage), which may limit his swallowing recovery. I expect that his symptoms will resolve, at least in part. He does have some control of his lips, cheek, and tongue, and reduced competence of his airway protection skills indicate that oral feeding should proceed cautiously."

<p>Patient Information (cont'd)</p>	<p>Know the person</p>	<p>“Although he is frail, Mr. D. is enthusiastic about advancing his diet and participates fully in his dysphagia intervention, and I believe that he will take responsibility for following through with his rehabilitation program. He enjoys meals at home and assists with meal preparation. He has a supportive spouse who will help to carryover mealtime recommendations and exercise programs. Because he is ambulatory, I believe that follow-up dysphagia therapy will occur on an outpatient basis.”</p>
<p>Reason for Referral to Occupational Therapy Mr. D. was referred to occupational therapy for dysphagia intervention, as well as to improve his upper extremity skills including self-feeding. The medical staff wants to be sure that he does not need alternative nutritional routes (nasogastric feedings or IVs) to nourish and hydrate himself while in the hospital and wants assurance that he is not at risk for aspiration. The doctors also want to assure that he can maintain his nutritional requirements so that he can safely be discharged home.</p>	<p>Appreciate the context</p> <p>Develop the provisional hypotheses</p>	<p>“Mr. D. is being seen as a hospital inpatient. Although eating and mealtime in this setting is very different from being home, due to natural recovery, his level of function may improve quickly, and I should be alert to update goals on a daily basis. I’ll be working together with the dietician to care for Mr. D.; she will monitor that he is eating and drinking enough and initiate any changes in diet that I recommend.”</p> <p>“Because Mr. D.’s muscle tone is low, I may be working with him to reinforce muscle activity for both muscles involved in swallowing and his upper extremity muscles involved in self-feeding.”</p>
<p>Assessment Process and Results A dysphagia evaluation was done using the <i>Dysphagia Evaluation Protocol</i> (see Resources 48-1). The evaluation (Fig. 48-3) revealed that Mr. D. had hypotonicity and reduced control of his lips, cheek, and tongue on the right side. Decreased airway protection skills were evidenced by his inability to phonate because of vocal cord weakness, inability to cough volitionally, and reduced laryngeal elevation during swallowing. He was not aphasic. Mr. D. was able to swallow foods from the beginning level dysphagia diet, including foods with soft, moist textures, such as pudding and applesauce, with mild food spillage out of the mouth due to poor lip control, delayed formation and propulsion of the bolus, and delayed initiation of the swallow. He had difficulty grasping utensils and cups because of hypotonicity of his dominant right hand.</p>	<p>Consider evaluation approach and methods</p> <p>Interpret observations</p>	<p>“I have chosen a standardized evaluation of dysphagia skills that also examines self-feeding and includes all components of swallowing that I need to assess.”</p> <p>“Given the evaluation results and observation over the course of several meals, Mr. D. should be able to nourish and hydrate himself with supplementary (not by mouth) nutrition or hydration.”</p>
<p>Occupational Therapy Problem List</p> <ol style="list-style-type: none"> Hypotonicity of oral, pharyngeal, and laryngeal structures, resulting in: <ul style="list-style-type: none"> Delay in and reduced coordination of bolus control both in the mouth and in propelling the bolus posteriorly to initiate the swallow Delayed initiation of the swallow Reduced upper extremity control, making use of his dominant arm to self-feed awkward 	<p>Synthesize results</p>	<p>“Reduced muscle tone is evidenced with both his swallowing and self-feeding.”</p>
<p>Occupational Therapy Goal List (five daily treatments prior to discharge)</p> <ol style="list-style-type: none"> Mr. D. will tolerate a more advanced dysphagia diet, adding soft chewables such as cooked fruit and soft pasta. 	<p>Develop intervention hypotheses</p>	<p>“I believe that focusing occupational therapy within a functional mealtime context can efficiently address both swallowing and self-feeding.”</p>

Occupational Therapy Goal List (cont'd)

- Mr. D. will tolerate these textures without clinical signs of aspiration (see Safety Note 48-2).
- Mr. D. will be independent in vocal cord adduction exercises.
- Mr. D. will support the right side of his lower lip and massage the right cheek during the oral preparatory stage to prevent food spillage and pocketing in his right cheek.
- Mr. D. will feed himself with his right hand with built-up utensils and an adapted cup while weight bearing on his right elbow.

Select an intervention approach

“Because Mr. D.’s stroke is acute and has great potential for improvement, the initial approach will be remedial, although a compensatory dysphagia modification will be used to reduce any possible risk of aspiration or laryngeal penetration at meal or snack time.”

Consider what will occur in therapy, how often, and for how long

“Because Mr. D. has an acute stroke, the intervention plan should be intensive; exercises should be done once or twice daily, and mealtime techniques be employed each time he eats, for both safety and to facilitate improvement.”

Intervention

Mr. D. was seen daily for occupational therapy during a week as a hospital inpatient. Constant supervision at mealtime was accomplished, and all meals and snacks took place with him seated upright in the chair. Occupational therapy intervention addressed exercises and positioning to enhance tone and control of oral motor skills, laryngeal exercises to strengthen his vocal cords and improve laryngeal elevation, and facilitation of tone and movement in his hypotonic right upper extremity to improve self-feeding skills. Mr. D. and his caregiver were educated and given handouts on the nature of his dysphagia, exercises, and mealtime procedures and precautions.

Assess the patient’s comprehension

“Mr. D., with the help of his wife, was able to understand all instructions and followed through with the treatment plan. He was anxious to progress to his normal diet and eating habits. He understood that the supervision at mealtime and exercises would help him to improve and prevent complications such as aspiration. He demonstrated improvements daily, and although his appetite initially was limited, he showed definite improvement through the week in terms of his intake. His progress was on target with what I expected, given that he developed no further medical complications. Happily, he achieved his short-term goals within a week.”

Understand what he is doing

Compare actual to expected performance

Know the person
Appreciate the context

Next Steps

Mr. D. was discharged from the hospital to home in the company of his wife. He and his wife were taught to thicken fluids with commercial thickeners at home. As his vocal cord strength returned, his volitional cough became stronger, and he gradually became able to speak in a loud whisper; laryngeal strengthening exercises continued. Mr. D. was able to discontinue use of external lip control strategies as oral motor control returned. He continued use of built-up utensils and weight bearing at the elbow while self-feeding. He continued with outpatient occupational therapy for 4 more weeks. During that time, the following long-term goals were accomplished:

- Mr. D. will tolerate a regular diet consisting of a variety of solid and liquid textures, dry cut-up chewable solids, and thin liquids without signs or symptoms of aspiration.
- Mr. D. will eat independently with his right upper extremity without use of adaptive equipment and without compensatory movements.

Anticipate present and future patient concerns

“I know that Mr. D. will be anxious to resume a normal diet and enjoy a normal range of food textures. He will also be concerned about being able to eat in a restaurant or with friends without his ‘elbow on the table’ weight-bearing strategy to improve his upper extremity control. For this reason and because of continued expected improvement, I’ll continue to see him as an outpatient until the remedial long-term goals are accomplished. Once he has regained ‘normal’ function, I’ll discharge him.”

Analyze the patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Dysphagia Evaluation and Intervention for Stroke Patients

Patients with cerebrovascular accidents (CVA) due to a left-hemisphere lesion (right hemiplegia) can demonstrate slow initiation of the oral stage of the swallow and slowed trigger of the swallow response. There may be reduced muscle tone in the right-side oral structures. The pharyngeal stage may be slowed. There may be apraxia for feeding and swallowing. Intervention focuses on activities to stimulate motion in the oral structures, providing a modified diet for safe swallowing, and creating a naturalistic setting at meals to stimulate motor planning. How are symptoms different in a patient with right-hemisphere stroke? How are they similar? How is intervention different?

Evidence Table 48-1 Best Evidence for Dysphagia Interventions Used in Occupational Therapy

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Remedial Approach	Oral motor exercises, compensatory swallowing techniques, positioning, dysphagia diet.	38 stroke patients.	Not provided.	Level IIIB3a	Yes; 61% of patients showed overall improvement on modified barium swallow testing and improved levels of nutrition.	Standardized assessment of videofluoroscopic swallow performance improved significantly, $p < 0.001$; a calculated overall dysphagia score showed significant improvement, $p < 0.05$; body weight showed significant improvement, $p < 0.05$.	Elmstahl et al, 1999
Remedial Approach	Individualized program that may include: remedial techniques such as oral motor exercises, laryngeal adduction and elevation exercises, and other remedial techniques including: Mendelsohn maneuver, supra-glottic swallow, repeated swallows, postural techniques, thermal stimulation, and diet modification.	63 patients with neurogenic dysphagia.	Not provided.	Level IIIA3b	Yes; 70% of patients showed immediate improvement, 43% improvement on follow-up; no deterioration was reported for any patient.	Improved feeding ability over time, $p < 0.05$; the relationship between post-intervention outcome and type of feeding at discharge and during follow-up, $p < 0.05$.	Bartolome, Prosiegel, & Yassouridis, 1997

SUMMARY REVIEW QUESTIONS

1. What are the stages of swallowing, and what events occur during each stage? Which stage or stages are most amenable to therapeutic intervention, and why?
2. What is aspiration, and what are its warning signs and symptoms?
3. Outline the three types of dysphagia; compare the specific dysphagia symptoms of selected diagnoses with the typical manifestations of the appropriate category: paralytic, pseudobulbar, and mechanical dysphagia.
4. Which components of a thorough dysphagia evaluation are most accurately completed with a patient who can follow multistep commands? How would you alter bedside evaluation for patients with various cognitive and perceptual deficits?
5. What are the instrumental evaluations for dysphagia, and how does the information that each provides assist in dysphagia rehabilitation?
6. What recommendations should a dysphagia evaluation provide?
7. Define compensatory and remedial and direct and indirect dysphagia treatments and provide examples of each for specific diagnoses.

ACKNOWLEDGMENT

I thank Denise Jules Wilhelm, OTR, for her assistance with photographs used in this chapter. Thanks also to Bette Pomerleau, MS, SLP, and Ray Autiello, LPN, RT, formerly of Universal Mobile Services in Haverhill, Massachusetts, for their assistance with the videofluoroscopic image reproduced in this chapter.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Convey the social and epidemiological history of HIV/AIDS in the United States, focusing on the populations most prevalently infected.
2. Summarize the natural history of HIV and its concomitant social trajectory.
3. Extrapolate the impact of HIV/AIDS at points along the disease trajectory on the occupations of people within different populations.
4. Select tools and assessment strategies to ascertain the specific occupational needs of individuals living with HIV/AIDS.

CHAPTER 49

Human Immunodeficiency Virus

Karin J. Opacich

Glossary

Global pandemic—An epidemic that affects many countries similarly.

HAART—An acronym for *highly active antiretroviral therapy*; combinations of pharmaceutical interventions configured to act on HIV at different points of reproduction.

Health disparities—Unintended differences in health status or health outcomes; seemingly associated with race/ethnicity, socioeconomic status, education, and access to health care.

Naturalistic paradigm—Research methodology that focuses on the lived experience, people in their natural environments; generally yields qualitative data rather than quantitative data from which themes or meanings are extracted.

Occupational competencies—Skills and abilities associated with effective execution of occupations and occupational roles.

Occupational coherence—Fluidity and complementarity of occupations that make outcomes predictable.

Occupational role integrity—Clusters of skills and abilities that support the tasks and activities associated with a given role; intactness of an occupational role.

Opportunistic illness—Infections and diseases that manifest because the normal protective responses of the immune system have been disabled.

Retrovirus—A virus that replicates itself using the mechanisms of host cells to convert RNA to DNA.

Since the symptoms associated with human immunodeficiency virus (HIV) were first described in 1981 (Masur et al., 1981; Siegal et al., 1981; Gottlieb et al., 1981), nearly a million cases have been recorded in the United States alone. Acquired immunodeficiency syndrome (AIDS) was officially defined in 1993 and periodically updated (Centers for Disease Control and Prevention [CDC], 1993), and surveillance systems for both HIV and acquired immunodeficiency syndrome (AIDS) have been established and revised by the Centers for Disease Control and Prevention (CDC, 1999; Nakashima & Fleming, 2003). HIV/AIDS is regarded as a **global pandemic** because it has dramatically affected nations and populations throughout the world. Initially thought to be a fatal diagnosis, life expectancies have increased due to advances in medical management. HIV/AIDS is now considered a chronic disease. Although the science associated with HIV/AIDS has rapidly compounded, arresting the disease still depends largely upon individual compliance with prevention strategies. Biological and physical aspects of HIV/AIDS have been systematically studied and documented, but the more variable social trajectory is shaped by the sociopolitical context in which individuals experience the disease. Consequently, quality of life after diagnosis is highly contingent upon resources, support, and access to relevant treatment. Among the services that can impact the lives of people with HIV/AIDS, occupational therapy can be valuable.

EPIDEMIOLOGICAL HISTORY

Epidemiologists have now established that HIV and AIDS are the result of human exposure to a chimpanzee virus in Africa that mutated perhaps as early as the 1920s. It is conjectured that this mutant viral strain has spread in modern

times due to increased slaughter and consumption of primate meat, widespread prostitution, and use of contaminated needles. After reexamination of stored specimens, it appears that HIV entered the United States sometime in the 1970s (Armstrong, Calabrese, & Taege, 2005). In the ensuing years, an increasing incidence of rare cancers and opportunistic infections precipitated curiosity among health scientists (Fan, Connor, & Villareal, 2004).

THE GLOBAL PICTURE

According to cumulative surveillance data, 42 million people in the world are living with HIV/AIDS. Of those, 29.4 million are from sub-Saharan Africa; 1.4 million are from Eastern Europe and Central Asia; and over 950,000 live in the United States (CDC, 2004; Joint United Nations Program on HIV/AIDS [UNAIDS], 2004). New infections are estimated to occur at a rate of 5 million per year. The most common route of transmission, based on global data, is heterosexual sex. In 2002, 3.1 million people died from AIDS (Curran, 2003; Ogunbodede, 2004).

HIV/AIDS in the United States

Unlike the epidemiological history in Africa, HIV/AIDS in the United States first manifested among gay men. In the early years of the epidemic in the United States, those considered most at risk for infection were gay men, people requiring blood products, and users of injected drugs (Fan, Connor, & Villareal, 2004). Women and children initially represented a very small proportion of those infected. Although predicted transmission has been contained, men who have sex with men still comprise the largest cohort of people with HIV/AIDS in the United States (CDC, 2004).

Data accumulated through 2002 show that women now represent nearly 25% of all people with HIV/AIDS and 30% of the new cases in the United States (National Institute of Allergy and Infectious Diseases [NIAID], 2005). Incidence among children rose until studies in the late 1990s demonstrated that drug therapies administered during the perinatal period could reduce transmission from mother to child. HIV infection among infants has nearly been eliminated, with only 59 new cases reported in children under age 13 in 2003 (CDC, 2004).

THE DISEASE MECHANISM

HIV is a **retrovirus** that results in a gradual deterioration of the immune system. Once the virus enters the human body, it overwhelms the CD4⁺ T cells that usually defend the body against viruses. HIV uses the cell machinery to convert its own RNA into a form that can be recognized and replicated using the DNA of the host, a process called transcription. Once emitted into the cytoplasm of the cell, this reconfigured virus translates itself prolifically, producing new copies and long chains of viral proteins that mature into new infectious particles that are emitted into other cells (NIAID, 2005). The most efficient vehicle for transmission is blood and contact with delicate mucosal tissue susceptible to cuts and tears. Studies have shown that HIV is not spread through casual contact with saliva, sweat, tears, urine, or feces. HIV status is confirmed by blood tests such as the enzyme-linked immunosorbent assay (ELISA), which detects exposure to the HIV virus via the presence of antibodies, or the Western blot, which targets the presence of the virus itself. Home screening kits are now available as well. Despite the availability of laboratory tests, initial diagnosis is sometimes not made until a person is hospitalized for pneumonia, persistent diarrhea, or other AIDS-related illness.

Although it is rare for health care providers to contract HIV through patient contact or even accidental needle sticks (NIAID, 2004), universal precautions (Safety Note 49-1) are advised, particularly if the provider is handling blood and blood products. Surgeons performing extraordinarily bloody procedures (e.g., orthopedists) are at greatest risk. Special care should be taken to avoid exposing HIV-positive persons to infectious agents because their compromised immunity makes them more vulnerable to serious infections.

SYMPTOMS

Within 2–4 weeks of initial exposure, most, although not all, people infected with HIV experience flu-like symptoms, such as fever, headache, fatigue, and enlarged lymph

SAFETY NOTE 49-1

Standard Precautions

You must routinely use standard precautions to protect yourself from exposure to blood or body fluids from all patients, regardless of their diagnosis. Standard precautions consist of the use of protective barriers to prevent contamination of the skin, clothing, and mucous membranes (eyes, ears, and nose). Hepatitis B virus, hepatitis C virus, and HIV are communicated through blood-borne pathogens. Modes of transmission include sexual contact involving the sharing of body fluid, needlestick, contact with blood through mucous membranes or broken skin, childbirth, receiving blood or blood products, and organ transplantation. Proper use of protective barriers prevents exposure. Protect yourself by always following these recommendations.

- Wear and change gloves.
- Do not wash or decontaminate disposable (single-use) gloves.
- Wear fluid- or moisture-resistant gown, apron, or lab coat when you anticipate contact with bodily fluids.
- Wear surgical cap and/or hood and shoe covers and/or boots when gross contamination is likely.
- Wear mask and eye protection with side shields and face shield when there is potential for splash, spray, or splattering of body fluids to the eyes, nose, or mouth.
- Wash your hands before and after contacting patients.
- Use a pocket mask or other ventilation guard device when doing CPR.

Needlestick or puncture is the most common mechanism for transmission for occupational therapists. To minimize risk use these precautions used by medical personnel:

- Use caution when handling all sharp objects.
- Do not bend, break, or manipulate items by hand.
- Place disposable sharp objects in puncture-resistant container immediately after use.
- Do not recap or remove needles from syringe by hand unless no alternative exists.
- Use a device instead of your hand to pick up or remove contaminated needles or other sharp objects.
- Place reusable sharp objects in containers that are puncture resistant, leak-proof on sides and bottom, and labeled.
- Use a mechanical device to clean up broken glassware.
- *Promptly* report all exposures to your supervisor and health care authorities.

nodes. Until the body's immune system is depleted of resources to combat the virus, the infected person may not experience further symptoms. Symptoms reported before progression to full-blown AIDS include lack of energy, weight loss, fevers and sweats, yeast infections, skin rashes, pelvic inflammatory disease unresponsive to treatment, and short-term memory loss. In many people, progression to AIDS takes 10–12 years, although approximately 10% of those who are HIV positive will progress to AIDS within 2–3 years of infection (NIAID, 2005). According to the prevailing CDC definition (CDC, 1993), HIV-infected people with fewer than 200 CD4⁺ T cells per cubic millimeter of blood and manifesting at least one Category C **opportunistic illness** are considered to have AIDS. As the disease progresses and opportunistic illnesses accrue, people with HIV often experience cognitive, motor, and behavioral manifestations including memory impairment, poor concentration, incoordination, weakness, irritability, and depression. More severe neurological deterioration may occur, especially with high viral loads (NIAID, 2005).

MEDICAL INTERVENTIONS AND ADVANCES

Clearly the best treatment for HIV is prevention. Prevention strategies entail raising public awareness, providing education, and promoting individual behaviors that avoid risk or minimize harm. Prevention strategies can have a dramatic impact as illustrated by the reduction in the rates of new infection among gay men and in Thailand, where safe sex campaigns have been successful (Curran, 2003). Scientists continue to focus on developing effective barriers to the virus and vaccinations that would protect people from sexual transmission (Armstrong, Calabrese, & Taegge, 2005).

For those infected with HIV, advances in pharmaceutical interventions have made notable impact upon survival and extended years of quality life. It is no longer unusual for people to experience 15 or more years of quality life from the time of diagnosis. The use of zidovudine during pregnancy (CDC, 1994) is among the most successful advances; it dramatically reduces transmission of the virus to infants born to HIV-positive mothers to a rate of about 1% (NIAID, 2005). Even though they may test positively for antibodies to HIV at birth, only a very small number of newborns now go on to develop the disease. As women tend to underestimate their risk and because prenatal transmission to infants can be prevented, in 2001 the CDC recommended that all pregnant women be routinely tested for HIV (CDC, 2001).

For infected adults, three categories of drugs have evolved and are currently used to treat HIV. Reverse transcriptase inhibitors interrupt the viral cycle early in its

proliferation, and protease inhibitors interrupt it later. The third class of drugs, fusion inhibitors, interferes with viral reproduction by blocking the cell membrane, preventing permeation of HIV. Combination therapies, called highly active antiretroviral therapy or **HAART**, are aimed at curtailing HIV at multiple points along its reproductive cycle. For those who tolerate and respond to HAART, the drugs can retard the progression of HIV and even restore some immune functions for those with AIDS (NIAID, 2005). Long-term use of HAART does seem to be associated with detrimental side effects including fat redistribution, insulin resistance, poor lipid profiles, and increased risk of myocardial infarction (Armstrong, Calabrese, & Taegge, 2005; NIAID, 2005).

PROGNOSIS AND MITIGATING FACTORS

Numerous strains of HIV have been identified, and the virus tends to customize itself within the individual. Some people seem to be more resistant to rapid translation than others. Viral load and strength of the particular HIV strain also seem to be associated with the rate of progression of the disease. Concurrent diseases or poor health status before infection can increase vulnerability and complicate medical interventions. Early detection of infections and adherence to medication regimens can prevent or slow the virus from usurping the entire immune system. Unfortunately, not everyone has access to testing, and not everyone responds positively to the drugs. For many people infected with HIV, sociopolitical circumstances erect barriers to health.

THE SOCIOPOLITICAL CONTEXT OF HIV/AIDS

HIV infection is most frequently attributed to unprotected sexual intercourse and behaviors that are generally not socially acceptable, such as illegal intravenous drug use and commercial sex. History demonstrates that people tend to underestimate their risk of exposure, and HIV infections are now permeating the mainstream heterosexual population in the United States. People with HIV often report being stigmatized or marginalized, and the potential for discrimination is very real. In the United States, HIV is most prevalent among men who have sex with men. Minorities, especially poor women of color, are disproportionately infected and vulnerable to exclusion, stigmatization, and discrimination (Dean et al., 2005; Duffy, 2005). The distribution of HIV represents one among many disconcerting **health disparities** in the United States.

Gay Men

Although discrimination against gay men has long been an issue, the gay community has some attributes that yielded some positive preventive responses. Higher levels of education, access to resources, and community mobilization allowed the gay community to promote education and prevention strategies (Curran, 2003; Fan, Connor, & Villareal, 2004). Concerns about confidentiality and employer discrimination may deter access to appropriate health care. To be effective, occupational therapists providing treatment to gay and bisexual men must be culturally sensitive. Unconventional life partners and families are likely to be involved in care, and the occupational therapist should be aware that the gay community has established many agencies, programs, and support networks that can enhance quality of life for people living with HIV/AIDS.

Women with HIV/AIDS

Poor women of color are disproportionately represented among those with HIV infection. According to the 2000 census data, African American and Hispanic women constitute approximately 25% of the total population but represent over 83% of HIV cases among women (CDC, 2006; United States Census Bureau, 2000). These women are generally socioeconomically disadvantaged and often disempowered. Their stories often reveal family violence, disrupted education, dependency upon exploitive men, and engagement in high-risk behaviors such as drug and alcohol use and commercial sex. General health literacy is poor, and health status even before infection may have been compromised. Therapists need to be particularly sensitive to the context in which these women live to avoid unreasonable expectations of them and exposure to increased harm from unempathic people. To attend to their own health, these women may need housing and transportation assistance, childcare, and partner or family counseling.

People Who Abuse Drugs and Alcohol

For people who have been actively using drugs and/or alcohol, sobriety is critical to improving health. HIV infection often leads to an epiphany that provides a powerful incentive for getting clean and sober (Opacich, 2004). Since chemical dependency is a complex biopsychosocial phenomenon, it is important to collaborate closely with expert colleagues and to encourage participation in programs designed to support sobriety.

Impact on Scientific and Health Resources

Despite the tremendous social and economic impact of HIV/AIDS on nations worldwide, resources are still

inadequate to meet needs. Over the years, programs have emerged that attend to the social complexities as well as the medical needs of people with HIV/AIDS. Many of these programs rely on grants and resources from state, federal, and private agencies. Treating HIV/AIDS successfully requires an array of health and human services and a culturally competent workforce to deliver those services. Labor statistics reveal shortages in many of those disciplines.

In 2004, \$415 billion were allocated to state and local health departments for AIDS prevention (Rand Health, 2005). Along with other sexually transmitted diseases, AIDS prevention efforts in the United States have largely been funded by the CDC. It appears that these efforts have been somewhat successful in containing gonorrhea, but their cost effectiveness in curtailing AIDS is yet unknown (Chesson et al., 2005). Cost of treatment for each person with HIV/AIDS has been estimated to be \$20,000 to \$100,000 each year (Schackman, Feedberg, & Goldie, 2005). Given the demographics of those infected in the United States, a large proportion of those who are HIV positive are uninsured. The Ryan White Comprehensive AIDS Resources Emergency Act (CARE Act) provided over \$2 billion in assistance to individuals and families through state-administered programs in 2004 (Government Accounting Office, 2005); however, poor health literacy, disempowerment, and stigmatization may still limit access to health resources.

CONTRIBUTION OF OCCUPATIONAL THERAPY IN THE TREATMENT OF HIV/AIDS

A growing body of professional literature attests to successful and potential occupational therapy contributions in addressing the needs of people with HIV/AIDS. Disease trends have stimulated research about the particular needs of women and the challenges people with HIV face in returning to work. To date, most of the literature has yielded program recommendations and educational strategies rather than evidence of effectiveness. Occupational therapy interventions for HIV/AIDS can be enhanced by the use of instruments that address underlying abilities and capacities that lead to competency in occupational performance and that measure outcomes of therapy.

Framing Occupational Problems and Developing Interventions

HIV insinuates itself into the human body and into every aspect of daily life. Although the diagnosis of HIV is devastating to some people, it becomes the vehicle to a more meaningful and productive life to others. An individual's response to untoward events, including HIV infection, seems to depend on both internal and external resources

and individual capacities. When establishing goals for occupational therapy treatment, it will help the therapist to think in terms of **occupational role integrity**, **occupational competencies**, and overall **occupational coherence**.

Since occupational functioning is the culmination of abilities and capacities that shape activities, tasks, and roles, multiple strategies may be needed to sort out occupational dysfunction. Although some problems in occupation may be directly attributable to AIDS-related illness, others may reflect contextual challenges or histories that prevented the development of occupational competency.

Neurobiological Changes That Affect Occupation

At times, it can be difficult to distinguish symptoms associated with HIV/AIDS and those related to the treatment of the virus. Nevertheless, these symptoms can impact quality of life. For many years, the *Whalen Symptom Index* (Whalen et al., 1994) has been used to indicate how frequent and troublesome the symptoms are. The index focuses on 12 of the most commonly experienced symptoms: fatigue, fevers, imbalance, paresthesias, memory loss, nausea, diarrhea, sadness, sleep disturbance, skin problems, cough, and headache. The client is asked about the frequency of these symptoms over a 2-week period, and each symptom is scored on a 3-point scale. Cumulative scores are thought to vary proportionally with the impact of symptoms on the person's life. Combined with other data, the index informs the occupational therapist and other health providers so they may help the person with HIV to manage symptoms. Occupational therapists can recommend lifestyle modifications and compensatory strategies to cope with a number of symptoms.

Psychosocial Manifestations

Awareness of the social trajectory is equally important in the treatment of people with HIV/AIDS. As with any serious illness, initial diagnosis is usually followed by a grief response. Depression is common both initially and intermittently throughout the disease process. Education is vitally important at this time because many misperceive HIV as a certain and imminent death sentence. Some programs link newly diagnosed people with a peer outreach worker who can comfort and inform them about HIV and helpful resources. If connected to relevant services, the person with HIV is less likely to become socially isolated or marginalized. As the disease progresses, neurological changes may predispose the person with HIV to mood swings, prolonged depression, and cognitive impairment. Occupational therapists should be prepared to employ psychosocial strategies to combat psychomotor retardation that

often accompanies depression and to facilitate participation in family and community life (see Chapters 35 and 36).

Qualitative Assessment Strategies

Each theoretical model of occupation is associated with instruments and strategies for framing occupation. An array of qualitative tools reflecting the **naturalistic paradigm** can be useful to reveal the nature of experience, in this case how an individual experiences HIV. Among these strategies, semi-structured interviews can elicit narrative reflecting occupations; one of the published narrative tools, the *Occupational Performance History Interview II*, is reflective of the Model of Human Occupation (Kielhofner et al., 1998). This particular template is used to probe how a given illness, condition, or untoward event shaped or altered the person's occupations. This narrative data can be analyzed a number of ways and used to generate plans and strategies for reconstructing occupation.

Quantitative Assessment Strategies

Quantitative strategies are useful when the phenomenon in question is well defined and the query is focused. An example of a quantitative criterion-referenced tool useful for people with AIDS is the *Assessment of Motor and Process Skills* (Fisher, 1997). This tool enables the therapist to observe the person with HIV engaging in familiar tasks, to quantify, and compare the person's occupational performance, and to recommend strategies and levels of support necessary for safe living. The therapist might consider incorporating quality-of-life measures that reflect occupations and inform decision making (Robinson, 2004).

Preserving, Restoring, and Adapting Meaningful Doing

The Occupational Functioning Model organizes roles and the definition of self into self-maintenance, self-advancement, and self-enhancement (see Chapter 1). Occupational therapy may address any or all of these aspects with the person with HIV/AIDS, depending on the occupational status of that person both before and after HIV infection. As previously noted, some cohorts of people with HIV have led marginal lives that are likely to have stymied their occupational potential.

Preservation

In the early stages of HIV infection, it is important that the individual resume or establish routines, habits, and behaviors that preserve healthfulness. Along with established roles, the newly diagnosed person must now incorporate medication regimens and attend appointments for regular lab tests and check-ups. For those whose lifestyles involved drug use or commercial sex, HIV treatment also

entails intensive redirection, psychotherapy, and peer support. If pharmaceutical interventions or the virus itself results in symptoms, the person with HIV can face additional challenges in work, parenting, self-care, or other occupational pursuits. Whether the patient is a child or an adult, preserving and adapting occupational roles is critically important for both physical and mental health. For people whose lifestyles entailed maladaptive behaviors, occupational therapy may well require role exploration that may have been derailed in childhood or adolescence or abandoned in adulthood. Strategies may include parenting classes, practicing independent living skills (e.g., laundry), and job training/retraining.

Restoration

As the disease progresses, it is common for people to experience periods of ill health and disruption of normal routines. Those with HIV/AIDS are immunocompromised and are therefore susceptible to illness and opportunistic infections. Improvement in health can occur when symptoms are addressed and HIV medication regimens bolster the immune system. Similar to cardiac rehabilitation, occupational therapy can be useful while the person is reconditioning and illness abates. During these times, therapy may entail work simplification or rebuilding endurance. Roles, routines, and habits related to work, self-care, and leisure may need to be negotiated and adjusted. When symptoms persist or abilities are

permanently altered, the occupational therapist and the HIV-positive client should focus on adaptation.

Adaptation

As the immune system is overwhelmed, the person with HIV/AIDS is likely to lose abilities. Sensory deficits, weakness, incoordination, compromised memory, and other sequelae can compromise occupational roles and independent living. During this stage of illness, occupational therapy can facilitate adaptations that enable the person with HIV/AIDS to participate in daily life as fully as possible. This may entail environmental adjustments, adaptive strategies or assistive devices, personal assistance, or changes in living situation (see Chapters 19, 30, 32, and 33).

Integrity of Occupational Roles

In the initial interview, the occupational therapist working with a person with HIV/AIDS needs to develop a clear picture of the roles that characterize the person’s life. Depending on the point along the disease trajectory at which the therapist encounters the recipient of services, evidence of role strain, role disruption, or role abandonment may be present. The therapist may find it useful to plot the person’s role status on the Matrix of Occupational Status (Table 49-1) to establish a baseline for decision making and intervention.

Table 49-1. Matrix of Occupational Status for People with HIV/AIDS						
Occupational Domain	Occupational Role	Discontinued	Disrupted	Adapted	No Change	Expanded
WORK	Parent/Caregiver Homemaker (IADL) Employee Entrepreneur Vocational Trainee Student					
PLAY/LEISURE	Participant/Observer Spectator Hobbyist Athlete					
SELF-CARE	Personal Care (ADL) Instrumental Activities of Daily Living (IADL) Health-Related Care Self-Advocacy Intimacy/Sexual Expression Spiritual/Devotional Expression					
Description of Occupational Context	Neighborhood/Community Home Environment Health Care Setting Social Network Employment Setting					

Role Strain

The occupational therapist should ascertain whether the HIV-positive person is responsible for the care of others. If there are children, life partners, elderly adults, or even pets in the household, the person with HIV may be experiencing the strain of taking care of others given the added burden of managing HIV. In addition, others in the family, however that family is constituted, may also have HIV.

Most people sustain multiple roles, and life is an exercise of juggling priorities and meeting obligations. Some individuals are very tenacious about their roles, even when their health is compromised. Since those with HIV frequently experience fatigue, it is important to designate time for rest and restoration throughout the day. The occupational therapist can help the person with HIV to establish role priorities, reserving time and energy to attend to personal health needs. This may entail negotiating and relinquishing some responsibilities and tasks to others or arranging for support (e.g., homemaker services).

Role Disruption

When immune system failure results in illness, the person with HIV might be confined to bed or hospitalized for brief or extended periods of time. This is not an unusual pattern and should be anticipated. The occupational therapist can help to plan strategies for dealing with health emergencies. Such strategies may include identifying babysitters, notifying family members, enlisting help from neighbors, calling health care providers, and arranging sick leave. When the individual with HIV is ready to resume a former role after a period of illness, the occupational therapist can assess, modify, and design rehabilitative strategies consistent with the person's state of health and abilities.

Role Abandonment

Many stories elicited from people with HIV reveal role abandonment. For those whose lives were dominated by chemical dependency, development may have been arrested and efforts diverted to the procurement of drugs or alcohol. For others who are HIV positive, depression or shame may have interrupted life plans. For still others, the symptoms and sequelae of HIV itself may have prevented full participation. Whatever the case, if reasonable health can be restored, then the occupational therapist may be the primary facilitator of role resumption or role exploration.

Occupational Competencies

At the start of therapy, the occupational therapist should generate a list of **occupational competencies** or skills relative to the roles the client fulfills. For example, if remunerative employment is relevant, the occupational

therapist can help to delineate the skills the client has or needs to acquire to resume or pursue work. Some people with HIV/AIDS who had been unable to work have been restored to a level of health through HAART that makes employment feasible again (Kielhofner et al., 2004). The therapist might advocate on behalf of the client to accommodate special needs (e.g., flexible work schedules, longer rest periods, or accommodations for adaptive equipment). The occupational therapist may need to assist clients to develop strategies to compensate for low vision or for poor coordination.

If the HIV-positive person is a homemaker, establishing routines to accomplish cleaning, shopping, laundry, and so on will be important. Safety in the kitchen, especially when handling sharp utensils, will prevent exposure of others to HIV-positive blood. If the person is living with family members or friends, the occupational therapist can help the individual to negotiate household responsibilities, rest and privacy needs, and accurate understanding of HIV/AIDS and healthy behaviors. Work simplification and energy conservation principles may be useful for coping with changes in strength, endurance, and sequencing tasks and activities. It is important to acknowledge that many people living with HIV/AIDS are impoverished and may be living in poor housing and unsafe environments, which pose additional challenges. For some, the social assistance surrounding HIV care may present new housing opportunities; the occupational therapist can guide the person through the establishment of a household, from obtaining utilities to paying bills to preparing meals.

Occupational Coherence

Occupational coherence speaks to the complementarity of roles, routines, habits, and behaviors that contribute to a progenerative life that, in totality, makes sense (Opacich, 2004). Coherence is a notion introduced by Antonovsky (1987), a sociologist, and later expanded by Nyamathi (1993). Coherence was first applied to occupations by Christiansen and colleagues (Christiansen, 1999; Christiansen, Little, & Backman, 1998) as an indicator for outcomes in the face of threats to health. Research on women with HIV/AIDS illustrates the construct by contrasting the lives of women living amidst chaos and uncertainty with those whose lives were more coherent (Opacich, 2004). If a person is ill with HIV, actively chemically dependent, and homeless, one would not describe that person as leading an occupationally coherent life. If that same person became sober, adhered to medical recommendations for arresting HIV, procured safe housing, and resumed remunerative employment, life would appear to be occupationally coherent and built upon meaningful doing. The ultimate goal of occupational therapy with people with HIV might well be the achievement of occupational coherence.

EVIDENCE OF EFFECTIVENESS OF OCCUPATIONAL THERAPY FOR PERSONS WITH HIV/AIDS

The literature pertaining to HIV/AIDS in occupational therapy is largely conceptual or phenomenological. It

reflects the experience of people with HIV/AIDS and informs the development of programs and services. A number of those studies have been mentioned in this chapter. Very few studies have been designed to examine particular interventions or to quantitatively measure effectiveness of occupational therapy interventions.

CASE

EXAMPLE

N.J.: Acquired Immunodeficiency Syndrome (AIDS)

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information N.J. (a 49-year-old African American female with AIDS) participated in an outpatient occupational therapy assessment. The following problems were identified: (1) insufficient endurance for some ADL and IADL; (2) mild memory impairment and confusion that interferes with self-care; (3) ambiguity of roles and routines; (4) intermittent loss of balance impacting environmental mobility; and (5) paresthesias that affect the execution of fine motor tasks.</p>	<p>Appreciate the context</p> <p>Develop intervention hypotheses</p> <p>Select an intervention approach</p> <p>Reflect on competence</p>	<p>(The assessment process in general, including ascertaining personal background information, is described in Chapters 4–11).</p> <p>“N.J.’s poor endurance is a direct result of her extended hospitalization and convalescence, during which she was bedridden and tube fed. Since her recovery, she has abandoned former dysfunctional pursuits, leaving her to redefine her roles, habits, and routines. Her remaining symptoms are natural sequelae of HIV/AIDS and/or drug interventions.”</p> <p>“The first order of therapy will be to identify critical ADL and IADL that support recovery, such as adherence to medication regimens, establishing intermittent rest periods, and planning for proper nutrition. Given the reported sensory and cognitive issues, precautions and compensatory strategies need to be implemented to assure the patient’s safety. Finally and probably most importantly, the patient needs to be supported in her role exploration and resumption for maximal participation in family and community life.”</p> <p>“Do I have adequate understanding of the relevant epidemiology, neurobiology, pharmacology, and psychodynamics? Am I sufficiently culturally competent, and can I be effective with this patient? I will need to collect tools and strategies for role exploration and practice any specific administration protocols.”</p>

Recommendations

The occupational therapist recommended home-based care two times a week initially for 4 weeks and one time a week for the next 2 months. In collaboration with N.J., long-term goals for treatment were established as follows: (1) N.J. will identify which ADL and IADL tasks are indispensable to her management of HIV and will establish a daily schedule and record system for these; (2) N.J. will learn and implement home safety strategies relying on cue cards posted where most needed; and (3) N.J. will explore two roles or interests that will lead to safe and productive use of time.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"Since the initiation of the HAART protocol, N.J. has been slowly regaining her health and is more hopeful than she has been in years. She describes herself as having died and been reborn to a different life, and she says that she is actually grateful for HIV. She sees herself as having some special purpose. Since she once had many occupational competencies, she seems eager and able to reach her goals. N.J. is currently residing with her daughter and young grandchildren; they have agreed to support her in these goals and to be present for at least one in-home occupational therapy session each week."

Summary of Short-Term Goals and Progress

1. N.J. will identify which ADL and IADL tasks are indispensable to her management of HIV and will establish a daily schedule and a record system for these.

N.J. and her therapist identified the following ADL and IADL tasks as indispensable: 15 minutes of morning meditation, showering once a day, preparing her own breakfast and lunch, eating her evening meal with the family, taking her medications at 6-hour intervals, and taking a nap for 1 hour in the afternoon. N.J. developed a schedule for herself that she kept next to her bed and checked off after completing each task. At each occupational therapy session, the therapist reviewed these with N.J. and addressed any problems.

2. N.J. will learn and implement home safety strategies relying on cue cards posted where most needed.

N.J. and her therapist practiced safe methods of handling sharp objects in the kitchen and posted pictures of her using these procedures under the cabinets. With the assistance of the therapist, the family installed grab bars in the bathroom. The therapist also instructed N.J. in the use of a walker for those days when her balance felt precarious. N.J. also generated a list of emergency numbers that she programmed into her cell phone. The family also established a call system to check on her well-being.

3. N.J. will explore two roles or interests that will lead to safe and productive use of time.

Through interviews with the therapist, N.J. will tell stories of things that she did in the past that she found enjoyable and fulfilling. Responding to the Occupational Performance History Interview, N.J. related that she loved to sing, and she began attending choir practice one evening a week and singing in the church choir on Sundays. She also decided that she would like to try working in her daughter's grocery store, and she began doing this for 2 hours two times a week in the early afternoon.

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance
Know the person

Appreciate the context

"As N.J. began to feel better, she seemed genuinely happy to have a structure to her life. She would relate stories of how dysfunctional she had become before she got so sick. Even on the days when she was very tired or experienced a setback, she expressed gratitude for being here to help raise her grandchildren."

"N.J. felt that she didn't need the safety procedures most of the time, but she began to accept that it was better to be cautious than to have an unnecessary accident. Even her family members would remind her to do things 'like in the pictures.' N.J. took the walker with her when she left the house because it just made her feel a little safer if she got dizzy."

"N.J. really enjoyed singing in church, and joining the choir gave her the opportunity to make some new friends who were very supportive. Working in her daughter's grocery store was tiring at first, but N.J. felt like she was able to help out and even began to repair the strained relationship with her eldest child. Even though she shares a room with her grandchildren in her youngest daughter's apartment, she seems very happy to be there."

Next Steps

Revised short-term goals (1 month):

- N.J. will identify one household task for which she will take responsibility on a daily basis.
- N.J. will continue to adhere to established safety strategies and will report to the therapist any problems or other situations that seem to pose a threat to safety.
- N.J. will increase her hours at the grocery store to a maximum of 3 hours daily depending on the state of her health.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“N.J. seems much healthier in a short period of time. She is enthusiastic about the church choir, and a few of the ladies have even begun to visit her at home. She is acutely aware of how important it is for her to eat well, rest, and take her medication. She has a frank and wonderful rapport with her physician, and she trusts her advice. N.J. has a tendency to do a little too much, and she needs to be reminded to add things into her schedule gradually. Despite everything that has happened to her, she is not at all bitter and seems to have accepted her diagnosis and its implications in her life.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

HIV and Health Disparities

N.J. is representative of a group of people (poor women of color) known to manifest health disparities. What social, economic, and political conditions may contribute to disparities in health? How might these have affected the course of N.J.'s illness to date? How might occupational therapy address some of the consequences of health disparities in this case?

Evidence Table 49-1 Best Evidence for Occupational Therapy Practice Regarding HIV/AIDS

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
<p>Four-phase vocational program:</p> <ul style="list-style-type: none"> (1) 8 weeks of self-assessment and preparation for work; (2) effort to require productive roles through experiences; (3) support successful employment; (4) support sustained employment 	<p>Model of Human Occupation (MOHO)-based program customized to individual needs to explore, develop skills, and seek employment.</p>	<p>Convenience sample of 129 men and women with HIV/AIDS (106 males, 21 females, and 2 transgender persons; mean age = 41 years); 30% attrition rate (39 of 129 participants).</p>	<p>Phase 1: 8 weeks, group session 1 time a week plus individual sessions. Effect size not reported.</p>	<p>Kielhofner et al., 2004</p>

SUMMARY REVIEW QUESTIONS

1. How does the epidemiology of HIV differ in the United States compared with other countries?
2. By what mechanisms does HIV overwhelm the immune system?
3. What are the routes of transmission for HIV?
4. Which populations are most vulnerable to HIV/AIDS and why?
5. What information is yielded from particular qualitative strategies and quantitative measures that is useful for developing interventions for people with HIV/AIDS?
6. How are occupational roles affected by HIV/AIDS?
7. How does the illness trajectory impact occupational therapy interventions?

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Understand the role of occupational therapy in cancer rehabilitation.
2. Identify role, tasks, and activity deficits that may affect occupational functioning, regardless of type of cancer diagnosis.
3. Identify types of interventions that may improve occupational functioning.
4. Become aware of some safety concerns when treating a person who has cancer.
5. Know how to access resources to improve the quality of care that one offers to a person who has cancer.

Glossary

Carcinoma—Cancers originating in the tissues of the body's organs.

Hematopoiesis—The process of blood formation.

Leukemia—Cancers involving the blood cells and blood-forming organs.

Lymphoma—Cancers arising in the lymphatic system; affect the B and/or T lymphocytes.

Lytic—Breakdown of bone marrow due to tumor invasion, putting person at risk of pathological fracture.

Palliative (care)—Supportive care aimed at symptom relief; relevant along the entire continuum of care; typically used at end of life when all other treatment has failed.

Sarcomas—Cancers of the bones and/or connective tissues.

Cancer: The word alone evokes fear and stigma. People equate the diagnosis of cancer with death. Yet heart diseases, not cancer, are the leading causes of death in the United States (American Cancer Society, 2006). One of two men and one of three women in the United States may be diagnosed with cancer in their lifetime. All ethnic groups are affected by the diagnosis, although some groups access screening and intervention earlier than others. Access to screening and intervention are among the determinants of prognosis and survival.

A diagnosis of cancer, then, challenges meanings and priorities in life. The person who lives with the diagnosis, as well as members of his or her support system, must adjust to changes and losses. The person with cancer (and this support system) is considered to be a survivor from the moment of diagnosis throughout the remainder of his or her life. Both the disease and its treatment can disrupt occupational functioning of the individual and his or her support system. Routines can be disrupted, valued roles and the activities associated with these roles can be lost, and impairments can lead to long-term disability in some cases.

Although this chapter focuses on the individual who has cancer, occupational therapists who work with this diagnostic population should also be aware of the impact the diagnosis has on the individual's social support system. Moreover, treatment of the person with cancer must take into account physical, emotional, cognitive, and spiritual needs to facilitate adjustment and maximize occupational performance.

predicted cases), lung (13%), and colorectal cancers (10%), while women are at greatest risk for breast (31%), lung (12%), and colorectal (10%) cancers. Other types of cancer, such as **leukemias** (cancers involving the blood cells, bone marrow, and other blood-forming organs), **lymphomas** (cancers arising in the lymphatic system), and **sarcomas** (cancers of the bones and/or connective tissues), have lower rates of incidence (ACS, 2006).

Cancers ultimately involve diseases of the body's cells. Anything that affects cells' reproductive function, altering genetic structures, can be considered a risk factor or cause for cancer. Environmental and cellular factors constitute the two primary sources of risk for developing cancer and contribute to cancers' underlying causes (ACS, 2006; Heath & Fontham, 2001; MDACC, 2006; Rohan & Budds, 2004).

Environmental factors may be considered in terms of lifestyle and environmental exposure. Lifestyle-related risk factors include diet (i.e., dietary exposure to carcinogens), obesity, and level of physical or leisure activity (ACS, 2006; Heath & Fontham, 2001). Smoking is part of the lifestyle of 90% of persons diagnosed with lung cancer (Van Cleave & Cooley, 2004). Other environmental factors include exposure to chemicals, such as asbestos or benzene; to radiation sources, as in ultraviolet rays present in sunlight; or to infectious processes, such as Epstein-Barr virus or hepatitis C virus. Cellular (or molecular) factors include genetic predisposition to cancer due to heredity or impaired immune system function (Heath & Fontham, 2001).

CANCER STATISTICS: INCIDENCE AND ETIOLOGY

The American Cancer Society (ACS) (2006) predicted that 1.4 million new cases of cancer would be reported in 2006. Most new cases are **carcinomas**, cancers originating in the body's organs (The University of Texas M. D. Anderson Cancer Center [MDACC], 2006). In terms of reported incidences, men are most often affected by prostate (33% of

MECHANISMS OF CANCER: PATHOLOGICAL BASIS OF DIMINISHED CAPACITIES AND ABILITIES

Once a cell's DNA or genetic components change, those changes are copied in new cells as the altered cell divides. If the body does not have sufficient immune function or capability to repair its DNA and stop the cell division of

the mutated cells, then cancer forms. The mutated cells subsequently lose functions and characteristics that define them histologically as a certain type of cell. They then proliferate to impinge on other cells or organs (Workman, 2004).

Cancers can be graded and staged. Tumors are graded in terms of degree of differentiation, that is, the degree to which the cell resembles the source tissue (Hutson, 2004). Staging is the process of determining the degree to which a cancer has progressed (Lenhard & Osteen, 2001). The TNM staging system, adopted by the International Union Against Cancer and the American Joint Committee on Cancer, is the most common method. It involves identification of (1) tumor size, (2) the number of lymph nodes to which the cancer has locally spread, and (3) the presence of metastasis (spread to more remote areas of the body). Staging helps physicians select the type of treatment that will be most appropriate for the patient, and it contributes to the estimate of prognosis. A stage I, grade 1 cancer is one where a tumor is present but has not infiltrated surrounding tissues, and its cells are well differentiated. In a stage III, grade 3 cancer, a tumor is large, has invaded other tissues and lymph nodes, and has poorly differentiated cells. Although they are beyond the scope of this chapter, the occupational therapist who works in oncology should know about the specific processes that occur in tumor formation and growth (angiogenesis) and during metastasis (Resources 50-1).

Lung Cancers

Thomas et al. (2001) and Van Cleave and Cooley (2004) describe two classes of lung cancer. Small-cell lung cancers (SCLC) are derived from neuroendocrine cells, while non-small-cell lung cancers (NSCLC) arise from the epithelial types of tissues that line the lungs. Lung cancers tend to be diagnosed at later stages, when the cancer has metastasized to other sites and when other symptoms, such as weight loss, fatigue, pain, or osteoarthritis (arthritis-like bone and joint pain), have become more prevalent and affect the individual's daily routines. These and other symptoms, such as weakness, shortness of breath, dyspnea, or neurologic changes indicative of brain metastasis, contribute to individuals' diminished capacities and abilities. Occupational therapists can intervene to help persons with lung cancers modify their lifestyles to accommodate these changes in bodily function, as seen in Case Example 50-1 about Joan.

Hematological Cancers

Hematological cancers consist of three major classes of stem cell diseases: leukemias, lymphomas, and multiple myeloma. As a group, these cancers comprise the fifth most

commonly occurring cancers and the second leading cause of cancer deaths in the United States (Hematological Cancer Research Investment and Education Act of 2001: S1094, 2002). More than 100,000 U.S. residents are diagnosed each year with blood cancers, and 60,000 people die annually. At any one time, about 700,000 individuals are living with blood cancers in the United States, and management of their cancers is a monumental task. Typically, patients diagnosed with blood cancers are managed by

CASE

EXAMPLE # 1

Joan: A Patient with Lung Cancer

Occupational Therapy Process

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Patient Information

Joan is a 60-year-old woman who has a history of metastatic lung cancer that was diagnosed 3 years ago. Prior to the diagnosis, she worked as a high-level manager with a premier telecommunications company; she retired after she was diagnosed with cancer.

The cancer was treated with chemotherapy and radiation. Most recently, she received whole-brain radiation to treat metastases in the brain. She has a history of liver metastases (mets), bilateral pleural effusions, and ascites (accumulation of fluid in the abdomen). She currently has mets to her lumbar spine, left ribs, left iliac crest, both femora, and her sacrum. She presents with fatigue, lymphedema, and decreased appetite.

Joan lives alone. She arrived for her appointment in the company of her brother, who lives about an hour from her in another community.

Understand the patient's diagnosis or condition

"Given the presence of brain and liver metastases, along with ascites and lymphedema, this cancer appears to be in advanced stages. Her doctor will not indicate her prognosis."

Know the person

"Joan's background indicates that she is someone who is used to being in control. She is also used to living alone, which might be compromised if she has any problems with self-care or mobility."

Reason for Referral to Occupational Therapy

Joan was referred to outpatient occupational therapy to assess her equipment needs.

Appreciate the context

"I wonder what equipment she might need and what she would be willing to accept. I will plan for possible wheelchair, bathroom equipment, and assistive devices for ADL; possibly other interventions are needed as well."

Develop provisional hypotheses

Assessment Process and Results

This setting uses a non-standardized, structured evaluation that includes measures of self-care, mobility, and sensorimotor and cognitive components and allows for interview.

Findings are noted as follows:

- Joan's chief complaints are lymphedema and difficulty with mobility and transfers. For example, she has difficulty getting in and out of her bed, the top of which is 28" from the floor; she has difficulty rising from the built-in shower bench she sits upon when she bathes; and she is unable to walk the length of her home without experiencing severe shortness of breath and fatigue.
- Her home and support system: Joan lives alone in a two-story home; her bedroom and bathroom are on the first floor. Doorways are wide for wheelchair accessibility, but the thresholds range in height from 3.5" to 6.0". Her shower has a 6" threshold, and there is a low built-in bench for her to sit on when she bathes. The shower walls are lined with marble, which she refuses to mar/modify. Her brother and her friends check on her regularly.

Consider evaluation approach and methods

"Using the center's evaluation lets me explore not just the problem that brought Joan to the clinic but also to make sure there are no other functional problems that might otherwise not be addressed. Time constraints may prevent selection of other standardized assessments."

Interpret observations

"Joan has a strong desire to remain in her home and to be safe there. We will have to work together within the boundaries of what she is willing to accept. She may accept ramps for thresholds to the outdoors, for example, but not grab bars in the shower. Will she accept a wheelchair?"

- Sensorimotor and cognitive capacities: Joan has a history of falls and has a call alert system. She rates her shortness of breath as 10/10 after activity. Her fatigue is 8/10 at rest and 10/10 after activity. Endurance is poor. She has no complaints of pain. Standing (static and dynamic) balance is impaired. She lacks approximately 50% of full ROM in both shoulders, her gross upper extremity strength ranges from 4 to 4–/5 (left weaker than right), and her grip strength is in the 25th percentile (35 lb on left; 40 lb on right). She has lymphedema in all extremities, and she has ascites. She complains of chemotherapy-induced neuropathy in both feet and is most comfortable walking bare-footed. Joan is cognitively intact.
- Self-care and home management: Joan is modified independent in most ADL and prefers to bathe with supervision. She has altered her clothing preference to accommodate limitations in upper/lower extremity dressing as well as the lymphedema and ascites, and she takes longer to perform self-care activities. She prepares meals in a microwave oven, “not doing normal cooking.” She requires assistance with housekeeping and grocery shopping. She has a dog that is staying with her brother, and she would like for her pet to return home if she could care for it and walk it. She enjoys doing needlepoint, reading, and gardening.
- Other: Joan lives in a community that is about an hour away from the medical center, and she is unwilling to come for outpatient treatment on a regular basis. She would be willing to come for 1–2 visits to plan for equipment.

Occupational Therapy Problem List

- Severe fatigue and poor endurance
- Limited mobility: getting in and out of bed, getting in and out of shower, moving about her home
- Needs wheelchair
- Consider home modifications

Synthesize results

“Besides problems with falling, her function is affected by severe fatigue and poor endurance. The lymphedema is not a problem that can be addressed; it is widespread, and there is no place for the fluid to go. The lymphedema limits her ROM. Distance and desire prevent her from attending many sessions, so treatment must be focused on issues and brief.”

Occupational Therapy Goal List

1. Joan will use adaptive equipment and assistive devices of her own choosing to move about her home with modified independence.
2. Joan will make changes in her daily routines to assure that she has adequate energy to complete desired activities.
3. Joan will identify acceptable home modifications to ensure her safety.

Develop intervention hypotheses

“Joan is cognitively able to grasp instruction in energy conservation and suggestions for home modification. She has her brother’s support to remain in her home safely.”

Select an intervention approach

“My intervention approach is based on the theory of Occupational Adaptation (Schkade & Schultz, 1992). The individual selects the activities and goals that are important to her, and my role is to facilitate her internal process. In this way, I can honor Joan’s autonomy and her ability to decide what is best for her by providing her sets of realistic choices.”

Consider what will occur in therapy, how often, and for how long

“In accordance with her wishes and goals, Joan will be seen for one to two visits, each lasting 1 hour, for the next 2 weeks.”

Intervention

- As part of the evaluation, Joan demonstrated the difficulty she had getting into and out of bed, which was fairly high. She and the occupational therapist used a hydraulic mat to simulate the bed height and were able to determine that a wide 6" high step would facilitate her mobility. Her brother constructed the step for her after the session. The occupational therapist also consulted with one of the staff physical therapists about using a standard walker with no wheels to step into and out of the shower and to help her rise from sitting on the built-in bench. After practicing, she purchased the walker as an out-of-pocket expense. Joan and her therapist reviewed principles of energy conservation, and the therapist provided her with written instructions about energy conservation.
- The occupational therapist arranged for an outside consulting occupational therapist to provide a "pro bono" home assessment. This occupational therapist visited her home between her outpatient sessions and also built a ramp for outdoor access.
- Joan would not accept a manual wheelchair, but she did accept powered mobility. At the last session, an assistive technology specialist worked with the occupational therapist to fit her in a power wheelchair. The occupational therapist drafted a letter of medical necessity, which was signed by the referring physician. Joan did accept a manual wheelchair as a "loaner" while she waited for the power wheelchair to be delivered.

Assess the patient's comprehension

"Joan clearly comprehended solutions and instructions. She provided directions regarding her needs to climb into and out of bed, which her brother could address. She offered her own strategies regarding energy conservation."

Understand what she is doing

"I was fortunate to be able to enlist the assistance of the outside consultant. We worked together to gain an appreciation of her home environment, and Joan appreciated his level of professionalism and service."

Compare actual to expected performance

"Joan viewed the powered wheelchair as a means of remaining independent in her home and in her community. Furthermore, it would not deplete her energy as a manual wheelchair would."

Know the person

Appreciate the context

Next Steps

Discontinue services.

Anticipate present and future patient concerns

"Joan felt that she had satisfactorily achieved her goals and expressed no other concerns. Her brother informed me that she died about 1 month after our visits. I canceled the power chair order, and the "loaner" chair was returned. Should I have ordered the power chair? I think so. First, her prognosis was not clear, and her doctor could not offer clarification. Second, she was able to accept an alternative arrangement that helped her to move around safely in her home. Finally, the diagnosis should not prevent me from facilitating the amelioration of an individual's quality of life."

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Building Rapport

Joan's case depicts a situation where the evaluation (and treatment) needs to be comprehensive yet focused. How does a clinician build rapport in such a short period of time? How can the clinician stay focused in his or her treatment?

multidisciplinary teams of health care professionals; occupational therapists are often key members of these treatment teams.

Hematopoiesis (blood formation) is an orderly biological process by which pluripotent stem cells form normal and mature blood cells including lymphocytes, granulo-

cytes, erythrocytes, and platelets (Weisman, 2000). With hematological cancers, abnormalities in cell signaling result in uncontrolled cell growth or division, followed by "arrested development" or poor differentiation of cells during the conversion of the stem cells into mature blood cells. These changes often result in an accumulation of im-

mature blood cells that cannot perform normal physiological functions of blood cells. In addition, the proliferation of one type of cell overwhelms the normal physiological functions of other cells, resulting in disease. The remainder of this discussion will focus on leukemia.

Leukemias are blood diseases originating in the blood-forming organs (Mandrell, 2004; Miller & Grodman, 2001). They can affect lymphocytes, white blood cells, red blood cells, or platelets. They are acute or chronic in nature. In acute leukemias, the cells fail to mature as they proliferate and infiltrate the bone marrow and other organs, particularly the lymph nodes, spleen, and liver, as well as the central nervous system (CNS) in some types of disease. In chronic leukemias, the cells proliferate, but they reach maturity and differentiate into distinct functional components (Mandrell, 2004; Miller & Grodman, 2001). The proliferation of cells still affects organs. Cell maturation and differentiation can continue for several years before a blast crisis (proliferation of cells that fail to mature) occurs.

In the case of acute leukemias, numerous symptoms can limit an individual's capacities and abilities. Anemia augments one's sense of fatigue and lack of activity tolerance due to poor endurance. Edema can occur that limits mobility. When cells infiltrate the bone marrow, the person may experience bone and joint pain or be at risk for pathologic fractures (Safety Note 50-1). When cells infiltrate the CNS, one's cognitive function may be affected. Susceptibility to infection and to bruising also affects functional capacities. With chronic leukemias, fatigue primarily affects individuals' functional capacities and abilities.

Sarcoma

As a collection of diseases, sarcomas include both soft tissue sarcomas and primary bone tumors. Of the two, soft tissue sarcomas are nearly four times more common (American Cancer Society, 2005), but they are rare in adults (Yasko et al., 2001). Soft tissue sarcomas include tumors that develop from fat, muscle, nerve, fibrous tissues surrounding joints, blood vessels, and deep skin tissues. Primary bone tumors arise from both bone and cartilage. Most sarcomas are found in the legs, but they can arise in any part of the body. According to Yasko et al. (2001), soft tumor sarcomas have no identified etiological factor, although some genetic conditions and previous treatment for cancer have been identified as predisposing factors. People who have either primary bone tumors or soft tissue sarcomas typically require the services of rehabilitation professionals during the course of treatment, particularly in the post-operative period.

The primary pathological basis of diminished capacities related to engagement in occupation for persons with sarcoma can be directly attributed to tumor growth at the primary site of disease and metastatic disease spread to secondary sites. Treatment of the disease itself can result

SAFETY NOTE 50-1

General Precautions in Treatment

- Before you enter a patient's room, read the chart and check with the patient's nurse to find out if any events or changes have occurred since your last visit.
- Practice universal precautions. You will protect the patient and prevent spread of infection to others.
- Be familiar with handling oncological emergencies (See Resource 50-1), and observe precautions as necessary. Categories of oncological emergencies include: obstructive/compressive, hematological/immune, metabolic, those related to increased pressure or fluid accumulation, and pathological fractures (Garrett & Kirchner, 1995; Hockett, 2004; Tatu, 2005). Although some of these conditions/emergencies may not prevent you from working with individuals who have cancer, you should know how to respond should one occur.
- Regarding the use of physical agent modalities:
 - Follow all standard precautions regarding their use.
 - Do NOT apply thermal or electrical modalities over areas of active or potential malignancies.
 - Avoid areas with altered skin integrity (i.e., radiation sites, graft vs. host disease, chemotherapy burns, etc.).
 - Inappropriate use of modalities may exacerbate conditions, such as lymphedema.
- Regarding the use of exercise:
 - Consider the impairment or condition. Aggressive exercise may be contraindicated, as in the presence of spinal cord compression, lymphedema, or pathologic fracture.
 - With myelosuppression, platelet counts are of concern. It IS safe to engage the patient in light ADL or to provide up to 5 lb of resistance when platelet counts are lower than 20 k/ μ L.
- When in doubt, consult with your clinical instructor or supervisor.

in a secondary pathological basis for diminished capacities in that it frequently alters body structures and/or functions to the point of disability.

Tumor growth, whether at the primary site or in the form of a metastatic lesion, will frequently result in weakened body structures. Primary and metastatic bone tumors, particularly **lytic** lesions, may weaken the bone to the point of pathological fracture. Tumor growth may also impair circulatory function, resulting in edema, and can compress nerves and invade muscle or joint structures, causing pain or altered sensory perception and limiting range of motion.

Effects of Treatment on Functional Capacities and Abilities

As noted earlier, not only do the various cancers affect individuals' functional capacities, but treatment for those cancers can also affect individuals' function and ability to engage in valued roles and activities. The course of treatment for different cancers can involve multiple modalities, such as surgery, chemotherapy, and/or radiation, as well as experimental therapies. These treatments occur at different intervals and present individuals with physical, cognitive, and emotional challenges. Treatment can lead to frequent disruptions of lifestyle and activities. Furthermore, cancer and its treatment generate feelings of uncertainty with regard to the future, which makes it difficult for some individuals to engage in planning daily activities and routines. Finally, in cases where the cancer is progressing or the treatment produces side effects, individuals experience progressive functional loss (Bertero, Eriksson, & Ek, 1997; Schumacher et al., 1998).

In general, people with cancers may present to the occupational therapy clinic with a myriad of somatic, cognitive, and psychosocial problems. Impairments that

impact the body's structures and functions can limit performance patterns and hinder performance in areas of occupation (American Occupational Therapy Association [AOTA], 2002). Chemotherapy-induced peripheral neuropathy can be extremely painful and limit mobility as well as hand dexterity. People may also display tremors following chemotherapy, which interfere with fine motor function. Radiation causes fibrosis (scarring of internal structures), which can limit movement and can sometimes impinge upon nerves to cause peripheral nerve injury (Cooper, 1998). Edema can occur independently of cancer treatment, while lymphedema is typically a sequela to surgery and/or radiation that involves one or more lymph nodes. Incidentally, lymphedema is a lifetime risk, and occupational therapists should seek training to provide specialized treatment (see Case Example 50-2). It is not uncommon to observe musculoskeletal changes, such as arthritis or arthropathy, fascial tightening, or frozen shoulder, in persons who undergo cancer treatment. Fatigue, pain, and nausea are frequent side effects of treatment.

CASE

EXAMPLE # 2

Mrs. K.: Assessing One's Clinical Competence

Occupational Therapy Intervention Process

Patient Information

Mrs. K. is a 50-year-old woman with a diagnosis of left post-mastectomy lymphedema with multiple infections and fibrosis. Mrs. K. underwent mastectomy for left breast cancer 15 months ago and had 20 of her lymph nodes removed on the left side. She had chemotherapy and irradiation and now shows no evidence of disease. She recently saw her oncologist with complaints of left upper extremity swelling and aching heaviness in the arm and across her chest and back. She reported difficulty with fit of clothing on the left, which causes her increasing embarrassment at work. Her sleep is also disturbed because of left arm discomfort. She is referred to outpatient occupational therapy for evaluation and treatment of lymphedema, including manual lymph drainage, compressive bandaging, fitting of custom compressive garments, and instruction in home exercises and skin care.

Clinical Reasoning Process

Objectives

Appreciate the context

Examples of Therapist's Internal Dialogue

"I wonder how much Mrs. K. knows about lymphedema and how to manage it. I wonder what kind of work she does along with other kinds of activities. Do any of these need to be modified in order to prevent recurrence of lymphedema once it is under control? Does Mrs. K. have a support system in place to which she can delegate tasks to prevent further exacerbation of the lymphedema?"

While the occupational therapist had previous experience treating cancer patients and instructing in self-care, home management, and work simplification strategies, she had no specific or specialized training in the area of lymphedema management. Because this new area of practice interested her, she searched the internet for information. She readily found information on lymphedema and its treatment (www.cancer.org) and guidelines for contacting a lymphedema treatment center, information about training programs, and names of clinicians with specialized training (www.lymphnet.org). She searched the National Library of Medicine (www.nlm.nih.gov) for abstracts of research regarding treatment of lymphedema.

Develop intervention hypotheses

Reflect on competence

“It appears that Mrs. K. needs a specialized form of intervention.”

“I am an occupational therapist working in a small physical disabilities setting at a suburban hospital in the Midwest. I have 5 years of experience, working in long-term care for 1 year and for 4 years in my present position. I typically work with both inpatients and outpatients, primarily with orthopedic or neurological problems. I am concerned that I don’t have the expertise that is required to perform the manual lymph drainage or the fitting for a compression garment in this case.”

Recommendations

Having some preliminary information, the occupational therapist used American Occupational Therapy Association Standards of Continuing Competence to assess her competence to treat Mrs. K. She concluded that she did not have the knowledge, critical reasoning, or performance skills necessary to assess and treat Mrs. K. She used information from her internet search to provide Mrs. K. with suggestions to help minimize the impact of lymphedema in her daily life and to refer Mrs. K. to another facility with specially trained therapists. She also decided to pursue training herself to make these services available to patients at her hospital.

Cognitive dysfunction is also a byproduct of cancer treatment. Patients who are in isolation sometimes experience the effects of sensory deprivation. In some, dysfunction manifests itself as impaired executive functions, slowed information processing, short attention spans, and impaired short-term memory. The symptoms may lead to social withdrawal. An occupational therapist might also observe altered safety awareness, judgment, and problem solving in some individuals. At times, cancer treatment can unmask underlying cognitive disorders, such as dementia, or neurological disorders, such as parkinsonism. Effects of treatment on psychosocial adjustment will be discussed later.

As one becomes more familiar with different types of cancer, one can begin to anticipate diagnosis- and treatment-related problems, just as one would with other conditions. For example, in the case of sarcoma, treatment-related changes to body structures may also limit engagement in occupation. Surgery may require amputation of all or part of an extremity. A limb salvage procedure, on the other hand, often results in significant, often lifelong, post-operative restrictions. Less invasive treatments for sarcoma, such as chemotherapy, are frequently associated with such symptoms as fatigue, nausea and vomiting, alopecia, and neutropenic fever related to anemia, leukopenia, and thrombocytopenia. Chemotherapy may also result in neurological changes such as hearing loss and peripheral neuropathy. External-beam radiation, a frequently used pre-operative treatment (Yasko et al.,

1997), may result in decreased elasticity of the skin or other soft tissues and in diminished or absent protective responses at the irradiated site.

EXPECTED COURSE OF RECOVERY (OR DECLINE)

The expected course of recovery depends on when cancer is detected and staged and on the individual’s response to treatment. Generally, the earlier the cancer is detected and treated, the better the prognosis is for the individual. Trends suggest that long-term survival is improving for many types of cancer (ACS, 2006).

Morbidity associated with cancer treatment can be debilitating if not addressed appropriately. One’s future ability to engage in occupation may be directly related to the intervention provided, and occupational therapists are instrumental in their understanding of the client factors that will influence performance. Unfortunately, stigma persists regarding the rehabilitation potential of cancer patients, which can subsequently limit their access to care. Pandey and Thomas (2001) identified the need to promote both physical and psychosocial rehabilitation for cancer patients while providing a comprehensive, multidisciplinary approach to prevent and treat disability. Occupational therapists need to be cognizant of their role in the rehabilitation of patients who have chronic conditions.

Lung Cancers

Lung cancers may be curable in early stages, but there is no effective screening method to detect them. They tend to be detected at advanced stages and have an overall 15% 5-year relative survival rate (ACS, 2006). Treatment of these cancers may entail surgery, chemotherapy, and/or radiation, which is determined by the type and stage of cancer and the goals of treatment (i.e., curative or **palliative**). People with lung cancer tend to be referred to occupational therapy to address quality-of-life issues related to maximizing performance in light of steady decline.

Hematological Cancers

People who have hematological cancers have periods of functional stability interspersed with varying rates of decline. Initially, they may attempt to remain engaged in areas of occupational performance, but immunosuppression, fatigue, and emotional distress may prevent them from doing so (Mandrell, 2004). This group of cancers has a 5-year relative survival rate of 49% (ACS, 2006). The trajectory of these cancers varies from person to person, depending upon exacerbations, type of treatment, and response to treatment. Leukemias are typically treated with multiple chemotherapies to induce and maintain remission or to reinduce remission should relapse occur. Following this course, the person may consider options for allogeneic (related or matched unrelated donor) bone marrow or peripheral-blood stem cell transplantation. Treatment can lead to debility, and people with hematological cancers benefit from rehabilitation and from interventions designed to facilitate psychosocial adjustment and activity planning.

Sarcoma

Sarcomas, too, can be cured if caught early. The 5-year survival rate for soft tissue sarcomas exceeds 90%. As previously discussed, the expected course of recovery is directly

related to the severity and extent of treatment required to achieve complete tumor removal (if possible). In the past, amputation was thought to be the only surgical treatment option. Recent studies, however, have shown no significant differences between 5-year survival rates of amputation versus limb salvage (Bacci et al., 2002; Veth et al., 2003).

Limb salvage is surgery that preserves, repairs, or reconstructs critical structures needed for limb function (Yasko et al., 1997). The typical rehabilitation period for limb salvage is longer than that for an amputated limb. In the long run, whether amputation or limb salvage is chosen, individuals typically resume engagement in occupation. For example, people with limb salvage and those with amputation reported high levels of return to driving, relatively high levels of employment and participation in sexual relations, and moderate levels of participation in sports (Table 50-1) (Refaat et al., 2002).

PSYCHOSOCIAL ADJUSTMENT ISSUES

Many people view their experience of cancer as life altering. Some use the diagnosis as a springboard for growth and development, regardless of outcome. Almost all the people that we have encountered in our practices have experienced psychosocial adjustment issues, and many of them note that intervention and support to help with the resolution of these issues is lacking among health care professionals. Occupational therapists are well-equipped to address these issues.

One of the most challenging issues that patients face is the loss of control (Bertero, Eriksson, & Ek, 1997; Schumacher et al., 1998). Cancer and its treatment disrupt performance patterns, leading to occupational deprivation and loss of valued routines and roles. Moreover, people report distress when they lose control of their bodily functions due to side effects of treatment, such as nausea, vomiting, and diarrhea. Changes in one's body—weight loss due to disease, weight gain due to the use of

Table 50-1. Percentages of People Returning to Occupational Function after Limb Amputation Versus Limb Salvage Associated with Sarcoma

Activity	Limb Amputation (%)	Limb Salvage (%)
Require device for ambulation	83	50
Employed	74	77
Able to drive	90	92
Engaging in sports	68	58
Participating in sexual relations	88	75

From Refaat et al., 2002.

steroids, hair loss—also affect one’s sense of well-being. Loss of control may induce a sense of helplessness and dependence, especially when one is unable to perform activities previously taken for granted or to meet role expectations. Some people express uncertainty about the future in light of disease progression and the frequency and effects of treatment.

Persons with cancer also experience disruption of their social and cultural contexts. They may be physically removed from their support systems should they have to seek treatment in a distant community, state, or country. The stigma of cancer or the perceived burden of care may result in the loss of key social supports or, conversely, in the person’s own social withdrawal. Finally, prolonged hospitalization, particularly when isolation is involved, may result in institutionalization, where the person becomes habituated to and dependent upon the hospital environment and fearful about leaving that environment.

Robinson et al. (1991) studied a group of 54 patients status post limb salvage to determine perceived quality of life and limb function 2 years after their procedure. The authors found that the most frequently reported deficit was decreased participation in leisure activities, an area of occupation frequently overlooked by clinicians working with cancer patients. Yet, the occupational therapist can facilitate psychosocial adjustment to changes in performance patterns by helping the client to identify alternative leisure opportunities and to develop the coping skills needed to deal with the reality of the expected outcomes of treatment.

Psychosocial adjustment certainly appears to be an area that needs attention. Nearly 25% of individuals studied after undergoing surgical treatment for sarcoma reported adjustment-related issues, such as depression, anxiety, sleep disturbance, need for pain medication, and diminished life satisfaction (Lane et al., 2001; Refaat et al., 2002). Procedures for Practice 50-1 provides further discussion about adjustment to loss.

MEMBERS OF THE TREATMENT TEAM AND THEIR ROLES

As with many diagnoses, the team involved in a person with cancer’s care can be extensive. The staff involved in a person’s care may vary according to the person’s specialized needs (Figs. 50-1 and 50-2). The individual with cancer and his or her support system constitute the core of the team. Family members or other caregivers are often the primary providers of routine care at home and, to some extent, while the person is hospitalized.

Nursing staff—registered nurses and licensed vocational nurses—are essential care providers when people are hospitalized. They are frequently the primary contact at all points of patient care in both the inpatient and outpatient

PROCEDURES FOR PRACTICE 50-1

Adjustment to Loss

Cancer, regardless of its type, treatment, or course, can result in loss. Many of those losses are obvious and often temporary, such as the physical changes due to chemotherapy treatment (i.e., hair loss or peripheral neuropathy). Other losses are permanent. They are not only physical, but they also affect one’s sense of identity. One’s sense of self or body image may be altered as a result of mastectomy, orchiectomy, or limb amputation/salvage. Additional losses may include a loss of locus of control, social isolation or withdrawal, role changes, and impaired or absent body functions.

Interventions aimed at facilitating the adjustment to loss are well documented and include strategies ranging from patient journaling (Smith et al., 2005) to teaching caregivers stress management techniques (Kurtz et al., 2005). Some research suggests that a younger age at diagnosis is predictive of better long-term adjustment (Schroevers, Ranchor, & Sanderman, 2004).

Adjustment to loss is an important consideration for any occupational therapist working with the person who has cancer. Carver (2005) describes individuals as “goal-seeking beings whose efforts toward desired outcomes are threatened by diagnosis and treatment of cancer” (p. 2602). Carver believes that adaptation allows a person to remain engaged in the pursuits that form his or her life. Loss, however, is not only perceived by the individual diagnosed with cancer, but also by family, friends, and caregivers, and the occupational therapist must consider this when planning treatment.

settings. A wound, ostomy, and continence nurse (WOCN) may be consulted to address wound care concerns and educate care providers in the management of poorly healing sores, incision sites, and ostomy sites. The certified nursing assistant attends to the day-to-day care of patients and as-

Figure 50-1 A patient with leukemia and her rehabilitation team.

Figure 50-2 Patient-generated occupational therapy project to engage other patients.

sists them with many self-care tasks, including bathing and dressing.

Physicians tend to specialize in specific treatment domains, such as neurology, orthopedics, cardiopulmonary, physiology, and psychiatry. Other specialists include the following. Pathologists determine the type, stage, and grade of cancer. Medical oncologists direct the treatment of primary disease. Surgical oncologists treat cancer by resecting tumors and reconstructing damaged sites. Radiation oncologists design and implement high-energy radiation to treat cancer. Pain and palliative care specialists manage symptoms related to cancer and its treatment, and often help the individual and his or her support system to deal with end-of-life issues and transitions.

In addition to occupational therapists, physical therapists, and speech and language pathologists, professionals in other services may be consulted during the course of an individual's treatment. These may include orthotists or prosthetists, audiologists, case managers, chaplains, child life and young adult specialists, dieticians, massage therapists, music therapists, patient advocates, nurse practitioners, physician assistants, neuropsychologists, respiratory therapists, and social workers.

Finally, volunteers, particularly those who are cancer survivors, are vital partners of the medical team. They

serve as friendly visitors in some instances, and as peer counselors and support group leaders in others. They help meet the needs of current patients through numerous hospital- or community-sponsored programs.

All team members are advised to recognize and try to prevent burnout so that they may best serve their patients (Procedures for Practice 50-2).

OVERVIEW OF OCCUPATIONAL THERAPY EVALUATION AND INTERVENTION PROCESS

Ideally, occupational therapy evaluation and treatment are guided by models of practice and evidence-based guidelines. A top-down approach allows the therapist and client to identify meaningful roles, levels of competency, and levels of satisfaction in carrying out the tasks and activities that support these roles. The therapist and client also identify the contexts in which valued roles are enacted. The client defines his or her values, goals, and quality of life.

Individuals with cancer have complex needs and priorities that can change, sometimes rapidly, depending on severity of illness, response to treatment, stage of cancer, stage of treatment, and so forth. The diversity of cancers and treatment regimens makes it challenging to establish definitive guidelines for practice. It is essential to continually reevaluate the client's performance, adaptation, goals, and plan of care.

Occupational Therapy Evaluation

Occupational therapists can establish rapport with a client by addressing immediate needs and by understanding who this person is, was, and wants to be through his or her narrative. The type of assessment chosen and the length of the evaluation process depend upon the individual's medical and cognitive status. Information can be collected from significant others, team members, and chart review. The clinician needs to understand the client's medical history, previous responses to and side effects of treatments, prognosis, and the current and potential impact of the disease and treatment on performance areas. In addition, precautions, such as immunosuppression, thrombocytopenia, isolation (to prevent exposure to vancomycin-resistant *Enterococcus*, *Clostridium difficile*, fungoides, etc.), and anemia should be noted because these factors impact functioning and occupational therapy treatment.

The *Canadian Occupational Performance Measure* (Law et al., 1998) and the *Occupational Performance History Interview II* (Kielhofner et al., 1998) are occupation-based assessments that facilitate identification of a client's sense of

PROCEDURES FOR PRACTICE 50-2

Recognizing and Preventing Burnout

Health care providers who specialize in oncology are susceptible to chronic work-related stress and resulting burnout. Burnout is a syndrome identified by three components: emotional exhaustion, depersonalization, and diminished feelings of personal accomplishment. The 22-item *Maslach Burnout Inventory–Human Services Survey (MBI-HSS)* is commonly used to assess burnout (Chopra, Sotile, & Sotile, 2004; Maslach, Schaufeli, & Leiter, 2001).

Burnout is a function of both individual and contextual factors. Individual factors include one's personality traits, attitudes, and perceptions, such as locus of control and sense of mastery. Maslach and Leiter (1997) identified workload, control, reward or recognition, community, fairness, and values as six contextual factors that, when mismatched with the individual, contribute to burnout. Other contextual factors contributing to burnout in oncology include exposure to issues of death and dying; patients' emotional distress; conflict between curative goals of medicine, patients' prognosis, and the functional desires and goals of the patient and therapist; and exposure to the sometimes painful, debilitating, and disfiguring consequences of medical treatment. In short, occupational therapists can themselves be traumatized when working with medically traumatized patients.

Symptoms of burnout may include somatic complaints (e.g., headaches, joint pain, etc.), withdrawal behaviors, lack of creativity, and decreased quality of care. Burnout can also be related to major depression. It is important to

differentiate between burnout and depression. Honest self-reflection is essential to the identification of risk factors for burnout and implementation of prevention strategies. Health professionals can implement the following strategies to prevent burnout:

- Balance in all occupational performance areas
- Rejuvenation through meaningful activity
- Creation of support structures within the work environment to address boundaries and provide emotional support
- Incorporation of pacing and break times at work
- Time off to reflect on values and priorities
- Time management strategies
- Relaxation techniques
- Humor
- Grief work
- Development of support systems outside of work (Brachtesende, 2004; Lyckholm, 2001)

Occupational therapy espouses life balance and engagement in meaningful activity. Occupational therapists are well versed in stress management strategies and adaptive coping, and they routinely use prevention strategies, such as those mentioned above, with their patients (Painter et al., 2003). The challenge then is for occupational therapists to routinely use these strategies with themselves.

self-efficacy and self-esteem, as well as satisfaction with life roles in self-maintenance, self-advancement, and self-enhancement. Observing clients as they perform tasks and activities provides information about performance levels, abilities, and habits. Other assessments may be indicated to determine limiting factors and underlying reasons for diminished ability to meet activity demands.

Individuals' motor, process, and/or communication performance skills may be affected by the side effects of treatment or by the effects of primary tumor or metastases. Assessment of these skills and of specific client factors (AOTA, 2002), such as mental functions, sensory functions and pain, neuromusculoskeletal and movement-related functions, skin and related structures, and cardiovascular, hematological, immunological, and respiratory system functions may be warranted. Specific assessments of performance skills and client factors have been described in detail in other chapters of this text. Some instruments that have been developed to monitor cancer-related symptoms and the effects of cancer on quality of life are described here.

Fatigue is the most common problem reported by individuals with cancer. The *Brief Fatigue Inventory* (Mendoza et al., 1999) provides a quick assessment of the severity of fatigue and its impact on daily function. Cleeland et al. (2000) also developed a global symptoms assessment, the *M. D. Anderson Symptom Inventory*, which measures the severity of many cancer-related symptoms and the degree to which they interfere with daily function. Either of these tools can be used routinely to monitor changes in the individual's status, side effects of treatment, and effectiveness of rehabilitation.

The *Functional Assessment of Cancer Therapy (FACT)* measures quality of life in persons undergoing cancer treatment (Cella et al., 1993). Several versions have been developed that are specific to different types of cancer. As clinicians develop their practice in oncology or with people who have other challenging conditions, they might consider incorporating instruments that measure psychosocial factors, such as locus of control, meaning-making, self-efficacy, or hope, into their repertoires. Finally, assessment should include exploration of the social

support that is available as well as environmental barriers and supports.

Goals and Moderating Variables that Affect Realistic Goal Setting across the Continuum of Care

The goal of therapy is to enable clients to optimize their quality of life by engaging in meaningful occupations and to facilitate living regardless of life expectancy. Many of the goals that are meaningful to the client who has cancer are the same as those encountered with persons who have other diagnoses. With cancer, however, distinct moderating variables may affect realistic goal setting. People with cancer experience rapid changes in medical and functional status across the continuum of care. It is sometimes difficult for the person and the therapist to determine how permanent these changes might be. The severity of the disease and the individual's expectations regarding function and recovery may be incongruous. The occupational therapist should continually monitor these changes and help the individual to modify valued goals and roles accordingly. At the same time, the therapist must walk a fine line to avoid dispelling hope.

The role of the occupational therapist varies according to the point at which he or she enters the patient's course of treatment. Duration of treatment depends on acuity of the condition and severity of the disease, along with the patient's wishes. Regardless, the treatment plan should be individualized and address the performance skills required to function at that point in the continuum of care.

In cases where surgery is involved, pre-operative goals typically focus on facilitating continued engagement in activities by managing or compensating for the side effects of treatment. Energy conservation, fatigue management, and exercise are common strategies aimed at improving the ability to manage daily life despite the side effects of chemotherapy and/or radiation. Another important aim of early treatment is to identify the performance patterns that may be altered by future medical treatment. Post-operatively, the therapist and patient generally focus on increasing independence in activities of daily living (ADLs) and instrumental activities of daily living (IADLs). Decreased performance skills related to changes in body structures can make engagement in these activities quite difficult. As the person becomes able or in the outpatient setting, treatment shifts to focus on social participation.

In the post-operative period, the therapist should also address the psychosocial factors related to altered body structures and/or body functions. It may be necessary to

assist the patient in understanding the realistic expectations for functional recovery as a result of the procedure and to help him or her identify methods of coping with these changes.

The patient's long-term goals should guide him or her toward resuming activities such as work, driving, leisure, social interaction, play, and education. Although some procedures may permanently restrict the activities of some patients, most patients are able to resume normal activities with few, if any, long-term restrictions. Similar goals may be considered for patients who do not undergo surgery. The various cancers and their treatment have similar impacts on function and body image.

Occupational Therapy Intervention

The types of intervention that occupational therapists employ with individuals who have cancer do not differ much from those used with persons who have other conditions. Interventions focus on promoting health in the face of disease; restoring performance skills and patterns; preventing disability; modifying contexts, activity demands, or performance patterns; and providing supports that help patients maintain function (AOTA, 2002). Thus, interventions include fatigue management and energy conservation; sensory reeducation or desensitization; wheelchair seating and positioning; scar management, including fibrosis; conditioning (endurance, range of motion, and strengthening); and fall prevention and other activities to promote home safety. Some interventions, such as physical agent modalities (see Safety Note 50-1) or lymphedema management, require specialized training (see Case Example 50-2 on clinical competence).

Occupational therapists also provide cognitive intervention, as warranted by specific problems. Intervention can address psychosocial issues, such as caregiver concerns regarding the activities of caregiving, stress and anxiety management, relaxation techniques, and pain management. Occupational therapists may be called upon to provide interventions at the end of a person's life, as exemplified by referrals from palliative care physicians during a person's advanced stages of cancer. Even at the end of life, some people struggle to remain productive, and occupational therapists can help these people plan and engage in realistic levels of activity. Furthermore, the use of purposeful activity can facilitate closure to the relationship between the person who is dying and members of his or her support system.

In all phases of intervention, one needs to be able to clearly articulate the rationale for the intervention. To do this, it may be helpful to adopt a stance that rehabilitation is helpful even with declining patients (Procedures for Practice 50-3).

PROCEDURES FOR PRACTICE 50-3

Reframing a Mindset for Rehabilitation with Declining Patients

There has been discussion about the rationale for treating people who have progressive and degenerative disease processes. With some diagnoses, such as neurodegenerative diseases, health care professionals have adopted the stance that these are chronic conditions with periods of remission, relapse, and progression. Cancers, too, can be viewed in a similar manner. Thus people with cancer have different occupational needs throughout the trajectory of the disease and treatment process.

Some of the factors that compel one to consider treating cancers as chronic conditions are:

- Public awareness campaigns promote screening and prevention of certain cancers.
- For some cancers, medical treatment has advanced, introducing hormonal therapies, biotherapies, tumor vaccines, and innovative surgical techniques.
- More people are achieving 5-year survival, from 50% relative survival in 1974–1976 to 65% in 1995–2001 (ACS, 2006).
- There is greater interest in studying and promoting health-related quality of life in persons with cancer.

Furthermore, disease and the treatment of disease can adversely affect people's function and participation in valued roles and activities:

- Treatment frequency and side effects can cause frequent disruptions of lifestyle and activities.

- Disease progression and/or side effects of treatment can cause progressive functional loss at varying rates.
- Psychologically, people experience uncertainty about the future, potential relapse, and/or death.

To cultivate a mindset for rehabilitation with declining patients, it is important for occupational therapists to:

- Recognize that, although medical treatment can deplete a person's energy during hospitalization, the person will recover some (not necessarily all) energy as blood counts recover
- Be aware that individuals with cancer may have phases of decline and then stabilization, where realistic activity planning, focused on short-term aspects of function and quality of life, can be facilitated by an occupational therapist
- Recognize that, even at the end of life, many people with cancer wish to engage in occupations, however limited
- Become aware of their feelings about their clients' adjustment to loss and about death and dying
- Keep in mind a goal of rehabilitation for persons with cancer, stated by Cheville (2001): "While rehabilitation cannot eliminate cancer's assaults on functional autonomy, it can certainly attenuate and decelerate them. It can also engage patients and families in constructive purpose such that functional decline is not experienced as helplessness" (p. 1040)

EVIDENCE FOR OUTCOMES OF REHABILITATION

Although the evidence supporting rehabilitation of the cancer patient is limited when compared to other diagnoses, what evidence exists supports its efficacy when used with this population. Most of the identified research focuses on quality of life and does not identify the specific aspects of rehabilitation that led to its improvement. Some authors, however, have described the impact of specific interventions on functional outcome. The

evidence is, in some cases, qualitative in nature. Evidence Table 50-1 includes an example of literature that comes from outside of occupational therapy and two studies by occupational therapists. Until more evidence is generated by occupational therapists, studies generated outside the profession should be examined, including studies by psychosocial and behavioral scientists, physicians, nurses, exercise physiologists, and physical therapists. The problem with such studies is that the unique perspective of occupational therapy is missing, and the clinician must add his or her own interpretation to the findings.

Evidence Table 50-1 Best Evidence for Occupational Therapy Practice Regarding Cancer

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Fatigue	Aerobic exercise (stationary bike) vs. progressive relaxation.	72 post-operative lung cancer (n = 27) and gastrointestinal cancer (n = 42) patients.	Aerobic exercise group: 30 minutes, 5 times a week; relaxation group: 45 minutes, 3 times a week; both for 3 weeks.	Randomized comparison group study. IA2a	Both groups reported similar improvements in fatigue; no difference between interventions; exercise group improved physical performance.	Fatigue rating (<i>European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core Module</i>): Exercise group improved 21%, $p = 0.01$; relaxation group improved 19%, $p = 0.01$. No difference between groups: $p = 0.67$.	Dimeo et al., 2004
Treatments used with patients with breast cancer	Survey of assessments, intervention, and time allocation.	5 occupational therapists at 2 sites, treating patients with breast cancer; interventions with 35 women recorded.	Log sheet completed daily for 1 month.	Survey (design not rated). A3c	Treatment is individualized. Most common interventions: educational program, support groups; relaxation training; wheelchair assessment and provision; transfer training; and equipment provision.	Descriptive study; unable to calculate.	Vockins, 2004
Treatment of brachial plexopathy	Activity modification using assistive devices; environmental modification (offered but declined).	One 67-year-old woman, treated for breast cancer with mastectomy and radiation 12 years prior to intervention under study.	Documentation of assessment and treatment.	Narrative case study. VC3c	Treatment is based on client's values; individualized due to nature of condition.	Narrative study; unable to calculate.	Cooper, 1998

SUMMARY REVIEW QUESTIONS

1. At what points in the care continuum might patients be referred to occupational therapy?
2. What issues might arise for patients regarding loss or loss of control during the course of their cancer experience?
3. How does loss of control affect a person's role and occupational performance?
4. The clinician is working with a person who has been treated with limb salvage for sarcoma. What general safety precautions should he or she be aware of? Would the application of physical agent modalities be appropriate? Justify.
5. What presenting symptoms would a clinician expect in a person who has acute leukemia? How might these symptoms affect occupational performance?
6. In what ways, if any, do symptoms and occupational performance in a person with lung cancer differ from those in a person with sarcoma? From those in a person with leukemia?
7. Discuss three interventions used by occupational therapists in cancer settings, and describe how they are used to improve occupational functioning.
8. How might a clinician best address patients' fatigue?
9. Based on the boxes and references in this chapter, what three resources might you use to improve the quality of the care you would offer to a person who has cancer?
10. In your opinion, what is the unique perspective that occupational therapy can add to the evidence regarding treatment effectiveness?

ACKNOWLEDGMENT

We wish to acknowledge and thank our patients, who have courageously shared their life experiences with us, and our students, who strive to master the complexities of practice. Both of these groups helped us to realize the importance of sharing more information about the role of occupational therapy in cancer care.
