vention plan. Ecological models provide a framework for practice but do not provide specific guidelines or theory about specific assessments or intervention techniques. However, the selection of practice models should be faithful to the values of the ecological models. Mostly, this means that the practice models that are used to guide assessment and intervention cannot be limited to person and occupational factors but most address the environment as well. The dynamic nature of the ecological models indicates that situations are constantly changing. Taking this change into account means that regular reevaluation should occur.

The five intervention options proposed by the EHP model require occupational therapists to utilize a wide range of intervention approaches. Intervention can take many directions, and those interventions that target the environment should always be considered as one option. Furthermore, occupational therapy practice is not limited to existing problems but includes enhancing occupational performance and prevention of occupational performance problems. The association of ecological models with disability rights means that occupational therapists should also be involved at the systems level, supporting policy that promotes full participation in all aspects of community life.

CASE STUDY: *The Asbury Café*

The Asbury Café is an employment program developed by the author. The Asbury Café operates every Wednesday night at a local church. Five individuals with serious mental illness are employees of the café. A meal is served at a reasonable cost for church members, neighbors, and friends. An occupational therapist oversees the running of the café, assisted by volunteers and college students. It is an example of a program that utilizes the principles of the ecological models to promote work performance for people with psychiatric disabilities. However, that is just one of the aims of the program, which on a larger scale aspires to make changes in social and cultural environments to reduce the stigma associated with serious mental illness. People with serious mental illness are frequently depicted in the media as dangerous, peculiar, and in need of care and protection.

Although serious mental illness is common, many people do not disclose their diagnosis because of the associated stigma. The Asbury Café provides an opportunity for people with and without mental illness to come together and interact in a positive environment (Figure 43.4).

The first aim of the program is to provide employment to individuals with psychiatric disabilities. Individuals who are referred by the vocational team to this work site are typically individuals who have less work experience, have more overt symptomatology, and need more extensive adaptations to the work environment. No formal assessments are completed; however, extensive skilled observation and task analysis are used to match employees with tasks and to make adaptations to the task and environment.

TARGET AREA OF OCCUPATIONAL PERFORMANCE: WORK

Ecological Model Components	Interventions
Person Factors	
Individuals with serious mental illness often have cognitive impairments that slow information processing and interfere with learning of the job tasks.	Establish/restore: Provide simple instructions with demonstration, models, and regular feedback. Alter: Match worker with café task that best meets the person's interests and abilities. Adapt: Pair workers so that one with stronger skills can model, help focus, and provide feedback to the worker with developing skills.
Psychiatric symptoms such as anxiety and auditory hallucinations can make it more challenging to focus work tasks.	Establish/restore: Teach the worker individual strategies to use when feeling anxious (e.g., deep breathing) or experiencing hallucinations (e.g., talk aloud to others). Adapt: Allow for frequent breaks, set up an environment of acceptance and support, use the environment to create distractions from hallucinations or worries.
Environmental Factors	
Fewer job opportunities are available to the employees the café in the neighborhoods where they live, and typical work sites do not offer the limited schedule needed and desired by current employees.	Adapt: The full Asbury Café program is an adapt strategy. Supervisors and volunteers have experience in mental health services. Employees at the café are individuals who need more extensive supports for successful work performance.
Employees at the café do not have cars, and no public transportation is available to the work location.	Adapt: Although this is not ideal, the mental health center provides transportation.
Occupation	
The major occupation is work is in the area of meal preparation, serving, and cleanup. Each task has many subcomponents.	Adapt: The tasks are often adapted so that there are fewer steps, or one task is done by two or three people so that the full task is not too difficult for an individual. Alter: Over time, the best matches become known, and individual workers assume responsibility for their tasks. They are able to perform these tasks without assistance or oversight.

CASE STUDY: *The Asbury Café*   *Continued*

The second purpose of the Asbury Café is to reduce the stigma associated with serious mental illness by promoting positive social interactions between people with and without mental illness.

TARGET AREA OF OCCUPATIONAL PERFORMANCE: SOCIAL INTERACTION

Ecological Model Components	Interventions
Person Factors	
Many of the customers at the café have limited exposure to individuals with serious mental illness.	Alter: Employees with mental illness are assigned work tasks so that they have opportunities to interact directly with the café customers (taking money, serving meals). Employees with mental illness are also assigned work tasks that require regular contact with church staff. This provides an opportunity for real work relationships to develop.
Environmental Factors	
Our culture tends to portray individuals with serious mental illness as dangerous, unpredictable, and in need of protection. Yet the church is an environment that is open to accepting diverse individuals and welcomes the program.	Establish/restore: Educational opportunities are provided through the church in the form of lectures, articles in the newsletter, and presentations by consumers of the mental health center to provide accurate information to potential café customers about serious mental illness. Adapt: The program director and volunteers create an environment that models positive interactions with individuals with serious mental illness (e.g., avoiding distinguishing between those who do and do not have mental illness; in addition to working alongside one another, also socializing together during breaks)
Occupation	
Eating together socially	Alter: The Asbury Café provides a naturally occurring opportunity for people to socialize in a natural setting. The café workers, supervisor, and volunteers eat during the time when the customers are eating so that there are more times for interaction.

The Asbury Café demonstrates how occupational therapy can have an impact outside of a traditional service setting. The café is true to the values of the ecological models, which emphasize client-centered practice and full participation in community life. The program enhances occupational performance in the areas of work and social interaction by providing interventions targeting the person, environment, and occupation. The program itself is designed to change the stigmatizing social and cultural environment that is currently so pervasive for people with serious mental illness.

EVIDENCE SUPPORTING THE ECOLOGICAL MODELS

Studies indicating a relationship between environment and occupational performance provide support for the ecological models. Occupational therapists are conducting more and more research in this area. For example, children with disabilities and their families identified physical, social, cultural, and institutional barriers as limiting transition to adulthood (Law et al., 1999). In a study of independence and employment for people with AIDS, environmental factors presented significant barriers to occupational performance (Paul-Ward, Kielhofner, Braveman, & Levin, 2005). One of the greatest barriers to independent living was the lack of low-income housing. Barriers to employment included procedures related

FIGURE 43.4 Jess and Janet at the Asbury Café. (Courtesy of C. Brown)

to social security benefits and stigma by employers. A qualitative study of the home environment for people with physical disabilities found that social support was a major factor in overcoming impairments and inaccessibility in the home (Lund & Nygard, 2004). Time use was affected by the availability of support from others, and these individuals often spend much time waiting for others before they can engage in a desired occupation. Another study found that the home can present physical environmental barriers for stroke survivors (Reid, 2004). For the most part, the stroke survivors were able to engage in desired occupations; however, getting through doorways and up and down stairs was difficult. Uneven ground outside the home was also a problem.

There are several examples of research that support the efficacy of occupational therapy interventions with an ecological basis. Some of these interventions were intentionally designed by using one of the ecological models, while others utilize the environment in the intervention approach. Brown, Rempfer, and Hamera (2002) used the EHP model as a conceptual framework to develop a grocery shopping intervention for people with schizophrenia. In the intervention, participants were taught strategies to better use the naturally occurring environmental features of the grocery store (e.g., overhead signs, generic products). The intervention was effective in improving grocery shopping accuracy and efficiency. The PEO model was used to develop a peer mentorship program for adolescents and young adults with physical disabilities (Stewart, 2003). The peer support of the mentorship program resulted in greater exploration of the self and the environment. This included an increased desire to try new things, socialize with others, and get out in the community. The Environmental Skill Building Program (ESP) (Corcoran et al., 2002), based on environmental press theory, incorporates environmental strategies to promote adaptive behavior in individuals with dementia. In ESP, the therapist works with a caregiver to adapt the home environment and teach inter-

action strategies. In a randomized controlled trial, caregivers who received the intervention were less upset with disruptive behaviors, had better affect, and had better overall well-being (Gitlin et al., 2003). Another study considered the social environment as a factor in play skill development (Tanta, Deitz, White, & Billingsley, 2005). Using a single subject design, preschool children with delayed play skills were paired with children who had a lower developmental play skills and a peer with a higher development play skills. The children with delayed play skills were more likely to initiate play and respond to the peer when paired with the child with higher play skills.

This growing body of research provides support for the impact of the environment on occupational performance. In particular, the research provides information about which specific environmental factors are the most important for a specific occupational performance for a specific group of people, again emphasizing the uniqueness of each situation. Therefore, as research provides occupational therapists with more specific information about environments, occupational therapists can design more relevant interventions.

CONCLUSION

Occupational therapy practice is aimed at promoting occupational performance. Ecological models provide a framework for understanding the multiplicity of factors that must be taken into account in assessing and providing interventions to enhance occupational performance. These models require that the occupational therapist use a client-centered approach and always consider the importance of the environment in the occupational therapy process.

PROVOCATIVE QUESTIONS

1. What are additional examples of interventions an occupational therapist might make to help support the goals of the Asbury Café? Do the interventions that you selected most often target changes in the person, changes in the environment, or making a person-environment match?
2. Can you think of ways in which the Asbury Café might interfere with its own goals? For example, might the Asbury Café interfere with its employees' future employment goals? Could the Asbury Café reinforce existing prejudices?
3. What are the features of this intervention that demonstrate the strengths of using an ecological approach?
4. If you wanted to duplicate the Asbury Café in your community, what affordances and barriers would you need to consider. How would you use the affordances? How would you address the barriers?
5. Using the Asbury Café as a model, apply EHP to describe another intervention that would address the needs of clients with mental illness and aim to reduce stigma in your community.

The Model of Human Occupation

GARY KIELHOFNER, KIRSTY FORSYTH, JESSICA M. KRAMER, JANE MELTON, AND EMMA DOBSON

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the major personal factors addressed by the Model of Human Occupation and articulate how each concept affects occupational life.
2. Describe the major environmental factors that are addressed by the Model of Human Occupation and articulate how each concept affects occupational life.
3. Identify the three levels that the Model of Human Occupation uses to describe and examine what a person does.
4. Describe the six steps of therapeutic reasoning in the Model of Human Occupation.
5. Articulate how change occurs in occupational therapy and identify client actions and therapeutic strategies that lead to change.
6. Describe how the Model of Human Occupation can be applied to clients with a variety of diagnoses across the life course in different practice contexts.

Betty is 82 years old. She was admitted to the hospital following a fall at home in which she fractured the neck of her femur. After surgery and two days in acute care, she was transferred to a skilled nursing facility (SNF), where she was to receive occupational therapy.

Lin is a 3-year, 6-month-old boy with a seizure disorder/epilepsy, hydrocephalus, hypotonia, and profound mental retardation. He has several seizures a day, eats a restricted pureed food diet in addition to receiving nutrition through a g-tube, and fatigues easily. During a special education interdisciplinary educational placement meeting, Lin's parents identified that their main goal was that Lin be able to accept food more easily.

Each of these clients' occupational therapy practitioners chose to use the Model of Human Occupation (MOHO) to guide their intervention. In

the course of the chapter, these cases will be used to illustrate the theory and application of this model.

INTRODUCTION

MOHO was introduced nearly three decades ago by three practitioners seeking to articulate an approach to occupation-based intervention. They described MOHO as a theory to guide thinking about clients and the therapy process (Kielhofner, 1980a, 1980b; Kielhofner & Burke, 1980; Kielhofner, Burke, & Heard, 1980). Evidence indicates that MOHO is now the most widely used occupation-based model in practice worldwide (Haglund, Ekbladh, Thorell, & Hallberg, 2000; Law & McColl, 1989; National Board for Certification in Occupational Therapy, 2004; Wilkeby, Pierre, & Archenholtz, 2006). A national study of occupational therapists in the United States (Lee, Taylor, Kielhofner, & Fisher, in press) indi-

cated that 75.7% of therapists make use of MOHO in their practice. These therapists reported that MOHO allows them to have an occupation-focused practice and a clearer professional identity. They also reported that MOHO provides a holistic view of clients, supports client-centered practice, and provides a useful structure for intervention planning.

MOHO has been developed through the efforts of an international community of scholars and practitioners. It is supported by a substantial evidence base of well over 400 articles and chapters that present theoretical, applied, or research aspects of MOHO. A current bibliography of this literature is maintained on the Website www.moho.uic.edu. The most comprehensive and authoritative discussion of MOHO is the book *A Model of Human Occupation: Theory and Application,* which is now in its fourth edition (Kielhofner, 2007). This chapter provides a brief overview of this model's focus, theory, and resources for application in practice.

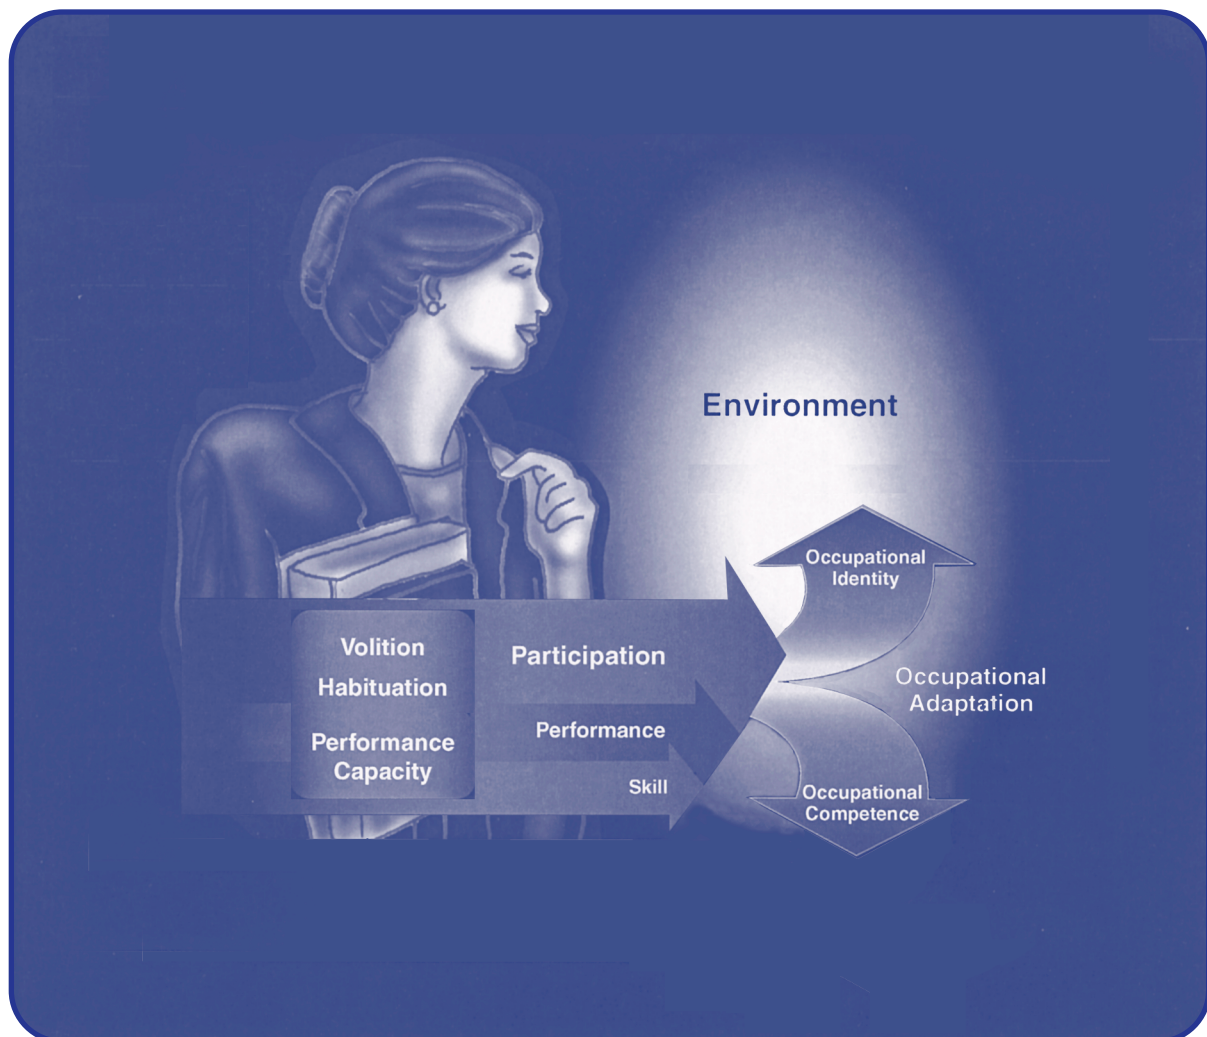

FIGURE 44.1   MOHO concepts. (Reprinted with permission from Kielhofner, 2007.)

THE FOCUS OF THE MODEL OF HUMAN OCCUPATION

This model emerged at a time when the field was just beginning to rediscover the importance of occupation as an outcome and means of intervention. In the 1970s, when MOHO was being formulated as an approach to practice, most occupational therapy theory and practice focused on understanding and reducing impairment. The impetus for developing MOHO was the recognition that many factors beyond motor, cognitive, and sensory impairments contribute to difficulties in everyday occupation. These include barriers posed by the physical and social environment, difficulties in choosing and finding meaning in occupations, and the challenge of maintaining positive involvement in life roles and routines. MOHO was developed to address these factors.

Consequently, the concepts that make up the theory of this model address the motivation for occupation, the routine patterning of occupations, the nature of skilled performance, and the influence of environment on occupation. These concepts seek not only to offer explanations of these factors, but also to provide a framework for gathering data about a client's circumstances, generating an understanding of the client's occupational strengths and limitations, and selecting and implementing a course of occupational therapy. A wide range of assessments and intervention strategies that correspond to the concepts of this model have also been developed to support practice. MOHO can be applied to clients with a wide range of impairments (physical, mental, cognitive, and sensory) throughout the life course. MOHO can also used in many types of intervention settings.

THE MODEL OF HUMAN OCCUPATION CONCEPTS

The Model of Human Occupation is ultimately concerned with the extent to which individuals can participate in life occupations and achieve a state of positive adaptation (Figure 44.1). The model begins with the idea that a person's inner characteristics and external environment are linked together into a dynamic whole. Moreover, the model asserts that inner capacities, motives, and patterns of performance are maintained and changed through engagement in occupations. MOHO conceptualizes occupational therapy as a process in which practitioners support client engagement in occupations in order to shape the clients' abilities, their routine ways of doing things, and their thoughts and feelings about themselves.

MOHO Concepts Related to the Person

To explain how occupations are chosen, patterned, and performed, MOHO conceptualizes people as composed of three interacting elements: volition, habituation, and performance capacity. The sections that follow will discuss these elements.

Volition

Volition refers to the process by which people are motivated toward and choose what activities they do. The concept of volition asserts that all humans have a desire to engage in occupations and that this desire is shaped by previous experiences. Volition consists of thoughts and feelings that occur in a cycle of anticipating possibilities for doing, choosing what to do, experiencing what one does, and subsequent interpretation of the experience. These thoughts and feelings are concerned with three issues: how capable and effective one feels, what one holds as important, and what one finds enjoyable and satisfying. They are referred to as personal causation, values, and **interests**.

Personal causation refers to thoughts and feelings about one's capacities and effectiveness that people have as they do everyday activities. These include, for example, recognizing one's strengths and weaknesses, feeling confident or anxious when faced with a task, and reflecting on how well one did after doing something.

Values are beliefs and commitments about what is good, right, and important to do. They include thoughts and feelings about activities that are worth doing, beliefs about the proper way to complete those activities, and the meanings that are ascribed to things one does. Values specify what is worth doing, how to perform, and what goals or aspirations deserve commitment. People experience a sense of correctness and belonging when they engage in activities that enact their values.

Interests are generated through the experience of pleasure and satisfaction in occupation. Interests begin with natural dispositions (e.g., the tendency to enjoy physical or intellectual activity). They further develop through the experience of pleasure and satisfaction derived from occupational engagement (Matsutsuyu, 1969). Therefore, the development of interests depends on available opportunities to engage in occupations.

Volition has a pervasive influence on occupational life. It shapes how people see the world and the opportunities and challenges it presents. Volition guides choices of what to do and determines the experience of doing. It shapes how people make sense of what they have done. To a large extent, how people experience life and how they regard themselves and their world have to do with volition. Volition is also central to the occupational therapy process. All therapy requires that clients make choices to do things; therefore, it must engage clients' volition. Moreover, how clients experience what they do in therapy (a function of volition) to a large extent determines therapy outcomes.

Habituation

Habituation refers to a process whereby people organize their actions into patterns and routines. Through repeated

action within specific contexts, people establish habituated patterns of doing. These patterns of action are governed by **habits** and roles. Together, they shape how people go about the routine aspects of their lives. Because of roles and habits, most routines of daily life unfold automatically and predictably.

Habits involve learned ways of doing things that unfold automatically. Habits operate in cooperation with context, using and incorporating the environment as a resource for doing familiar things. They influence how people perform routine activities, use time, and behave. For instance, habits shape how people intuitively go about self-care each morning, organize the weekly routine, and complete a familiar task.

Roles give people an identity and a sense of the obligations that go with that identity. People see themselves as students, workers, and parents and recognize that they should behave in certain ways to fulfill these roles. Much of what people do is done as a spouse, parent, worker, student, and so on. The expectations that others hold for a role and the nature of the social system in which each role is located serve as guides for learning how to behave within most roles. Thus, through interaction with others, people internalize an identity, an outlook, and a way of behaving that belong to each role they have internalized.

The habits and **internalized roles** that make up habituation guide how people interact with their physical, temporal, and social environments. When habituation is challenged by impairments and/or environmental circumstances, people can lose a great deal of what has given life familiarity, consistency, and relative ease. One of the major tasks of therapy is to reconstruct habits and roles so that the person can more readily participate in life occupations within the everyday environment.

Performance Capacity

Performance capacity refers to underlying mental and physical abilities and how they are used and experienced in performance. The capacity for performance is affected by the status of musculoskeletal, neurological, cardiopulmonary, and other bodily systems that are called on when a person does things. Performance also calls on mental or cognitive abilities such as memory. Biomechanical, motor control, cognitive, and sensory integration approaches to practice address this aspect of performance capacity from an objective point of view by focusing on physical and mental capacities as phenomena that can be observed, measured, and modified (Ayres, 1979; Trombly & Radomski, 2001).

MOHO recognizes the importance of approaches that address physical and mental capacities for performance and is typically used in conjunction with such models. MOHO stresses the importance of also paying attention to the experience of performance and, in particular, the experience of having limitations in performance. It asserts that by paying careful attention to how people experience

impairments, practitioners can be more helpful to clients. This includes, for instance, paying attention to how people's bodies feel to them and how they perceive the world when they have impairments. For example, research based on this approach has shown that people with a variety of physical impairments are often alienated from or do not feel at one with their bodies. Therapy can support people to "reclaim" their bodies or parts of their bodies and to integrate their bodies into a new way of doing things.

MOHO Concepts Concerning the Environment

MOHO stresses that all occupation results from an interaction of the inner characteristics of the person (volition, habituation, and performance capacity) with the characteristics of the physical and social environment. The **environment** can be defined as the particular physical, social, cultural, economic, and political features within a person's context that influence the motivation, organization, and performance of occupation. There are several dimensions of the environment that may have an impact on an individual's occupational life. For example, people encounter different physical spaces, objects, and people, as well as expectations and opportunities for doing things. At the same time, the larger culture, economic conditions, and political factors also exert an influence. Accordingly, the environment includes the following dimensions: the objects that people use when they do things; the spaces within which people do things; the occupational forms or tasks that are available, expected, and/or required of people in a given context; the social groups (e.g., family, friends, coworkers, neighbors) that make up the context; and the surrounding culture, political, and economic forces.

The things that people do and how they think and feel about these things reflect a complex interplay of motives, habits and roles, and abilities with the dimensions of the environment noted above. Political and economic conditions determine what resources people have for doing things and what occupational roles are available to them. Culture shapes the formation of ideas about how one should perform and what is worth doing. The demands of a task can determine the extent to which a person feels confident or anxious. The match of objects and spaces to the capacity of the individual influence how the person performs. In these and a myriad of other ways, the environment has an impact on what people do and how they think and feel about their doing. In turn, people also choose and modify their environments. For instance, people select environments that match and allow them to realize their values and interests.

Dimensions of Doing

As Figure 44.1 shows, MOHO identifies three levels at which we can examine what a person does: occupational participation, occupational performance, and occupational skill.

Occupational participation refers to engaging in work, play, or activities of daily living that are part of one's sociocultural context and that are desired and/or necessary to one's well-being. Examples of occupational participation are volunteering for an organization, working in a full- or part-time job, regularly getting together with friends, doing self-care, maintaining one's living space, and attending school. Each area of occupational participation involves a cluster of related things that one does. For example, maintaining one's living space may include paying the rent, doing repairs, and cleaning. Doing a task related to participation in a major life area is referred to as **occupational performance**.

During occupational performance, we carry out discrete purposeful actions. For example, making coffee is a culturally recognizable occupational form or task in many Western cultures. To do so, one *gathers* together coffee, coffeemaker, and a cup; *handles* these materials and objects; and *sequences* the steps necessary to brew and pour the coffee. These actions that make up occupational performance are referred to as **skills.** Skills are goal-directed actions that a person uses while performing (Fisher, 1998; Fisher & Kielhofner, 1995; Forsyth, Salamy, Simon, & Kielhofner, 1998). In contrast to *performance capacity,* which refers to underlying ability (e.g., range of motion and strength), *skill* refers to the actions within an occupational performance such as reaching or sequencing. There are three types of skills: motor skills, process skills, and communication and interaction skills. Detailed taxonomies of each of the three types of skills have been developed (Bernspang & Fisher, 1995; Doble, 1991; Fisher, 1995; Forsyth, Lai & Kielhofner, 1999; Forsyth, Salamy, Simon, & Kielhofner, 1998).

Occupational Identity, Competence, and Adaptation

Over time, what people do creates their **occupational identity.** This identity, generated from experience, is the cumulative sense of who people are and who they wish to become as occupational beings. The degree to which people are able to sustain a pattern of doing that enacts their occupational identity is referred to as **occupational competence.** These two essential elements of **occupational adaptation** entail the creation of an occupational identity and the ability to enact this identity in a variety of circumstances. As Figure 44.1 shows, people's occupational adaptation is reflected in the extent to which they can create and enact a positive occupational identity.

THE PROCESS OF CHANGE AND THERAPY

A basic premise of MOHO is that all change in occupational therapy is driven by clients' occupational engagement. The term **occupational engagement** refers to clients'

doing, thinking, and feeling under certain environmental conditions in the midst of therapy or as a planned consequence of therapy.

When clients engage in occupational forms or tasks in therapy or as a result of therapy, volitional, habituation, and performance capacity are all involved in some way. For example, in any moment of therapy, a client may be (1) drawing on performance capacity to exercise skill in occupational performance, (2) evoking old habits that shape how the occupational performance is done, (3) enacting or working toward acquiring a role, (4) experiencing a level of satisfaction and enjoyment (or dissatisfaction and displeasure) with occupational performance, (5) assigning meaning and significance to what is done (i.e., what this means for the client's life), or (6) feeling able (or unable) in doing the occupational form/task.

Each of these aspects of what the client does, thinks, and feels shapes the change process. For this reason, practitioners using MOHO are mindful of their clients' volition, habituation, performance capacity, and environmental conditions in the midst of therapy and how these elements are interacting as the therapy unfolds. To help practitioners think about the process of occupational engagement, MOHO identifies the nine dimensions of occupational engagement shown in Table 44.1. These identified dimensions of occupational engagement do not exhaust the possibilities for what clients do to achieve change. Nonetheless, they provide a basic structure for thinking about how clients achieve change and for planning how therapy goals will be achieved. This process is discussed in the next section.

USING MOHO IN PRACTICE: THE SIX STEPS OF THERAPEUTIC REASONING

Using MOHO in practice involves thinking with its theoretical concepts, a process referred to as *therapeutic reasoning.* Therapeutic reasoning refers specifically to the use of MOHO concepts in thinking about clients' needs throughout the occupational therapy process (American Occupational Therapy Association, 2002). The therapeutic reasoning process has six steps: (1) generating questions about the client, (2) gathering information on and with the client, (3) using the information gathered to create an explanation of the client's situation, (4) generating goals and strategies for therapy, (5) implementing and monitoring therapy, and (6) determining outcomes of therapy. Practitioners generally move back and forth between these steps over the course of therapy. Each step is briefly discussed below.

Generating Questions

Practitioners must come to understand their clients in order to plan and implement therapy. This understand-

TABLE 44.1   DIMENSIONS OF CLIENT OCCUPATIONAL ENGAGEMENT

Dimensions of Occupational Engagement	Definition
Choose/Decide	Anticipate and select from alternatives for action.
Commit	Decide to undertake a course of action to accomplish a goal or personal project, fulfill a role, or establish a new habit.
Explore	Investigate new objects, spaces, social groups, and/or occupational forms/tasks; do things with altered performance capacity; try out new ways of doing things; examine possibilities for occupational participation in one's context.
Identify	Locate novel information, alternatives for action, and new feelings that provide solutions for and/or give meaning to occupational performance and participation.
Negotiate	Engage in a give-and-take with others that creates mutually agreed-upon perspectives and/or finds a middle ground between different expectations, plans, or desires.
Plan	Establish an action agenda for performance or participation.
Practice	Repeat a certain performance or consistently participate in an occupation with the intent of increasing skill, ease, and effectiveness of performance.
Reexamine	Critically appraise and consider alternatives to previously held beliefs, attitudes, feelings, habits, or roles.
Sustain	Persist in occupational performance or participation despite uncertainty or difficulty.

ing begins with asking questions about their clients. MOHO theory allows a practitioner to generate these questions systematically. That is, the major concepts of the theory (environmental impact, volition, habituation, performance capacity, participation, performance, skills, occupational identity, and occupational competence) orient the practitioner to be concerned about certain things when learning about a client. For example, practitioners using MOHO would ask what their clients' thoughts and feelings are in relation to personal causation, values, and interests. Moreover, they would ask about their clients' roles and habits and how these affect the clients' routines. These questions would, of course, be tailed to the clients' circumstances.

Gathering Information

To answer the questions generated in the first step, practitioners must gather information on and with the client. Practitioners may take advantage of naturally occurring opportunities to gather information. For example, a practitioner might learn about a client's personal causation by observing the client's emotional reaction when attempting to learn a challenging new task or by engaging in informal conversation about the client's fears about the future. Practitioners also use structured assessments that have been developed to generate information that is relevant to MOHO con-

cepts. Some MOHO assessments gather specific information on such factors as interests and roles. Other assessments attempt to capture more in-depth information on one aspect of MOHO, such as assessments that focus on volition. Still other MOHO assessments will capture comprehensive information on several aspects of the person and the environment. A wide range of MOHO-based assessments have been developed; they are summarized in Table 44.2. See Unit XVII for additional information about these assessments. Thus, practitioners using MOHO have a range of choices when they decide which assessment(s) to use.

Creating a Theory-Based Understanding of the Client

The information that the practitioner gathers to answer questions about a client is used to create a theory-based understanding of that client. In this step, the practitioner uses MOHO theory as a framework for creating a conceptualization or explanation of that particular client's situation. As will be demonstrated in the cases of Betty and Lin, the therapists use MOHO to create a conceptualization of each of these client's occupational circumstances to guide the next step of generating goals and strategies for therapy.

As part of creating a conceptualization of clients' circumstances, practitioners identify problems or challenges

TABLE 44.2 MOHO ASSESSMENT SUMMARY TABLE

MOHO Assessment	Method of Administration	Description
Assessment of Communication and Interaction Skills (ACIS)	Observation	Gathers information about the communication and interaction skills that a person displays while engaged in an occupation across the domains of physicality, information exchange, and relations. Used to generate goals for therapy related to communication/interaction skills and to assess outcomes/changes in skill.
Assessment of Motor and Process Skills (AMPS)	Observation	Gathers information about the motor and process skills that a person displays while engaged in an occupation. Used to generate goals for therapy related to motor and process skills and to assess outcomes/changes in skill.
Assessment of Occupational Functioning-Collaborative version (AOF-CV)	Interview and/or client self-report	Yields qualitative information and a quantitative profile of the impact of a client's personal causation, values, roles, habits, and skills on occupational participation. Used to inform intervention.
Child Occupational Self Assessment (COSA)	Client self-report	Children and youths rate their occupational competence for engaging in 25 everyday activities in the home, school, and community and the importance of those activities. Used to generate goals and assess outcomes/change in competence and values.
Interest Checklist	Client self-report	Checklist that indicates strength of interest and past, present, and future engagement in 68 activities. Used to inform intervention.
Model of Human Occupational Screening Tool (MOHOST)	Observation, interview(s), and/or chart review	Information gathered assesses impact of volition, habituation, skills, and environment on client's occupational participation. Used to generate goals and assess outcomes/changes in participation.
NIH Activity Record	Client self-report	Self-report "log" records information in half-hour intervals throughout the day on perceptions of competence, value, enjoyment, difficulty, and pain experienced when engaging in various occupations in that time period. Used to inform intervention and assess outcomes/change in participation.
Occupational Circumstances Assessment-Interview and Rating Scale (OCAIRS)	Interview	Interview yields information to assess values, goals, personal causation, interests, habits, roles, skills, readiness for change, and environmental impact on participation. Used to generate goals and assess outcomes/changes in participation.
Occupational Performance History Interview-II (OPHI-II)	Interview	Detailed life history interview that yields (a) scales measuring competence, identity, and environmental impact and (b) a narrative representation/analysis of the life history. Used as an in-depth, comprehensive assessment to generate goals, inform intervention, and build the therapeutic relationship.
Occupational Questionnaire (OQ)	Client self-report	Self-report "log" records information in half-hour intervals throughout the day on perceptions of competence, value, and enjoyment experienced when engaging in various occupations in that time period. Used to inform intervention and assess outcomes/change in participation.

TABLE 44.2   MOHO ASSESSMENT SUMMARY TABLE   *Continued*

MOHO Assessment	Method of Administration	Description
Occupational Self Assessment (OSA)	Client self-report	Clients rate their occupational competence for engaging in 21 everyday activities and the importance of those activities. Allows clients to set priorities for change. Used to generate goals and assess outcomes/change in competence and values.
Pediatric Interest Profiles (PIP)	Client self-report	Assessment includes three age-appropriate scales (some with line drawings) for children and adolescents to indicate participation, interest, and perceived competence in a variety of play and leisure activities. Used to generate goals and assess outcomes/changes in participation.
Pediatric Volitional Questionnaire (PVQ)	Observation	Guides a systematic observation of a child across multiple environments to assess volition and the impact of the environment on volition. Used as an in-depth assessment of volition to generate goals and assess outcomes/change in volition.
Role Checklist	Client self-report	Checklist provides information on past, present, and future role participation and the perceived value of those roles. Used to inform intervention and assess outcomes/changes in role performance.
Short Child Occupational Profile (SCOPE)	Observation, interview(s), and/or chart review	Information gathered assesses impact of volition, habituation, skills, and environment on child's/adolescent's occupational participation. Used to generate goals and assess outcomes/changes in participation.
School Setting Interview (SSI)	Interview	Interview works with students to gather information on student-environment fit and identify need for accommodations. Used to generate goals, inform intervention, and assess outcomes/changes in student-environment fit.
Volitional Questionnaire (VQ)	Observation	Guides a systematic observation of a client across multiple environments to assess volition and the impact of the environment on volition. Used as an in-depth assessment of volition to generate goals and assess outcomes/change in volition.
Worker Role Interview (WRI)	Interview	Interview yields information to rate the impact that volition, habituation, and perceptions of the environment have on psychosocial readiness for the worker role/return to work. Used to generate goals and assess outcomes/changes in psychosocial readiness for work.
Work Environment Impact Scale (WEIS)	Interview	Interview works with client to assess environmental impact on participation in the worker role and to identify needed accommodations. Used to generate goals and inform intervention.

that need to be addressed in therapy as well as strengths that can be drawn on in therapy. Problems and challenges may be a function of volition, habituation, performance capacity, or the environment.

Generating Therapy Goals and Strategies

This step involves creating therapy goals (i.e., identifying what will change as a result of therapy), deciding what kinds of occupational engagement will enable the client to change, and determining what kind of therapeutic strategies will be needed to support the client to change.

Goals indicate the kinds of changes that therapy will aim to achieve. Change is required when the client's characteristics and/or environment are contributing to occupational problems or challenges. For instance, if a client feels ineffective, therapy would seek to enable the client to feel more effective, or if a client has too few roles, therapy would seek to enable the client to choose and enact new roles, or if the environment was affecting the client's performance in a negative way, therapy would seek to modify that environment. In this way, identifying challenges or problems in the third step allows one to select the goals in the fourth step.

The next element in this step is to identify how the goals will be achieved. This involves indicating what occupational engagement on the part of the client will contribute to achieving these goals and how the practitioner will support the client. The previous section on change offered nine dimensions of occupational engagement, and these serve as a framework for thinking in this step. MOHO also identifies key therapeutic strategies that practitioners will use; these are listed in Box 44.1.

The text *The Model of Human Occupation: Theory and Application* (Kielhofner, 2007) provides a comprehensive resource, the Therapeutic Reasoning Table, for this component of the therapeutic reasoning process. It identifies a wide range of problems and challenges that correspond to the concepts of MOHO along with types of changes that would be warranted. The table also indicates what types of occupational engagement could contribute to achieving those changes and what type of support from the practitioner could facilitate change. Table 44.3 shows one small section from this Therapeutic Reasoning Table related to personal causation.

Implementing and Monitoring Therapy

To implement therapy means not only following the plan of action that was set out in the previous step, but also monitoring how the therapy process unfolds. This monitoring process might confirm the practitioner's conceptualization of the client's situation or require the practitioner to reconceptualize the client's situation. The monitoring process also can confirm the utility of the

> **BOX 44.1**
>
> ## THERAPEUTIC STRATEGIES IDENTIFIED BY MOHO
>
> ◆ **Validating:** Attending to and acknowledging the client's experience.
> ◆ **Identifying:** Locating and sharing a range of personal, procedural, and/or environmental factors that can facilitate occupational performance.
> ◆ **Giving feedback:** Sharing your understanding of the client's situation or ongoing action.
> ◆ **Advising:** Recommending intervention goals/strategies.
> ◆ **Negotiating:** Engaging in a give-and-take with the client.
> ◆ **Structuring:** Establishing parameters for choice and performance by offering a client alternatives, setting limits, establishing ground rules.
> ◆ **Coaching:** Instructing, demonstrating, guiding, verbally and/or physically prompting.
> ◆ **Encouraging:** Providing emotional support and reassurance in relation to engagement in an occupation.
> ◆ **Physical support:** Using one's body to provide support for a client to complete an occupational form/task.

planned client occupational engagement and therapist strategies or require the practitioner to change the goals and/or planned client occupational engagement and therapist strategies. When things do not turn out as expected, the practitioner returns to earlier steps of generating questions, selecting methods to gather information, conceptualizing the client's situation, setting goals, and establishing plans.

Collecting Information to Assess Outcomes

Determining therapy outcomes is an important final step in the therapy process. Typically, therapy outcomes are documented by examining the extent to which goals have been achieved and readministering structured assessments that were administered initially. Both these approaches are valuable in documenting outcomes. Assessing outcomes by examining goal attainment is helpful in reflecting on the extent to which the therapeutic reasoning process resulted in good decisions for therapy. Using structured assessments also allows one to compare change across different clients or when different strategies are used. In this way, they can contribute to evidence-based therapy.

TABLE 44.3 EXCERPT FROM THE THERAPEUTIC REASONING TABLE SHOWING A PROBLEM/CHALLENGE RELATED TO PERSONAL CAUSATION, AND CORRESPONDING INTERVENTION GOALS AND STRATEGIES

Problem/Challenge	Goal	Client Occupational Engagement	Therapeutic Strategies to Support the Client
◆ Feelings of lack of control over occupational performance leading to anxiety (fear of failure) within occupations.	◆ Reduce client's anxiety and fear of failure in occupational performance (e.g., "The client will complete a simple 3-step meal in 20 minutes without verbalizing anxiety or concern."). ◆ Build up confidence to face occupational performance demands (e.g., "The client will identify and participate in 3 new leisure activities with minimal support in 1 week").	◆ *Reexamine* anxieties and fears in the light of new performance experiences. ◆ *Choose* to do relevant and meaningful things that are within performance capacity. ◆ *Sustain* performance in occupational forms tasks despite anxiety.	◆ *Validate* how difficult it can be to do things that provoke anxiety. ◆ *Identify* client's strengths and weaknesses in occupational performance. ◆ Give *feedback* to client about match/mismatch between choice of occupational forms/tasks and performance capacity. ◆ Give *feedback* to support a positive reinterpretation of their experience of engaging in an occupation. ◆ *Advise* client to do relevant and meaningful things that match performance capacity.

FIGURE 44.2 Betty's OCAIRS Ratings (see case study p. 456)

CASE STUDY: *Betty: An 82-Year-Old Woman with a Hip Fracture*

Collecting Information and Creating a Theory-Based Understanding of Betty

On arrival in the rehabilitation ward, Betty required physical assistance with all activities owing to limited mobility. She was using a walker and required physical assistance to ambulate. Betty clearly lacked a sense of efficacy and was anxious when engaging in activities of daily living. The therapist's major questions about Betty were as follows:

1. What had been her major life roles and routines before the injury?
2. How was her volition affected by her injury and subsequent impairment?
3. What was her functional capacity?
4. Was her functional capacity likely to improve to the level necessary to meet her goals?

In addition to a functional evaluation, the therapist elected to use the Occupational Circumstance Assessment Interview and Rating Scale (OCAIRS) (Forsyth et al., 2005) in order to gain a comprehensive understanding of Betty's occupational life. The therapist selected this semistructured interview as the method of assessment because Betty had the cognitive and emotional ability to engage in an interview and related well through conversation. The OCAIRS interview was completed in one session. The interview was conducted informally to encourage Betty to share her experiences, thoughts, and feelings about her occupational participation before the fall, currently, and in the future. Betty responded well to the interview and thanked the therapist for the opportunity to share her experiences and her concerns about the future.

The results of the OCAIRS interview were summarized in a rating scale (shown in Figure 44.2). As the OCAIRS ratings show, Betty has values and interests that facilitate her participation; the major factor restricting her participation is her personal causation. The pattern shown in the OCAIRS scale is reflected in the following conceptualization that the therapist wrote concerning Betty's occupational circumstances:

> At the time of her fall, Betty lived alone since her husband passed away four years ago. She lives in her family home in the same small town where she spent her whole life. Betty has a daughter and two grandsons, whom she sees on weekends since they live in another town. She talks with her daughter daily on the phone.
>
> Betty worked in a shop before she was married, but once married, remained at home to raise her daughter. She still highly values her homemaker role. Prior to admission, she was independent with all household tasks, including self-care, cooking, and shopping. Betty spends much of her time in leisure pursuits of knitting, baking, and listening to country music on the radio. She attends community groups at a local church on a weekly basis and attends the weekly church service. She has good friends from the church who provide social support.
>
> Betty reports feeling that she has lost family roles, particularly since her husband died and her daughter moved away.

Her daughter and grandsons are very important to her and she looks forward to their weekly visits. She very much wants to regain her role of homemaker and churchgoer, as these roles structured her daily and weekly activities.

Returning home is the most important thing to her, and she is highly motivated to regain her previous daily routine and roles, though she is unclear on how she is going to achieve this, given her current situation. Betty does not have a good sense of what her physical capacity will be. She very much values her independence and is unhappy about requiring assistance from staff. She feels unsure about her current abilities and her future. Overall, Betty feels that she had lost control of her life and is anxious about her situation. At the same time, she has clear interests and goals as well as intentions for reinstating her previous habits and roles.

Therapy Goals and Strategies

Following the interview, the therapist validated Betty's feelings and concerns and advised her that the goal of returning home was achievable. Together, they identified the following goals for therapy:

- With modifications, independently complete all personal self-care ADLs in two weeks,
- With modifications, independently complete home I-ADLs, including making a bed, sweeping, and preparing a three-step meal in two weeks,
- Demonstrate improved confidence while completing ADLs and I-ADLS in two weeks, and
- Identify ways to resume three leisure activities with modifications in preparation for return home.

Implementing and Monitoring Therapy

The therapist collaborated with Betty to identify daily goals and to review Betty's progress daily with feedback from the therapist. Therapy first consisted of Betty's engaging in activities of daily living. The therapist provided advice, encouragement, and physical assistance as required. As Betty practiced self-care tasks with modifications and sustained engagement when the tasks were difficult, she gained a greater sense of efficacy. She then began engaging in leisure activities as well as I-ADLs in the SNF's model apartment, such as cooking and household chores. Throughout this time, the therapist and Betty monitored her progress and discussed its implications for her ability to return home safely and independently.

Outcomes

After two weeks, Betty had achieved independence with ADLs and I-ADLs within the SNF environment. She was spontaneously engaging in leisure, homemaker, and self-care activities and displayed confidence and a sense of capacity of her abilities within the SNF. Betty's discharge plan confirmed that Betty was ready to return home.

CASE STUDY: *Lin: A Preschooler with Seizure Disorder and Other Developmental Problems*

Collecting Information and Creating a Theory-Based Understanding of Lin

Because the therapist knew that attaining the parents' desired goal and Lin's success in school depended on arousing his motivation, the therapist asked the following questions:

1. What volitional factors might motivate Lin in the educational environment?
2. What aspects of the environment would best support Lin's participation in school activities?

The therapist first informally observed Lin in the classroom. Lin did not seem interested in any of the activities in the room and refused hand-over-hand support to participate in play or educational activities. He rarely smiled or made eye contact.

The therapist decided to use the Pediatric Volitional Questionnaire (PVQ) (Basu, Kafkes, Geist, & Kielhofner, 2002) in order to better understand Lin's volition and the environmental factors that that might support it. The therapist also decided to use the Short Child Occupational Profile (SCOPE) (Bowyer, Ross, Schwartz, Kielhofner, & Kramer, 2006) to document how various personal and environment factors influenced Lin's level of participation in the classroom. Both assessments can be administered from observation and do not require specific task performance, so they were suitable for Lin. The therapist supplemented her observation with parent and teacher interviews to complete the SCOPE.

The therapist asked Lin's parents about the things he enjoyed, the family routine at home, and Lin's engagement in activities. Lin's mother shared that Lin was a pleasant and easygoing child who enjoyed listening to music and singing and being held. Lin's father said that Lin was compliant during bathing, dressing, diaper changes, g-tube feedings, and other routines. However, he had problems with oral feedings. Lin's parents' concern for his health and well-being led them to protect him and limit his fatigue. As a result, they did not expect Lin to actively engage in any activity. Mealtime, however, was one occupation that demanded Lin's active engagement.

The next day, the therapist attempted to engage Lin in play, using a toy his mother reported to be his favorite (a crib toy that featured different music and a projected light display) as well as other toys and objects. When placed on his stomach with the light next to his head, Lin turned his head toward the toy, but he did not raise his head up against gravity or reach toward the toy. When the music stopped, Lin would softly whine until the therapist pressed the small button to start the music. Lin also showed interest in a similar toy that also vibrated and was activated by

a large, soft touch pad. The therapist attempted to use hand-over-hand assistance to have Lin reach, press the pad, and start the music and vibration again. Lin showed no inclination or interest in being able to turn on the toy by himself. The therapist conducted a second observation during mealtime. The therapist encouraged Lin to hold his spoon and bring it to his mouth with hand-over-hand support, but Lin resisted. When the therapist put a spoonful of food in his mouth, Lin dropped his head, and the pureed mixture fell onto his bib. The therapist used this information from the interview and observations to rate the PVQ and the SCOPE (see Figures 44.3 and 44.4). As the SCOPE shows, Lin's skills mainly restrict his participation and his volition and habituation mostly interfere with his participation. His main resources for participation are his vocal expressions and his environment. The therapist rated the PVQ twice on the basis of the floor play and lunch observations. Lin's scores indicate that he is passive or hesitant in demonstrating volitional behaviors in both contexts. His scores are indicative of a child with very limited volition.

On the basis of the PVQ and SCOPE scores, the therapist arrived at the following conceptualization of Lin's occupational circumstances:

Lin's low tone, poor coordination, limited endurance, and unstable health have led to a pattern of his passive involvement in his environment. His parents provide him with his basic needs as well as pleasurable experiences. He has had limited demands and opportunities to test his abilities. As a result, Lin's sense of capacity to affect the environment is mainly limited to his ability to affect others' actions through vocalizations. His interests are based on passive sensory stimulation such as music, light, and vestibular input. At this point, Lin's volition is a major barrier, since he tolerates and enjoys only passive involvement in learning, play, and self-care activities. While Lin's impairments contribute to his limited skill set, his lack of interest in exploring his environment has also limited the development of skills necessary for learning and participating in the educational environment.

Lin is able to comply with routines related to his care as long as he is expected only to be passive. When there are expectations for performance, he withdraws or becomes resistive. He does not have an awareness of role behaviors and routines associated with being a student.

Goals and Strategies for Therapy

The therapist established the following goals for school occupational therapy:

◆ Lin will develop the volition to actively explore educational toys and activities by reaching, looking, and interacting with toys for 10 minutes with verbal cues and environmental modifications,

I = Involved (Shows behavior with minimal amount of support, structure, and encouragement)
S = Spontaneous (Shows behavior without support, structure, and encouragement)

FIGURE 44.4 Lin's Initial PVQ Ratings

CASE STUDY: *Lin: A Preschooler with Seizure Disorder and Other Developmental Problems* *Continued*

◆ Lin will participate in classroom activities and interact with teachers and peers using environmental supports and modifications implemented by educational staff (i.e., positioning, modified switches),

◆ Lin will actively participate in feeding at lunchtime by bringing his spoon to his mouth and keeping his head up with minimal assistance.

The therapist recognized that it was first necessary to address Lin's limited volition, since he would not choose to explore, engage in school activities, or more actively cooperate with daily routines and, in fact, resisted these types of occupations. Therefore, the therapist planned to structure the environment so that Lin could explore new interests and experience a sense of efficacy and success when trying new things. In addition, the therapist planned to work with the classroom teacher to ensure that expectations for performance in the classroom would be aligned with Lin's current abilities and interests.

Implementing and Monitoring Therapy

The therapist began attending Lin's classroom during floor time and worked with the teaching assistant to develop a positioning schedule to facilitate Lin's interaction with the environment. When Lin was positioned in a corner seat, standing in a supine stander, or lying prone on a wedge, the therapist or teaching assistant encouraged and physically assisted Lin to lift his head, reach, and touch toys and switches. The therapist ensured that Lin's attempts to affect the environment were pleasurable and successful.

This experience increased Lin's sense of capacity for play. After four weeks, Lin was able to actively explore for 10 minutes during floor time.

During oral feeding, the therapist graded her expectations and began by increasing Lin's head control. In addition to providing physical assistance and verbal encouragement, the therapist played a tape of Lin's favorite music as long as he kept his head up. This interest was enough to encourage Lin to cooperate with the therapist and keep his head up. With his head upright, Lin was better able to manage the bolus during feeding.

Outcomes

The therapist used specific PVQ items as indicators to track Lin's volitional progress halfway through the fall school term. At this point, Lin showed curiosity and visually attended to four new toys while positioned. He demonstrated his preferences by lifting his head against gravity when the therapist or teaching assistant brought out a favorite toy. Lin showed that he had an increased sense of capacity by initiating a reach with his right arm to interact with an educational toy. During lunch, Lin could keep his head upright and engage in the lunch routine for the five minutes. He was unable to hold the spoon on his own, even with adaptations such as a built-up handle, and did not tolerate a hand strap. However, he demonstrated an increased awareness of and cooperation with this self-care routine. Overall, Lin demonstrated an increased sense of personal causation to engage in play and feeding.

CONCLUSION

This chapter provided an overview of the theory and practice resources of MOHO. Two cases were used to demonstrate how MOHO concepts are used to guide the process of therapeutic reasoning. As the cases illustrate, therapists can use MOHO to support a client-centered and occupationally focused practice. This chapter was able to demonstrate only a small fraction of the theoretical, empirical, and practical resources that are available under this model. Anyone who wishes to use MOHO is encouraged to take advantage of those resources.

PROVOCATIVE QUESTIONS

1. Think of an occupation that you participate in. Identify how your volition (including personal causation, values, and interest), habituation (including habits and roles), performance capacity, and various environments (including spaces, objects, social groups, and occupational forms/tasks) influence your occupational participation. Imagine that your performance capacity has changed because of an illness or impairment. How would your volition, habituation, performance capacity, and the environment now impact your occupational participation?

2. Read the following mini-case about Joseph. When you have finished, use the therapeutic reasoning process to generate MOHO based questions about Joseph's current occupational circumstances. Create a conceptualization of Joseph's current occupational circumstances using MOHO terms to describe the factors impacting his occupational participation.

Joseph, a 30-year old African-Caribbean, was referred to occupational therapy during admission to a mental health inpatient unit. He had recently been experiencing psychotic symptoms. His neighbors sought help from the police when Joseph was observed pacing the street and wearing no shoes on a cold wet day.

Observation of Joseph on the unit indicated that he was mainly withdrawn and inactive during the day, wary of others, and did not engage in self care. His personal belongings were shoved under his bed. Joseph was frail and refused many of his meals on the ward. He often dozed off while sitting and watching television. Nonetheless, when certain music was being played on the ward radio, Joseph quietly sang along to the music or tapped the rhythm with his hands and became more visibly relaxed. During occupational therapy group, he expressed interest in painting, but then refused to engage in the activity because "he would not do a good enough job." When touring the OT kitchen area, Joseph mentioned that he was known for his home-cooked vegetarian meals, but didn't think he could remember any of his recipes.

During her brief conversations with Joseph, the practitioner learned that he lived alone in a small apartment. Since the age of 16, when he left school, Joseph had drifted in and out of employment as an unskilled laborer working in restaurants and hotels. For the past few years, he played drums in a band, and spent his leisure time listening to music, practicing alone, rehearsing or performing with the band. Joseph had a long term relationship with a woman who was part of the band. Recently, this relationship ended and Joseph chose not to continue with the band.

Theory of Occupational Adaptation

SALLY SCHULTZ

Learning Objectives

After reading this chapter, you will be able to:

1. State the features of occupational adaptation (OA) that most distinguish it from other occupation-based theories of practice.
2. Describe the necessity of using the Guide to Therapeutic Reasoning for an OA-based treatment program.
3. Describe key aspects of the OA Guide to Evaluation and Intervention.
4. Explain why the therapeutic use of self is one of the most powerful therapeutic tools.
5. Explain why it is necessary for therapists to use an articulated theory to develop an authentic occupation-based practice.

Alfonso is an 11-year-old boy attending public school in the fifth grade. He was referred to occupational therapy for help with attention deficit disorder, reading problems, and behavioral problems both in the classroom and at recess. His occupational therapist, Claudette, plans to include Alfonso in a therapy group with other boys who are having similar difficulties. This group is based on the theory of occupational adaptation. Some of Claudette's work with Alfonso, is described in the case study later in the chapter.

INTELLECTUAL HERITAGE

In 1987, a group of Texas Woman's University occupational therapy faculty was charged by Dr. Grace Gilkeson (Dean of the School of Occupational Therapy at the university) to develop a Ph.D. program in occupational therapy. One of the group's challenges was to name and frame how the program would contribute to the discipline and practice of occupational therapy. After lengthy study and debate, the committee reached agreement that there were two concepts that were unquestionably fundamental to occupational therapy and should be emphasized throughout the doctoral program. These two concepts were occupation and adaptation. The committee saw occupation and adaptation as integral to the profession's

beginnings, central to its philosophy, and essential for the integrity of its future. The research focus for the new doctoral program was thus identified as occupational adaptation (OA).

The design of the doctoral program progressed, and responsibilities were divided among the committee members. Sally Schultz and Janette Schkade were asked to develop the group's conceptualization of occupational adaptation into the perspective that would be the core of the doctoral program. Drs. Anne Henderson, Lela Llorens, and Kathlyn Reed, noted occupational therapy scholars, provided ongoing consultation in the development of the Ph.D. program and the research focus on occupational adaptation. The program was established in 1994. By 2007, there were more than 30 graduates of the program. Schkade and Schultz expanded on the initial concept of **occupational adaptation**. They introduced OA as a frame of reference (Schkade & Schultz, 1992; Schultz & Schkade, 1992) and most recently (Schkade & Schultz 2003) as an overarching theory for occupational therapy practice and research.

The theory of occupational adaptation describes the integration of two global concepts that have long been present in occupational therapy thinking: **occupation** and **adaptation**. The intellectual heritage of this theory dates back to the writings of William Dunton (1913) and Adolph Meyer (1922). Schkade and Schultz were also significantly influenced by the writings of several contemporary theorists both within and outside the field of occupational therapy (i.e., Gilfoyle, Grady, & Moore, 1990, King, 1978; Llorens, 1970; Selye, 1956). OA interventions for specific populations were first published in 1992 (Schkade & Schultz, 1992). A model outlining home health interventions appeared in 1994 (Schultz & Schkade, 1994). Numerous population-specific OA applications have appeared over the years (e.g., Ford, 1995; Garrett & Schkade, 1995; Pasek & Schkade, 1996; Ross, 1994; Schkade, 1999; Schkade & McClung, 2001; Schkade & Schultz, 2003; Schultz, 1997, 2000, 2003; Schultz & Schkade, 1994; Werner, 2000).

GUIDING ASSUMPTIONS OF OA THEORY

All theories are based on assumptions. Most occupational therapy is driven by the assumption that as clients become more functional, they will be more adaptive. The theory of occupational adaptation takes the opposite point of view. Practice based on occupational adaptation is driven by the assumption that if clients become more adaptive, they will become more functional.

The founders of the theory of occupational adaptation (Schkade & Schultz, 1992) proposed six guiding assumptions about the relationship between occupational performance and human adaptation. The assumptions are presumed to be normative and applicable across the lifespan. These six assumptions are as follows:

1. Competence in occupation is a lifelong process of adaptation to internal and external demands to perform.
2. Demands to perform occur naturally as part of the person's occupational roles and the context (person–occupational environment interactions) in which they occur.
3. Dysfunction occurs because the person's ability to adapt has been challenged to the point at which the demands for performance are not met satisfactorily.
4. The person's **adaptive capacity** can be overwhelmed by impairment, physical or emotional disabilities, and stressful life events.
5. The greater the level of dysfunction, the greater is the demand for changes in the person's adaptive processes.
6. Success in occupational performance is a direct result of the person's ability to adapt with sufficient mastery to satisfy the self and others.

These six assumptions are not about occupational therapy. They are about the normative relationship between occupational performance and human adaptation. The assumptions are relevant to occupational therapy because they provide the practitioner with a way of viewing the client and the problems that are presented in therapy. The most common viewpoint the occupational therapy practitioner experiences is the medical model and its underlying assumptions. In medicine, patients are generally viewed in terms of their body systems. Treatment is focused on correcting the breakdown within the identified system(s). Medicine's underlying assumptions about illness and treatment shape the view and the interventions that are used. For example, a nurse reviews the chart's lab results, vital signs, and progress. The nurse visits the 68-year-old white male and asks, "How are you doing today?" The patient answers, "Pretty good, but I'm still having a lot of pain, and I get tired so easily." The nurse asks the physician to write an order for more pain medication and increased activity.

A practitioner whose practice is based on OA will view the client through the filter of the six assumptions that ground the theory. The OA constructs, models, and intervention methods are all based on these assumptions. They form the core of the theory of occupational adaptation. The OA-based practitioner visits the same 68-year-old client. The practitioner is aware that the man is a retired bus driver, that he is married to the mother of his four children, and that they have nine grandchildren. The practitioner wonders aloud to the client, "What would you be doing today if you hadn't broken your hip?" The client responds, "Oh, I don't know, the only thing that matters now is getting me back on my feet." The practitioner replies, "Yes, we'll focus on that. You had a pretty bad break, and you might need to do some things differently

when you go home. I will help with that. Let's talk about what matters the most to you."

INTRODUCTION TO THE THEORY OF OCCUPATIONAL ADAPTATION

The first publication on the theory of occupational adaptation was presented in two parts (Schkade & Schultz, 1992; Schultz & Schkade, 1992). Part 1 presents the theory's assumptions about the relationship between human adaptation and the performance of everyday occupations. A normative model, the **occupational adaptation process**, was proposed to describe the interaction of the person, the environment, and the internal adaptive processes that occur when individuals engage in their occupations of daily living (Schkade & Schultz, 1992). The model is presented in a linear format. However, the author recognizes that the actual process of occupational adaptation is characterized by complexity, randomness, and nonlinearity (e.g., Davies, 1988; Gleick, 1987; Prigogine & Stengers, 1984). Such

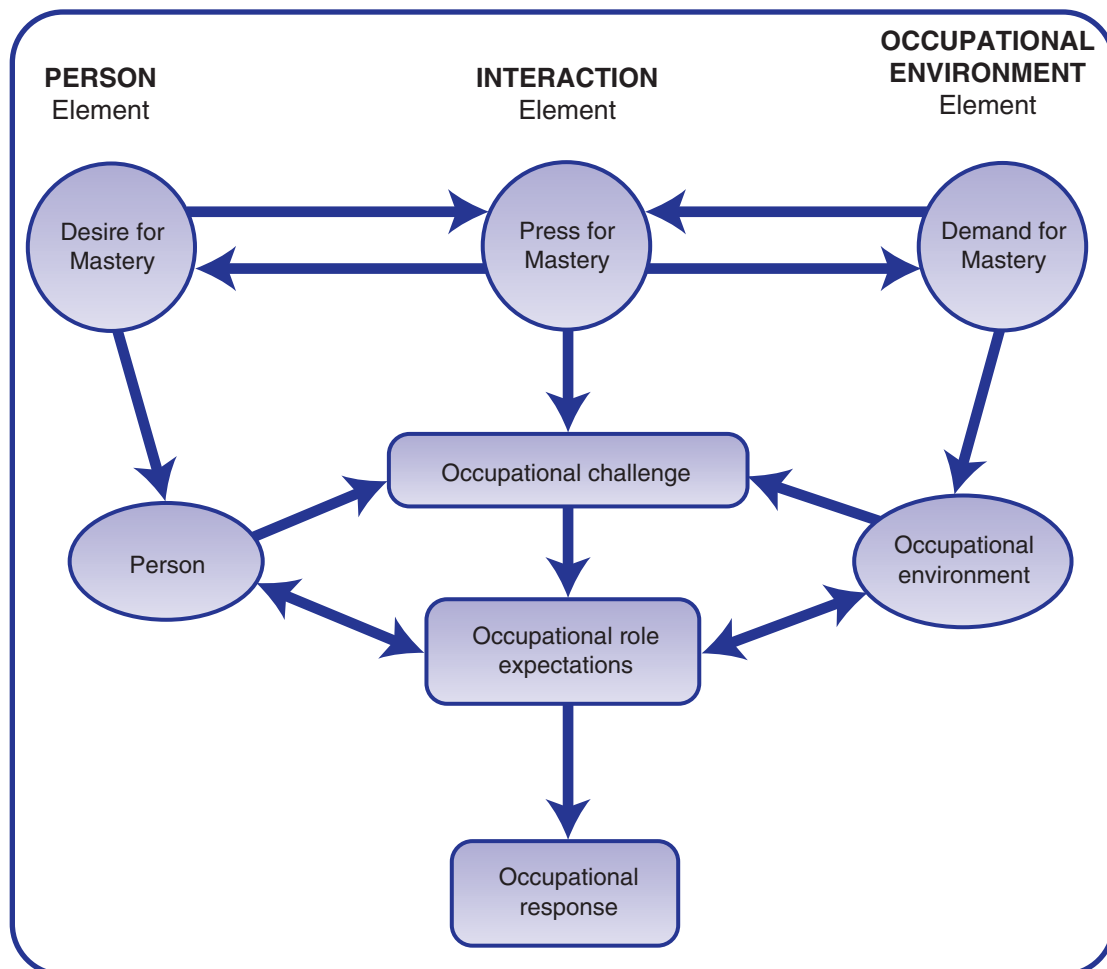
human processes are inherently not describable in two-dimensional models. On the other hand, the benefit of a linear model is that it provides a rudimentary organization of highly interactive and complex phenomena. Such organization is necessary to engage in a systematic examination. In sum, the occupational adaptation process is a highly interactive, complex, and self-organizing process that has the goal of achieving mastery over the environment. The linear model provides a basis for scholarly dialogue. The objective in dynamic self-organizing processes is not to achieve a determined balance or equilibrium. The theory of occupational adaptation proposes that equilibrium or homeostasis can actually result in a state of dysadaptation. Personal adaptation is proposed in the theory as a human phenomenon that is in a continuous process of order and disorder and reorganization. Figure 45.1 presents a modified version of the original 1992 model. The revised model is somewhat simplified from the one that was presented in 1992. It is also a linear model that was created to serve as a vehicle for examining these very complex processes. Although dynamic models are often more inclusive of the multiple phenomena,


FIGURE 45.1 Model of the Occupational Adaptation Process. Adapted from the OA Process Model (Schkade & Schultz, 1992).

an identifiable process is often elusive. The model of the OA process (Figure 45.1) is based on three overarching elements: the person, the **occupational environment**, and their interaction. Each is a dynamic, ever-changing state that influences the other. The following discussion elaborates on Figure 45.1. Terminology that is specific to the theory and/or model is initially presented in italics.

Person: Internal Factors of the OA Process

The left side of the model is devoted to the internal factors: those that occur within the *person.* The process begins with a *desire for mastery.* The desire for mastery is proposed in OA theory as a constant factor in the OA process; it is ever present. Even at the cellular level, there is constant demand for adaptation and mastery (Reilly, 1962). Seeking mastery over the environment is understood to be an innate human condition. The second factor, the person, is made up of the individual's unique sensorimotor, cognitive, and psychosocial systems. These person systems are unique to the individual, with specific attributes and deficits. They are also uniquely affected by the individual's genetic, biological, and phenomenological influences. The theory of occupational adaptation posits that all occupations are holistic. That is, all occupations involve the sensorimotor, cognitive, and psychosocial systems. The relative contribution of each system shifts on the basis of the circumstances surrounding the occupation.

Occupational Environment: External Factors of the OA Process

The right side of the model is devoted to external factors that affect the *person* (see Figure 45.1). Correspondingly, the external process also begins with a constant factor: the *demand for mastery.* OA theory proposes that any circumstance presents itself with at least a minimal degree of demand for mastery. The second external factor is the *occupational environment.* The term was coined by the founding authors with the intent to capture the dynamic meaning that they ascribed to the complexity of factors that are external to the person in the OA process. The occupational environment is highly significant in that it not only has an expectation of the person, but also has a direct impact on the person. The occupational environment represents the overall context within which the person engages in the particular occupation and *occupational role.* There are three broad types of occupational environment: work, play/leisure, and self-care. Each type of occupational environment is affected by the physical, social, and cultural influences that are part of the individual's experiential context. The physical influence consists of the actual setting in which the occupation occurs. The social influence is made up of the individuals who are participants within the occupational environment. The cultural influence presents the habits, mores, and traditions and rituals that exist in the occupational environment. The occupational environment is also a continuously dynamic and experiential context.

The OA Process: Interaction of Internal and External Factors

The internal and external factors are continuously interacting with each other through the modality of occupation. The ongoing interaction of the person's desire for mastery and the occupational environment's demand for mastery creates a third constant: the *press for mastery.* This constant forms the middle of the OA process model. The press for mastery yields the *occupational challenge.* The *occupational role expectations* of the person and of the occupational environment intersect in response to the unique occupational challenge that the individual experiences. A demand for adaptation occurs. The person makes an internal adaptive response to the situation and then produces an *occupational response.* The *occupational response* is the outcome—the observable by-product of the adaptive response. It is the action or behavior the individual carries out in response to the occupational challenge. The occupational adaptation process begins at the top of both the left and right sides of the model at the same time.

The OA Process: Adaptive Response Subprocesses

Within the broad occupational adaptation process, there are three subprocesses that are internal to the person. They are proposed to provide an explanation of the adaptive processes that the individual activates in response to an occupational challenge. The OA subprocesses enable the individual to plan the adaptive response, evaluate the outcome, and integrate the evaluation into the person as adaptation. The three subprocesses are identified as the generation subprocess, the evaluation subprocess, and the integration subprocess.

The *adaptive response generation subprocess* is the anticipatory portion of human adaptation (see Figure 45.2). The generation subprocess is activated by a mechanism that explains how an adaptive response is created. The *adaptive response mechanism* consists of *adaptation energy, adaptive response modes* and *adaptive response behaviors.* The mechanism and the three components are interactive; they are neither liner nor hierarchical. These components provide the resources that the individual draws from to generate an adaptive response to an occupational challenge. The adaptive response mechanism is best understood as a dynamic system (e.g., Davies, 1988; Gleick, 1987; Prigogine & Stengers, 1984).

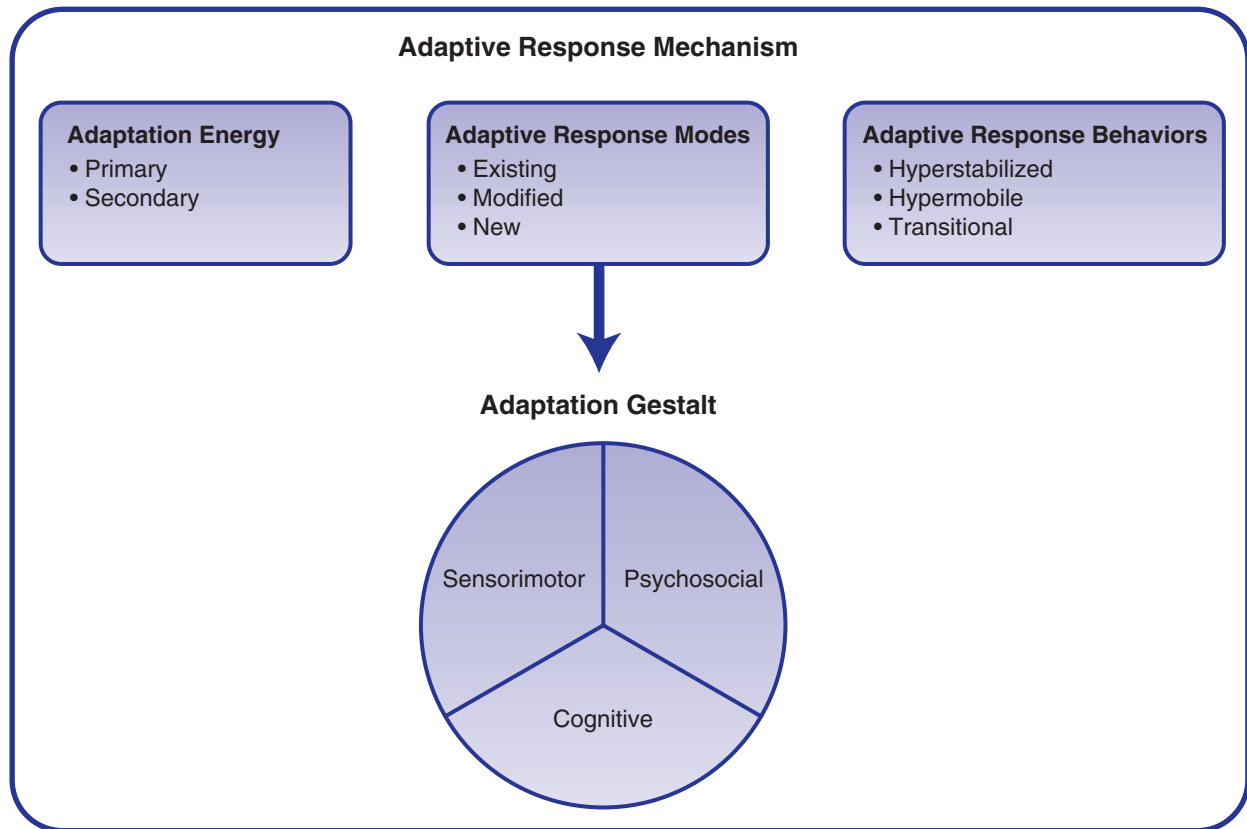
OA theory proposes that the individual uses adaptation energy at either a primary or a secondary level of cognitive awareness. If the individual is at a high level of cognitive awareness when attempting to generate an adaptive response: the *primary* level of adaptation energy is being used.


FIGURE 45.2 The *Adaptive Response Generation Subprocesses* are internal to the person (see Figure 45.1)

If the individual is not highly engaged in creating an adaptive response, a *secondary* level of adaptation energy is being used. To illustrate, an individual may work and work on a problem (using primary energy). When a solution is not forthcoming, the individual might decide to mow the lawn or cook dinner (such routine activities allow secondary energy to continue to process and work on the problem). Often, when the individual returns to the original problem, a "light comes on," and the individual has a new idea—a solution that was elusive while the individual was focused on the problem. In some cases, the solution appears even sooner while the individual is still engaged in the routine activity. The common explanation for this occurrence is something like "I just had to get it off my mind." However, OA theory proposes that the problem was not off the individual's mind; rather, the problem was still being processed at another level, that is, with secondary energy. The following paragraph provides a more thorough discussion on this phenomenon.

The notion of adaptation energy is based on Selye's (1956) research on stress and its effect on adrenal glands in laboratory animals. Selye concluded that unremitting stress led to excessively high use of the adaptive capacity of the animals' endocrinological systems and led to premature death. He posited a general adaptation syndrome to describe this process, and he extrapolated the presence

of a similar process in humans. On the basis of Selye's work and that of Posner (1973), OA theory posits that the above example illustrates the use of adaptation energy, which occurs at both primary and secondary levels of cognitive attention. Posner's notion of information processing at simultaneous or parallel levels was a major influence on this assumption. A second influence was the literature on creative problem solving (Whetton & Cameron, 1984). Creative problem solving involves methods for seeking alternatives to existing approaches ("breaking set") when other attempts have failed to produce solutions.

In the first part of the above scenario, the individual used adaptation energy at the primary level of cognitive awareness. When engaged in the routine activity, the individual had not "gotten it off his or her mind." As the individual changed to other activities, the problem was shunted to the secondary level of awareness. The secondary level is not inferior to the primary level. The secondary level of awareness continues to work on the problem (using adaptation energy) at a more efficient and sophisticated manner than that of the primary level. The idea of a secondary level of cognitive attention bears some conceptual similarities to Ayres's (1972) concept of subcortical processing. However, in the theory of occupational adaptation, the secondary level of cognitive processing is understood to remain within the cortical area of the brain.

The second component of the adaptive response mechanism is identified as the adaptive response modes. This set of modes contains the adaptive patterns or strategies that the individual has established through life experiences. They are classified as existing, modified, or new. Adaptive response modes begin as reflexive or random actions in the infant. They are reinforced as they are generalized to new challenges with successful outcomes. When first confronted with an occupational challenge, the individual usually selects an existing adaptive response mode and acts on it. If the outcome is unsuccessful, the individual may modify the mode and then achieve a successful outcome. The individual develops a new mode when the challenge is a significant departure from those previously experienced. However, the degree of challenge can exceed the individual's experiences and *adaptive capacity.*

The third component is identified as the adaptive response behaviors. According to OA theory, there are three general classes of such behaviors: hyperstable, hypermobile, and transitional. This classification system was drawn from that of Gilfoyle, Grady, and Moore's theory of spatiotemporal adaptation (1990). As with the other two components of the adaptive response mechanism, these behaviors exist within the person's repertoire of experience. When faced with an occupational challenge, the individual selects one of the behaviors to use in response to the challenge. Hyperstable behaviors are those in which the individual either continues to attempt the same solution or becomes "stuck" (e.g., the individual who sits and stares at the computer screen waiting for ideas to come). The individual who selects a hypermobile behavior will move rapidly from one solution to another with a great deal of activity but no resulting product. Transitional behavior is a blending of hyperstable and hypermobile that allows for greater opportunity for a positive outcome.

In summary, when an individual is faced with an occupational challenge, the adaptive response mechanism is activated. The individual will draw from prior experience that is available within the adaptive response mechanism. The individual selects a level of adaptation energy, an adaptive response mode, and an adaptive response behavior to use in adapting to the challenge. At this point, the plan of action has been created. This completes the first stage of generating an adaptive response.

The second stage is equally significant. The individual configures his or her person systems (sensorimotor, cognitive, and psychosocial) to carry out the plan. The configuration results in what is termed an **adaptation gestalt** of the individual's idiosyncratic sensorimotor, cognitive, and psychosocial functioning. Figure 45.2 presents the systems as equally balanced within the gestalt of the whole. However, in real-world situations, the relative balance of the person systems will adjust according to the occupational challenge and the individual's personal functioning. As with the adaptive response mechanism, the adaptation gestalt is also drawn from the individual's previous experience. Gestalts that the individual previously found effective might prove ineffective for future needs. Depending on circumstances, the individual might produce a gestalt that is destined to fail. For example, the challenge might demand a high level of cognitive activity and calm emotions; but because of anxiety, the person's gestalt might be overloaded in the psychosocial and sensorimotor realms and thereby compromise the remaining gestalt available for cognitive processing.

The adaptive response mechanism and the adaptation gestalt produce the internal adaptive response to the occupational challenge. The occupational response is the product of the individual's internal adaptive response. Although the adaptive response is not directly observable, it does become operationalized within the occupational response. The nature of the internal adaptive response can be readily gleaned from careful observation and analysis of the individual's approach to the task, his or her problem-solving methods, and the resulting outcome.

The *adaptive response evaluation subprocess* is activated when the individual assesses the quality of the occupational response (see Figure 45.3). The individual assesses the quality by evaluating his or her experience of mastery. Because this is a personal assessment, the evaluation is relative to the individual—hence the term *relative mastery.* There are four measures within **relative mastery**: efficiency (use of time, energy, resources); effectiveness (the extent to which the desired goal was achieved); satisfaction to self; and satisfaction to society. Relative mastery is inherently phenomenological. If the individual's assessment of the occupational response is positive overall, there is probably little need for further adaptation. If the result is negative, the *adaptive response integration subprocess* (see

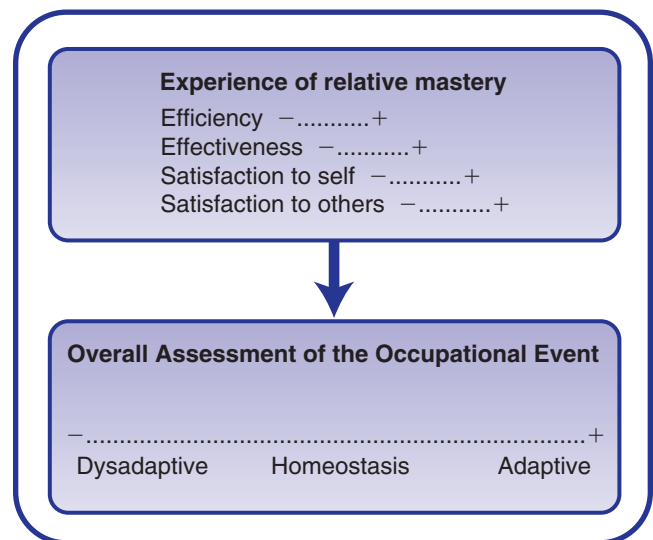

FIGURE 45.3 Adaptive Response Evaluation Subprocess: The *Adaptive Response Subprocesses* are internal to the Person (see Figure 45.1)
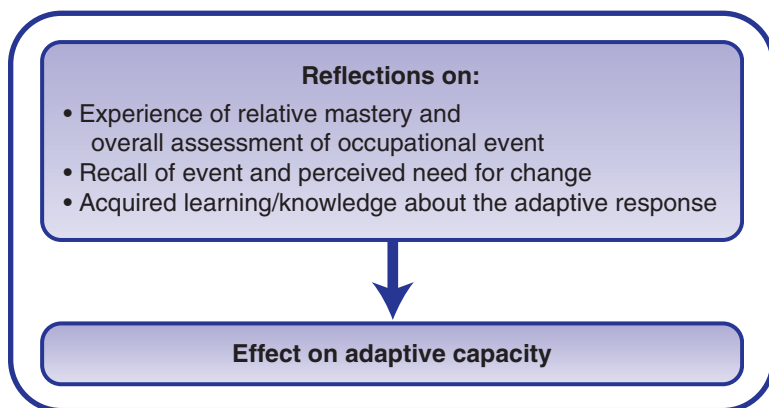

FIGURE 45.4 Adaptive Response Integration Subprocess: The Adaptive Response Subprocesses are internal to the Person (see Figure 45.1)

Figure 45.4) communicates this information to the person. The individual may then generate a modified or new adaptive response in order to better reach the desired level of mastery in any one or all of the measures of relative mastery. The above describes the normative adaptive response generation, evaluation, and integration subprocess.

INTRODUCTION TO PRACTICE BASED ON THE THEORY OF OCCUPATIONAL ADAPTATION

It is often difficult to distinguish between prominent theories of occupational therapy. Students and practitioners have often stated, "There's so much overlap, and it seems like there are only slight differences between the various theories." What is the uniqueness of occupational adaptation for practice? The following provides a reply to this question.

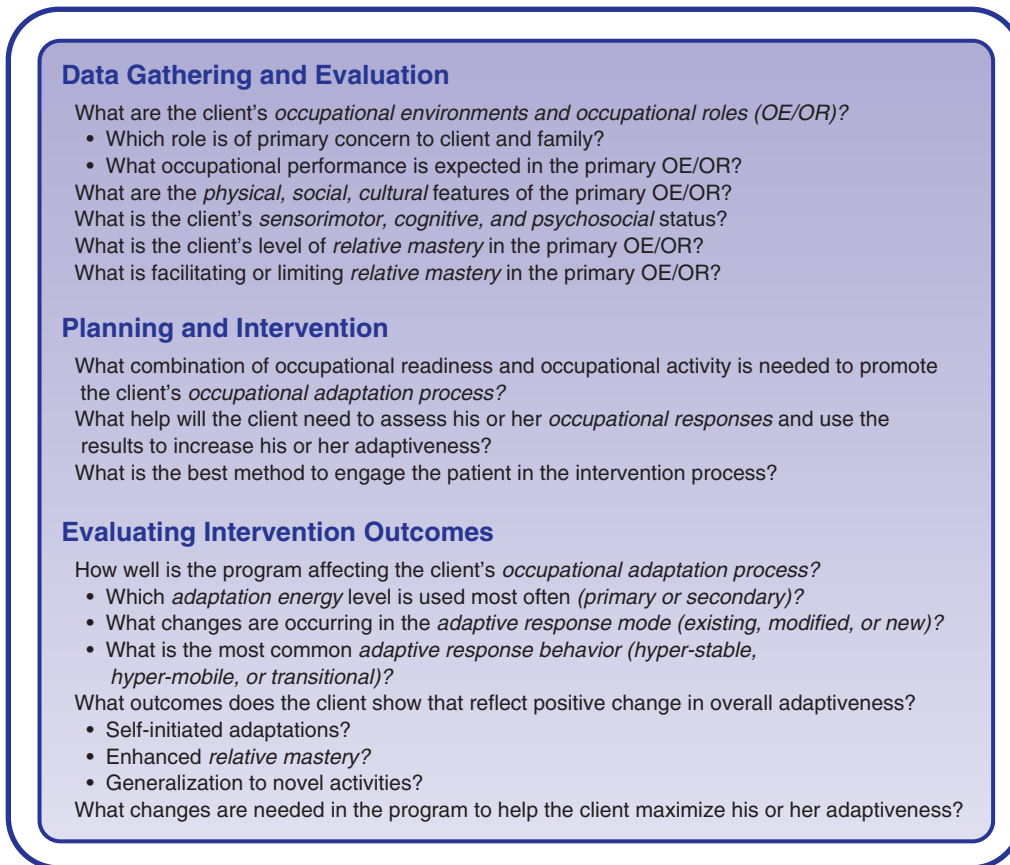
The theory of occupational adaptation directs practice to be focused on the therapeutic use of occupation to promote adaptation. Occupation is the tool. It is the medium that the practitioner uses to improve the client's **adaptiveness**. Therefore, the foremost intervention goal is to maximize the client's effectiveness in using his or her own ability to be adaptive. The theory of occupational adaptation is based on a unique core assumption: that as the individual becomes more adaptive, he or she will become more able to be an active participant in daily life. This is a departure from other prominent occupation-based theories of practice, which emphasize increased function and/or occupational performance as the goal of therapy. All therapy is driven by core assumptions, whether or not these assumptions are in the consciousness of the practitioner. OA theory focuses on developing the individual's adaptiveness. Occupation is the means to accomplish that goal. An OA-based practitioner selects interventions that are congruent with the theory's most basic assumption. The practitioner accomplishes the overarching therapy goal by presenting interventions that will activate and improve the individual's internal adaptation process. The practitioner guides the individual to select an occupational role on

which he or she wants to focus. Individuals will readily identify activities that they want to be able to do. However, it is important for the practitioner to help clients tease out a life role in which they have a significant investment. OA theory posits that activities take on meaning only within the context of a role.

The theory asserts that it is the client's adaptiveness that determines occupational performance. Some individuals are characteristically very adaptive and will respond effectively whether they face a divorce, the birth of a child, a stroke, depression, or a major move to a new city. They take charge of their lives and adapt. They are adaptive people. Others are, by nature, more easily overwhelmed by life's challenges. Their adaptive capacity (ability to generate effective adaptive responses) is limited.

Each occupational therapy client presents with his or her own unique pattern of personal adaptation. Adaptiveness is relative to the individual. Each client also presents with a variety of cognitive, sensorimotor, and psychosocial factors that may impair or facilitate the client's ability to be adaptive. With each added complication, including internal and external role expectations, the demand on the individual to adapt becomes greater and greater.

In an OA-driven practice, the practitioner's focus must be on increasing the client's ability to adapt. The goal is not to help the client adapt. The goal is to help the client become adaptive. In the beginning stage of therapy, the practitioner might teach the client adaptive methods and might introduce assistive devices or teach specific skills (**occupational readiness**). However, the therapy must progress as quickly as possible to **occupational activities** that the client finds meaningful (Frankl, 1984). The OA Clinical and Professional Reasoning Process provides a systematic progression of questions that the practitioner uses to frame his or her overall thinking and therapeutic program (see Figure 45.5). Figure 45.6 presents the OA Guide to Assessment and Intervention.

Clients are most inclined to discover their own ability to adapt when they are challenged within occupational activities, that is, activities that are meaningful, have a beginning and an end, are process-oriented, and have an end product (Schkade & Schultz, 1992). It is human


Data Gathering and Evaluation

What are the client's *occupational environments and occupational roles (OE/OR)?*
  • Which role is of primary concern to client and family?
  • What occupational performance is expected in the primary OE/OR?
What are the *physical, social, cultural* features of the primary OE/OR?
What is the client's *sensorimotor, cognitive, and psychosocial* status?
What is the client's level of *relative mastery* in the primary OE/OR?
What is facilitating or limiting *relative mastery* in the primary OE/OR?

Planning and Intervention

What combination of occupational readiness and occupational activity is needed to promote
  the client's *occupational adaptation process?*
What help will the client need to assess his or her *occupational responses* and use the
  results to increase his or her adaptiveness?
What is the best method to engage the patient in the intervention process?

Evaluating Intervention Outcomes

How well is the program affecting the client's *occupational adaptation process?*
  • Which *adaptation energy* level is used most often *(primary or secondary)?*
  • What changes are occurring in the *adaptive response mode (existing, modified, or new)?*
  • What is the most common *adaptive response behavior (hyper-stable,*
    hyper-mobile, or transitional)?
What outcomes does the client show that reflect positive change in overall adaptiveness?
  • Self-initiated adaptations?
  • Enhanced *relative mastery?*
  • Generalization to novel activities?
What changes are needed in the program to help the client maximize his or her adaptiveness?

FIGURE 45.5   Occupational Adaptation: Therapeutic Reasoning Process

nature to be motivated to participate enthusiastically if the activity is personally meaningful. The individual's attraction to the activity fuels the desire to adapt. The client's *adaptive capacity* is triggered by meaning. Meaningful activity gives the practitioner a powerful tool to observe the client's internal adaptation process. Adaptation patterns that interfere with the client's ability to adapt can be readily observed. The practitioner intervenes when opportunities are presented during the client's engagement in the activity. Such opportunities are typically inherent in the activity and call for the client to make an adaptive response. The practitioner seizes this window of opportunity to facilitate the client's adaptiveness. The intervention may focus on the client's overall approach to the problem, difficulty generating an adaptive response or evaluating the effectiveness of responses, repetition of ineffective techniques, diminished adaptive capacity, depression, frustration, and so on. These are common roadblocks that interfere with the client's *adaptive response processes.* The practitioner intervenes through a progressive system of posing questions and making observations to the client. The framing of questions and observations is tailored to the client's cognitive and psychosocial functioning. The practitioner guides the client, through questions and observations, to assume the role of decision maker and problem solver. The practitioner provides no more direction than is absolutely essential. It is better to err on the side

of too little direction than too much. The more the practitioner directs, solves, and teaches, the less adaptive the client will become.

The therapeutic relationship is of critical significance in the theory of occupational adaptation. The relationship evolves into an artful dance between the client and practitioner. It is a partnership in which the client takes the lead. The practitioner becomes the facilitator. That is, the practitioner's function is to help the client discover his or her own ability to be adaptive. The practitioner is the agent of the occupational environment. The client is the agent of change (Schkade & Schultz, 1993).

INTERRUPTION IN THE OA PROCESS

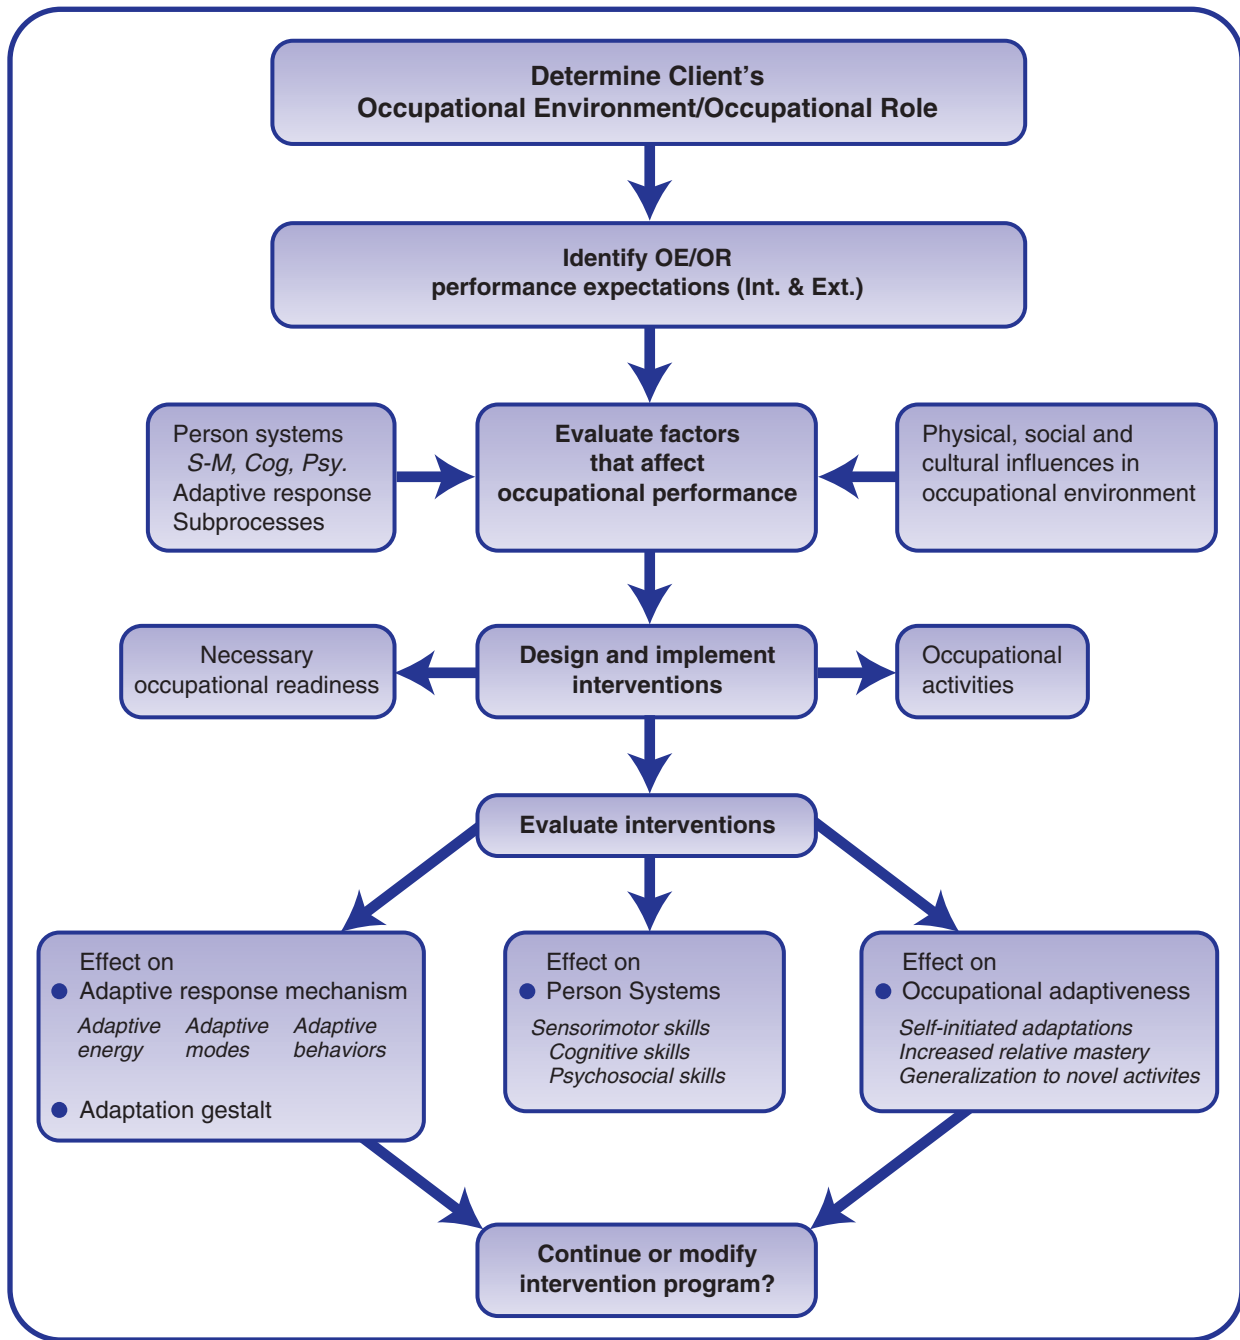
Although the theory of occupational adaptation is not about mastery, per se, it is the constant presence of the desire, demand, and press for mastery that provide the impetus for the individual to adapt. In other words, these constants are pervasive and ongoing influences. As long as the individual can reach a mutually satisfactory balance between the desire and demand for mastery, the normative occupational adaptation process (see Figure 45.1) is working effectively and occurs with little fanfare. Day-to-day challenges occur, and adaptive responses are generated, evaluated,


FIGURE 45.6   Occupational Adaptation: Guide to Evaluation and Intervention

and integrated. The individual is able to draw from the existing person systems and repertoire of adaptive responses in order to produce a satisfactory outcome.

When the normative OA process is seriously disrupted, the person's adaptive responses are often inadequate. Impairments in person systems place significant limits on the individual's ability to effectively use former or existing adaptive responses. Cognitive issues often further limit the ability to adapt. Depression emerges, and the person's relative mastery becomes lower and lower. This sce-

nario is a common occurrence for clients who are referred to occupational therapy. The challenges exceed the client's ability to adapt.

The case study depicts a school-based situation. However, the approach will be the same whether the client is a hospital patient with a stroke or a mother with a fragile premature baby. OA-based therapy is focused on working with the client to develop his or her ability to respond more adaptively to occupational challenges. At times, occupational readiness needs may supplant those for increased

CASE STUDY: *Alfonso Learns a New Response to Frustration*

Claudette greets Alfonso at the door as he enters the classroom. "Hello, Alfonso, my name is Ms. Murphy. Welcome to the group. Why don't you look around for a while . . . we can talk some later." As Alfonso begins to find his way into the occupational environment, there is a notable hum of activity—talking and doing. The group members (six altogether) notice Alfonso. Some greet him; others don't. He hesitantly observes a couple of the boys working on their individual projects. Claudette notices that Alfonso is waiting for her to take control. He is reluctant to touch any of the materials. He glances toward Claudette for direction. She slowly nods and turns her attention to another student. Claudette's manner of including the student in the group is integrally related to her intervention approach.

The group is grounded by the theory of occupational adaptation. This is reflected in the therapeutic tools that Claudette uses (see Box 45.1). One tool is her management, or agency, of the therapeutic occupational environment (OE). The second is Claudette's management of herself, that is, her ability to incorporate "therapeutic use of self" in the therapy sessions. This skill is intrinsically interwoven throughout the case study. The reader is referred to the early classical work of Gail Fidler (1963) for elaboration on specific methods and techniques. The third tool is Claudette's understanding of how occupation can be used to help an individual become more adaptive and respond more effectively to occupational challenges. The fourth and most powerful tool is her unwavering acceptance of the student as the agent of change.

Occupational activities (arts and crafts that are meaningful to the students) are the chosen intervention modality. The media are selected for their range of occupational challenge and attractiveness to the students. Some of the media are inherently structured; others are very open-ended. Claudette has very carefully created the nature and substance of the therapeutic OE; that is, she arranged the physical space, selected the media, and established the social climate and cultural standards for the therapy group.

Claudette follows the clinical and professional reasoning process identified in Figure 45.5. The practitioner must engage in the reasoning process to design appropriate OA-based interventions. The format in Figure 45.5 prompts the practitioner on what questions he or she must ask throughout the course of therapy. Figure 44.6 presents a model of intervention that puts into action the reasoning presented in Figure 45.5. Claudette's methods and interventions are consistent with both Figures 45.5 and 45.6.

In school-based therapy, the OE and related occupational role are predetermined. The overarching OE focuses on education-related work and play. (Each has its own physical, social, and cultural influences.) The occupational role is, by definition, that of being a student. The OE has a specific demand for mastery and occupational role expec-

tations (see Figure 45.1) of the student. These include a demand for a minimal level of performance in learning and behavior. Before meeting Alfonso, Claudette completed her assessment of the general OE in which Alfonso is a participant. She also assessed the OE's occupational role expectations for Alfonso. She found that school personnel expect Alfonso to cause trouble and to drop out of school when he is old enough. These are the actual occupational role expectations that Alfonso experiences, day in and day out.

As is shown in the OA process model (Figure 45.1), an individual's occupational role expectations are affected by those of the OE. After the initial therapy sessions, Claudette deduces that Alfonso has been strongly affected by the school's expectations. In fact, he has integrated them as his own. His innate desire for mastery has become one of a power struggle with the OE. He and the school are enmeshed in a no-win situation.

Claudette has also reviewed the school's records on Alfonso's person system deficits. His attention deficit disorder, hyperactivity, and difficulty with reading are clearly documented. She could incorporate occupational readiness interventions with the goal of increasing his ability to stay on task and help him learn how to better regulate his hyperactivity. Claudette has also observed during the therapy groups that Alfonso has a severe developmental delay in his adaptive response subprocesses. See Figures 45.2, 45.3, and 45.4 for further clarification. (These subprocesses are internal to the person.) Claudette has observed that whenever Alfonso has difficulty with projects, he tends to generate the same adaptive response mode repeatedly: He experiences himself as a failure. He routinely acts out this mode by tearing up the project or work. making a joke out of his work. or causing trouble with another student in the group. Alfonso's teacher reports that this situation is also a frequent occurrence in the classroom.

As a result of his adaptive response mode, Alfonso's adaptation gestalt (Figure 45.2) is composed largely of angry emotion and sensorimotor agitation. Very little cognitive activity is present within the adaptation gestalt. As a result, the next step in his adaptive subprocesses, the evaluation of outcome, does not occur (see Figure 45.3). His adaptation gestalt doesn't allow room for very much cognitive reasoning. Claudette concludes that it is very unlikely that Alfonso will respond more effectively to occupational challenges unless he acquires new or modified adaptive response modes. His current sense of himself as a failure (the adaptive response mode) leads to an occupational response (behavior that is observed) that is neither efficient, effective, nor satisfying to himself or others. His relative mastery is very low.

Claudette completes her assessment of the factors that are affecting his occupational performance (see Figure 45.6)

Continued

CASE STUDY: *Alfonso Learns a New Response to Frustration* *Continued*

and concludes that her interventions should be focused on increasing Alfonso's ability to generate a more effective adaptive response mode. Because Claudette's practice is OA-based, she will not focus therapy on changing Alfonso's behavior; this would be incongruent with the theory. Claudette's interventions will be designed to expand his adaptive response repertoire with a new mode, such as "When I have trouble with a project, I can stop and figure out what the problem is." This will be an entirely new response mode for Alfonso. As he begins to acquire the new mode, it will affect his adaptation gestalt by decreasing the negative emotion and agitation that is present and freeing up space in the gestalt for cognitive processing. With his current adaptive response mode, Alfonso is at the mercy of his emotions. They are in control. As he experiences an adaptive response mode in which he has a greater sense of mastery, he will have the potential not only to control his emotions, but also to control his behavior.

Claudette plans to work with Alfonso using occupational activities that he self-selects. Most occupational therapy is driven by the assumption that if the client becomes more functional, he or she will be able to adapt. The theory of occupational adaptation takes the exact opposite point of view. Practice based on occupational adaptation is driven by the assumption that if the client becomes more adaptive, he or she will be able to function.

Through activities that Alfonso enjoys and finds meaningful, Claudette can more closely observe his adaptive processes and begin to intervene as appropriate. On the basis of OA theory, Claudette believes that Alfonso must develop the wherewithal to respond to occupational challenges in new ways. Her method will be to facilitate this through the four core intervention tools listed in Box 45.1. Claudette's challenge is to seize the opportunities for intervention that Alfonso presents during occupational activities. Intervention in the adaptive response generation subprocess cannot occur after the occupational response (observed behavior). The intervention must occur at the same time that the client is beginning to generate an adaptive response. This is a brief "window" that tends to open and close very quickly. Catching the window is an artful skill that requires a great deal of practice. To accomplish the goal, Claudette realizes that she must use each of the four therapeutic tools. The following presents an example of how the four tools may actually play out in a practice situation.

As she continues to observe Alfonso's adaptive response patterns and resulting occupational responses, Claudette begins to recognize the cues for when the opportunity for intervention might present itself. She sits next to Alfonso, makes a general matter-of-fact comment, and begins to watch and wait. He has started a project, a soapbox derby–type wooden car. This is his second attempt. Claudette

believes that his desire for mastery in the activity is beginning to emerge. The first car ended up in the trash after he tried to hammer the axle into the tire rather than sanding the axle. Soon, he faces the same challenge as he had with the first wooden car. He starts to pick up the hammer. The window for intervention has presented itself. Claudette believes that the most direct route to Alfonso's adaptive response mode will be through his adaptation gestalt. His adaptation gestalt is so overweighted with emotion and tension that the adaptive response mode is not readily available for therapeutic access. Claudette's therapy begins with a technique that she believes will have the desired positive effect on his gestalt. She will accomplish this through her role as agent of the OE. Claudette initiates the intervention by slowly stating to the student (as she reaches for the axle and wheel), "I wonder why this thing is so hard to get in here?" It is a rhetorical statement, not really a question to Alfonso. It is an observation that she is making aloud for the student to hear. It is as if she is giving a voice to the adaptive response mode ("I can stop and figure this out") that Alfonso lacks. She is not teaching it to him; she is showing it. As she quietly and slowly manipulates the objects, Claudette notices that Alfonso has sat back some in his chair; his adaptation gestalt appears to be changing. He relaxes somewhat; his affect softens. Claudette has used her agency of the OE to affect his adaptation gestalt. With calmness and curiosity, she has assumed physical control of the derby car. Her action reduces the sensorimotor demands that Alfonso was experiencing. The change in his OE allows him to distance himself from the emotions that he was experiencing as well. Through her management of the OE, Claudette has promoted a powerful shift in Alfonso's adaptation gestalt. Shortly, he exhales loudly, "Whew!" After a few moments, Claudette responds to his verbalized self-awareness. She comments, "It's frustrating when things don't work!" (The fewer the words, the more powerful the impact.) Again, her comment is not being made directly to Alfonso. It is an observation that is presented for him to hear and perhaps use, allowing him to gain some control over his emotions by turning feelings into a cognitive thought.

As a result of the intervention, Alfonso experienced a new adaptation gestalt. Claudette now directs the intervention toward his first experience with the new adaptive response mode ("I can stop and figure things out") by presenting him with another observation. "Well," she says, "You tried hammering it in before, and that didn't work, so. . . ." Claudette's observation is the first step in helping Alfonso to develop the new mode. She is prompting him to experience himself in the new mode—that is, to experience himself as a problem solver. The key to the interventions being described is that they are not artificial. They are not

contrived or role-played; they occur in vivo. Alfonso interjects with excitement, "Maybe it's just a crummy kit. I'll get another one." Alfonso retrieves another car and soon discovers the same problem. His enthusiasm drains away. Claudette does not become enmeshed with his disappointment. She maintains her therapeutic focus and again initiates an intervention to affect his adaptation gestalt by managing the OE. She states aloud, "Hmm, I wonder if the directions say anything about how to put the axle in the wheel." She has again made a statement that prompts Alfonso to be in the problem solver role. Alfonso replies, "I don't know, I don't like directions." This is a pivotal point in the intervention. Because it is the first direct intervention with Alfonso, Claudette knows that she needs to provide enough support but no more than is absolutely necessary. Claudette also believes that Alfonso finds the project very meaningful and might be willing to risk trying to read the instructions. (The instructions are consistent with his read-

ing potential.) As may be anticipated, he attempts to replay his typical battle with the OE by stating to Claudette, "Why don't you show me what to do? Isn't that your job?" Claudette matter-of-factly replies, "It's not my project . . . it's yours." She is careful to offer this statement with the same delivery as her others. It is presented merely as an observation. Through such a comment, she communicates her commitment to Alfonso that he is the agent of change. His comment was a test of her authenticity. Claudette will continue to work with Alfonso, following the principles of OA and using the four core therapeutic tools. Each intervention will be focused on helping him to acquire a new adaptive response mode ("I can stop and figure things out"). As he begins to assume the new mode, Claudette will shift her focus to the second subprocess: his ability to evaluate the outcome of his adaptive response. Figures 45.5 and 45.6 provide the reader with a more in-depth explanation of the complete process of evaluation and intervention.

adaptiveness. This is a judgment that the practitioner makes. Many times, both can be addressed during therapy. The greater the severity of impairment or limitation, the greater is the need for the client to become as adaptive as possible.

STRENGTHS AND LIMITATIONS

The theory of occupational adaptation presents practitioners with a theoretical orientation that is holistic. Its assumptions adhere to the ideas of occupation and adaptation that are inherent in the profession's history and philosophy (Schultz & Schkade, 1997). It provides an organized way to think and communicate about occupational therapy intervention that is occupation-based, process-oriented, and client-focused. Another strength is OA's compatibility with terminology from the World Health Organization

BOX 45.1   ## OCCUPATIONAL ADAPTATION: CORE THERAPEUTIC TOOLS

1. Practitioner is the agent of the occupational environment.
2. Practitioner incorporates principles of therapeutic use of self.
3. Practitioner uses occupation to promote adaptiveness.
4. Client is the agent of change.

(2004) and its concern with the ability of individuals and groups of individuals to participate fully in society. From an OA standpoint, occupation plays a significant role as a facilitator of social participation. Likewise, dysfunction in occupation becomes a significant factor in limiting social participation. The theory of occupational adaptation provides practitioners with one way to think about, describe, and plan occupation-based intervention.

Practitioners often question whether the theory of occupational adaptation is applicable to people with an impaired cognitive system. This is an unfortunate misunderstanding of the theory. The theory of occupational adaptation is as applicable to people with cognitive deficits as to those with sensorimotor or psychosocial deficits. The demand to adapt is as great for someone with a severe cerebral vascular accident (CVA) as it is for someone with a hand injury. The practitioner must adjust communication and methods of intervention to suit the person's ability to process information. The goal remains to help the person become as adaptive as possible. The more the individual is unable to manage his or her person systems, the more the practitioner must manage the occupational environment to facilitate the person's potential to experience the highest possible level of relative mastery.

At times, the primary avenue for communication with the person might be limited to the sensorimotor system. The effectiveness of such intervention was borne out in the author's consultation with a state hospital for adults with severe and profound mental retardation. The direct care staff used a reward system with the patients. When the clients were "good," that is, compliant with care routines and not yelling out, they were rewarded with the desired

stuffed animal, music, or video. The staff was attempting to stop the patient's negative behavior. Change was externally driven. I worked with the staff to redesign the rehabilitation program to reflect the residents' occupational interests. A daily schedule of occupational activities was created for each person. Routine care was reframed from that of tasks that the staff must do for the patients to tasks that will help the patients to do what they found meaningful. The new objective was to increase the residents' experience of mastery over their environment. The necessity of turning the patient to prevent bedsores became one of positioning with purpose—for example, in order to watch the preferred video or to better hold the stuffed animal. For a patient who hated bath time, the preferred music helped her to relax. The occupational environment was managed so that residents had the potential to increase their experience of mastery over situations that they disliked. In the OA approach, change was driven by the patient's preferences. As a result of the patients' increased sense of relative mastery, they demonstrated less spasticity and fewer emotional outbursts. Although unable to communicate their relative mastery through words, they expressed it very clearly through their sensorimotor system.

Another limitation of this intervention approach lies within those practitioners who are willing to stay enmeshed in intervention practices and settings of the past 50 years. Such practitioners believe that intervention based on meaning is not practical in the everyday world of practice. These providers appear indifferent to the wide variety of modalities that a practitioner may use in practice. Outcomes are the issue at hand for practice. Research based on occupational adaptation interventions supports the notion that clients whose therapy has been based on meaningful activity and the development of adaptiveness will outperform those whose therapy has concentrated on activities of daily living that might have little meaning for the clients (e.g., 1999; Buddenberg & Schkade, 1998; Dolecheck, & Schkade, Ford, 1995; Jackson & Schkade, 2001; Johnson & Schkade, 2001).

Another frequently mentioned limitation is the lack of an OA assessment tool. I have been reluctant to encourage development of such a tool for several reasons. From my point of view, the most significant deficit that the profession faces is that the majority of practice is not theory driven. It appears that assessment tools are driving practice. Practitioners seem to prefer to use a static measure, rather than a theory, to guide their thinking process. This affects the nature of practice and the quality of research that can be carried out. A theory-driven practice is mandatory for occupational therapy to become clearly differentiated in health care. OA assessment is inherent in the Therapeutic Reasoning Process (see Figure 45.5). The new OA Guide to Evaluation and Intervention (Figure 45.6) was developed to provide additional direction for the therapist. It appears there are some dynamic systems process-oriented approaches to assessment that may be compatible with the theory of occupational adaptation and are worthy of exploration.

RESEARCH

Research on the effectiveness of OA intervention has included various methods. Most have been quasi-experimental with random assignment to treatment and control groups. There have been two main OA assumptions and related outcomes under study. The first assumption is that OA-based interventions will have a greater effect on functional independence than therapy based on traditional activities of daily living. The second OA assumption is that OA-based interventions will result in greater generalization of skills learned in therapy than traditional occupational therapy rehabilitation methods. The Functional Independence Measure (FIM) was used to test the first assumption. Performance on a patient selected novel activity was used to test the second assumption. In Gibson and Schkade (1997), the FIM scores of CVA inpatients were significantly higher on eight of the FIM scores than those of the control group. Jackson and Schkade (2001) conducted a similar study with hip fracture in-patients and found comparable FIM results. Buddenberg and Schkade (1998) researched generalization of skills learned in therapy to novel activities with hip fracture inpatients. The OA-based group performed significantly better on tasks on which they had not been previously trained than the control group. Dolecheck & Schkade (1999) studied the affects of an OA-based program with CVA in-patients. They served as their own control group over a period of six weeks. The patients were able to stand longer when engaged in personally meaningful occupation than when engaged in the facility's traditional occupational therapy. Johnson & Schkade (2001) conducted a single subject study with three CVA patients who had been discharged from home health because of insufficient progress in mobility. At the conclusion of the OA-based intervention, each of the patients made significant gains in mobility, self-care, and overall level of activity level. This description represents a portion of the research efforts to evaluate the effectiveness of OA-based interventions in practical applications.

CONCLUSION

The theory of occupational adaptation is presented as an overarching theory for practice. Traditional interventions such as neurodevelopmental approaches, sensory integration, and biomechanics are readily interfaced as part of the occupational readiness portion of intervention planning. Occupational readiness interventions are limited to addressing deficits in the person systems. The focus in such interventions is on improved performance. However, OA embraces a broader perspective. Intervention is focused on increasing the patient's adaptiveness.

OCCUPATIONAL THERAPY PRACTICE

"A client-centered intervention in which the occupational therapy practitioner and client collaboratively select and design activities that have specific relevance or meaning to the client and support that client's interests, need, health, and participation in daily life."

Occupational Therapy Practice Framework, American Occupational Therapy Association

The Occupational Therapy Process

JOAN C. ROGERS AND MARGO B. HOLM

Learning Objectives

After reading this chapter, you will be able to:

1. Explain the occupational therapy process and discuss the importance of each of its components.
2. Apply the Person-Task-Environment transaction to client cases.
3. Discuss the advantages and disadvantages of three approaches to implementing the occupational therapy process: bottom-up, top-down, client-in-context.
4. Develop a structured problem statement to guide intervention and explain its usefulness for guiding intervention.

This chapter focuses on the occupational therapy process and consists of eight major sections. In the first section, we present an overview of the occupational therapy process and its major components: theory, evaluation, problem definition, intervention planning, intervention implementation, and re-evaluation. In the second and third sections, the salience of theory in explaining occupational performance—the transaction of the person, task, and environment—is traced historically and then each of the three factors is elaborated on in detail. This discussion provides the background for understanding the complexity of the behavior that occupational therapy practitioners evaluate and treat. In the fourth through seventh sections, the remaining components of the occupational therapy process are discussed in turn—evaluation, problem definition, intervention planning and implementation, and re-evaluation. Section eight revisits the entire occupational therapy process to emphasize its integrative nature. The chapter ends with a conclusion.

OVERVIEW OF THE OCCUPATIONAL THERAPY PROCESS

The **occupational therapy process** is the therapeutic problem-solving method used by practitioners to help clients improve their occupational performance. It consists of six major components—theory, evaluation, problem definition, intervention planning, intervention implementation, and re-evaluation (Figure 46.1) (Line, 1969; Rogers & Holm, 1989). During evaluation, practitioners systematically collect and organize data about occupational performance. During problem definition, these data are synthesized to formulate a profile of the client's abilities and disabilities in occupational performance, and to delineate problems that are to be targeted through occupational therapy interventions. During intervention planning, specific occupational therapy strategies and modalities for alleviating targeted problems are proposed. Simultaneously, **outcomes** are established to mark the endpoints of therapy and serve as markers of the effectiveness of the intervention plan. During implementation, the intervention plan is operationalized, that is, actions are initiated to achieve the stated outcomes. During re-evaluation, the same data that were collected during the evaluation that led to problem definition are re-collected. Initial data are matched to re-evaluation data to determine if the anticipated, stated outcomes were met. If intervention outcomes are met, new outcomes, appropriate for the client's improved performance, are added or occupational therapy services are discontinued, because they are no longer needed. If the outcomes are not met, the outcomes or the intervention plan are modified, or occupational therapy services are discontinued, because maximum benefit has been achieved. At any point in the process, occupational therapy practitioners may refer clients for other occupational therapy (e.g. special services, such as a driving or a home safety evaluation), medical, educational, or social services.

The occupational therapy process is theory-based and data-driven. (In this chapter, our use of the term *theory* is synonymous with that of frame of reference, conceptual model, theoretic framework, conceptual framework, or framework as discussed in Chapter 42). In Figure 46.1, the theory component of the process is represented by the oval at the top of the diagram. Each component of the occupational therapy process is influenced by the theory the practitioner uses to explain occupational performance in a particular client. The underlying theory determines the data that are to be collected, the meaning of that data and its organization into problem statements, the selection of interventions to manage identified problems, the timing and duration of interventions that are implemented, and the choice of outcomes to be used to evaluate whether the interventions achieved the intended purpose.

Like many helping professions, occupational therapy is a multitheory profession. This means that practitioners adhere to several theories (e.g., neurodevelopment, Model of Human Occupation, biomechanical frame of reference, rehabilitation frame of reference) to explain occupational performance on not just one theory. These theories have been generated by occupational therapists (e.g., Model of Human Occupation), other rehabilitation practitioners (e.g., rehabilitation theory), and other professionals (e.g., developmental model). Different theories may be applied to achieve different outcomes. For example, the Model of Human Occupation may be used to revitalize daily living habits, while the biomechanical frame of reference may be applied to restore transfer skills. Different theories may also be applied to the same performance problem to achieve the same outcome. For example, in a client with upper extremity weakness, independence in feeding (outcome) may be achieved using the biomechanical approach, through functional resistive activities to increase upper extremity strength. However, in the same client, feeding independence may also be accomplished using a compensatory approach—using eating utensils with enlarged handles that substitute for reduced hand grip strength. Accordingly, if a stated functional outcome is not well managed by one theory, another theory may be tried. When one theory replaces another theory, the entire occupational therapy process is repeated.

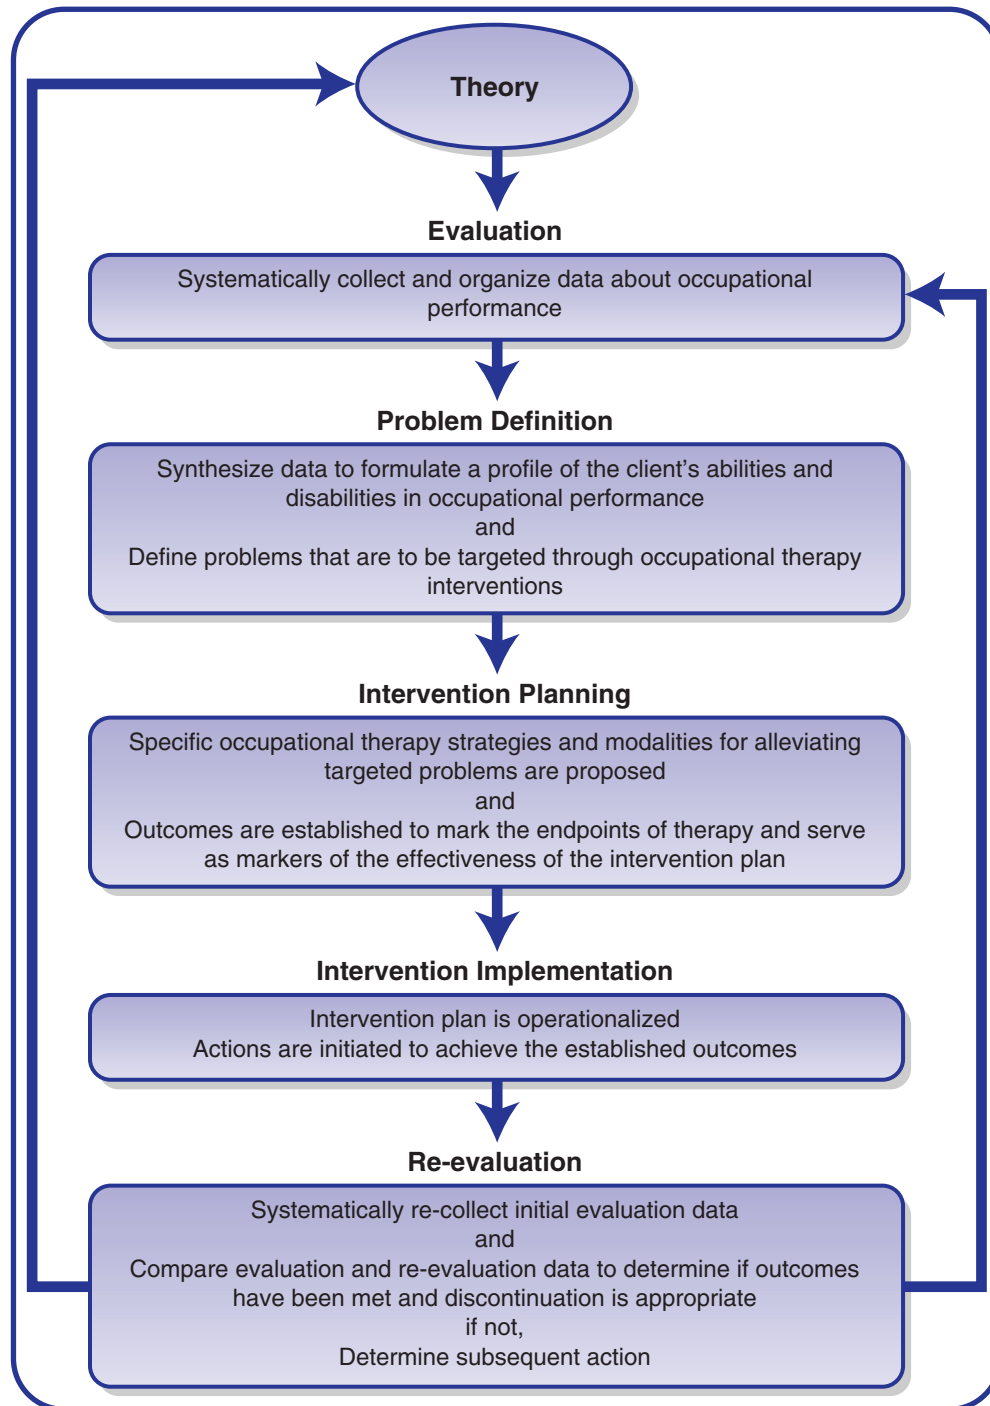
As the science underlying occupational therapy progresses, more data about the effectiveness of occupational therapy interventions will be available, and the occupational therapy process will become more precise. Information on


FIGURE 46.1 The occupational therapy process.

specific occupational therapy theories is addressed in other chapters in this book (see Units VIII, X, XI, and XII). What is important to realize in this chapter is the pivotal role that theory plays in directing the occupational therapy process.

Several characteristics of the occupational therapy process warrant highlighting in addition to its reliance on theory.

1. First, the occupational therapy process of evaluation, problem definition, planning, implementation, and re-evaluation is generic. Its basic structure is neither condition (disease, trauma etc.) nor age specific and is culturally sensitive. It supports all therapeutic reasoning, regardless of occupational construct (e.g., occupational area, performance skills or patterns) or theory

(e.g., sensory integration, occupational behavior). It can be applied in any practice setting—hospital, outpatient clinic, client's home, school, or workplace. The process becomes specific in the practice situation depending on a client's condition; the practitioner's skill, knowledge, and experience; and, the client's reason for seeking occupational therapy services.

2. Second, the occupational therapy process is dynamic. In introducing the occupational therapy process, the five major components were presented as though they occurred in a linear sequence, with evaluation followed by problem definition followed by intervention planning and so on. However, in the practice situation, the components are highly interactive. For example, practitioners formulate and refine problem statements in "real time" as data are collected, rather than waiting until all evaluation data are gathered (Elstein, Shulman, & Sprafka, 1978).

3. Third, in addition to being dynamic, the process is cyclical. For example, when re-evaluation data indicate that the intervention plan is not achieving desired results, the plan is revised, thus there is movement from component 5 (re-evaluation) to component 3 (plan). Similarly, as some performance problems are resolved (e.g., sitting balance), other problems may be targeted (e.g., dressing or computer usage). Thus, having completed the process for one problem the practitioner may begin the process anew for other problems.

4. Fourth, the occupational therapy process is accomplished collaboratively between clients and their advocates and practitioners (Cipriani et al., 2000; McAndrew, McDermott, Vitzakovich, Warunek, & Holm, 2000). The validity of evaluation and re-evaluation data rests on clients' willingness to respond openly and truthfully when interviewed or on questionnaires and to put forth the needed effort during performance testing. Problem definition takes into account clients' preferences and priorities. Stated outcomes center on activities that are meaningful to clients in their living, working, and playing environments. Occupational therapy interventions require the active participation of clients in developing the skills and habits required in daily living.

5. Fifth, the occupational therapy process is problem-focused. The statement of the problem or 'occupational diagnosis' is pivotal for intervention planning (Rogers & Holm 1989; Rogers & Holm, 1991). An accurate description of the problem (what is dysfunctional and why) is critical for selecting the most efficacious intervention (solution) for achieving specific outcomes (desired results). With the advent of occupational therapy practice in preventive, health promotion, and wellness settings, the definition of problem needs to be broadened to include potential problems as well as existing problems. Problems may potentially develop in the near (e.g., prediction of upper extrem-

ity musculoskeletal pain with prolonged typing) or distant (prediction of diabetes and related sensory problem in clients who are presently obese) future. Awareness of potential problems reflects a proactive approach that does not wait until problems develop but rather recognizes conditions that portend problems and seeks to manage them before they cause harm.

6. Sixth, the occupational therapy process is results-oriented. The entire process is intended to achieve an outcome (Evans, Small, & Ling, 1995). Occupational performance is expected to change, in a positive direction, as a result of intervention.

7. Lastly, the occupational therapy process provides the foundation for therapeutic reasoning but it is distinct from it. It outlines the building blocks for thinking but it does not explain how practitioners move from one component to another or how they integrate information efficiently and effectively to make therapeutic decisions.

OCCUPATION PERFORMANCE: HISTORICAL PERSPECTIVE

Because occupational performance drives the entire occupational therapy process, it is critical for practitioners to understand its nature and appreciate its complexity. Occupational performance is hypothesized to be a function of the **transaction** between factors internal (person) and external (task and task environment) to humans. The operative word in this equation is transaction, which requires that the person, task, and environment be viewed as a single, integrated unit as opposed to three separate units, with the task and environment being viewed in isolation from the person (Wachs, 1999). Transaction implies negotiation for the purpose of reaching agreement, that is, a balance or equilibrium among person (client) and task and environment factors that optimally supports occupational performance. If occupational therapy practitioners are to understand occupational performance, and evaluate it with the goal of improving performance, the client must be perceived as connected to the task and the environment or environments in which the task usually occurs.

Thus, incorporating the transactional perspective into the occupational therapy process requires not only that client, task, and environmental factors be considered, it requires that the three factors be considered *together*. When *evaluating* bathing performance, for example, it is not sufficient to evaluate client factors, (e.g., upper and lower musculoskeletal capacities) in isolation from the demands of bathing (e.g., reach feet, reach faucet) and of the bathing area (e.g., bathing equipment, wet tub, caregiver support for independent bathing). Similarly, when *intervening* to improve bathing (task) safety, recommending a safety device, such as a bathtub rail would be useless unless the recommendation was accompanied by client

(person) and caregiver (environment) training in using the device for bathtub transfers.

Just as juggling three balls increases the difficulty of juggling, so too evaluating three distinct but integrated factors and intervening to change one, two, or three of these factors to achieve optimal performance is extremely complex. Early leaders in occupational therapy acknowledged the contribution of the environment to occupational performance, with Slagle (1922), Meyer (1922), and Haas (1944) suggesting adapting the environment to improve clients' performance. However, serious attempts to elucidate this complexity and translate early occupational therapy philosophy into practice models date from the 1980s. Since then a series of ecological models concerned with interactions between people and their environments have been developed by occupational therapy and rehabilitation theorists to assist practitioners in understanding the person-task-environment transaction. A brief review of these models in occupational therapy and rehabilitation and healthcare is instructive for fostering understanding of occupational performance.

Person-Environment Models in Occupational Therapy

In 1982, Rogers borrowed concepts from the behavioral sciences to modernize and enrich the fundamental premises about the link between functional independence and the environment. Independent behavior was viewed as a result of the interaction between the competence of the person and the demands of the physical, social, and temporal environments. Normally, habits of daily living enable humans to respond automatically and appropriately to a variety of environmental demands. The balance achieved between personal competence and environmental demands may be disrupted by physical, cognitive, and affective impairments related to disease, accident, developmental disorders, or advanced age. A fundamental therapeutic strategy for increasing functional independence reduced by these impairments is to initially lower environmental demands, and then raise them gradually as competence improves. Kiernat (1982) further articulated the concept of the environment as a therapeutic modality.

Barris (1982) developed the concept of environment proposed by Kielhofner and Burke (1980) in the Model of Human Occupation. Accordingly, individuals choose environments to become involved with based on environmental properties such as novelty, complexity, and compatibility with interests and values. Environmental demands for performance, which are associated with the people and objects in the environment, strongly influence the development of roles, habits, and skills. The development of competence involves the ability to interact successfully with an increasingly broader range of environments. Thus, Barris clarified three aspects of person-environment interrelationships and the ways in which choice, objects, and settings can be used therapeutically.

Howe and Briggs (1982) formulated the Ecological Systems Model in which humans and their environments shape each other. People are at the center of the ecosystem and are surrounded by three interacting environmental layers—the immediate setting, social networks and institutions, and ideology. These layers make up the life space for the performance of life tasks and roles. Behavior is functional when person–environment interactions enable individuals to achieve goals that are consonant with their view of quality of life. Goal achievement involves adaptation to changing environments and by changing a client's relationship to the environment the adaptive process may be called forth therapeutically.

When defining occupation, Nelson (1988) distinguished between occupational form and occupational performance. He argued that occupational performance, or action, can be understood only in the context of occupational form—that is, "an objective set of circumstances, independent of and external to a person" (p.633). One dimension of occupational form involves the physical stimuli present in the environment, including the materials used, the surrounding environment, the human context, and temporal relationships. A second dimension of occupational form is the sociocultural. The first dimension focuses on the doing aspect of performance, while the second dimension emphasizes the symbolic aspect (e.g., values and norms). According to Nelson, occupational performance, then, is the "action elicited, guided, or structured" by an occupational form (p.633).

Holm and Rogers (1989) described the person-task-environment (PTE) transaction as a relationship between the capabilities required of a task performer and the inherent properties, procedures, equipment, and materials involved in functional activities. Emphasis was placed on the natural setting, as opposed to the clinical setting, as a means of eliminating contrived environmental influences. Subsequently, Rogers and Holm (1991) adapted Lawton's (1982) ecological model of aging to explicate further the PTE transaction. Lawton described behavior as resulting from the interaction of person capabilities and environmental demands or press. As a person's capabilities become impaired, the influence of the environment on behavior increases. By implication, then, occupational performance depends on the match between the capabilities of the person and the demands the environment places on these capabilities. To highlight the role of the nonhuman environment on performance, and as a resource for resolving or alleviating performance problems, Rogers and Holm (1991) expanded the definition of the environment to include assistive technology devices, objects in the environment, and the structural environment.

The Person-Environment-Performance Model introduced by Christiansen (1991) viewed person factors (e.g., motivation, experience, beliefs, abilities, and skills) as intrinsic enablers of performance. Performance includes activities, tasks, and roles of occupations, and the environ-

ment includes physical, social, and cultural factors. A unique contribution of this model is the emphasis on person capabilities as enablers of performance.

The Occupational Adaptation frame of reference detailed by Schkade and Schulz includes the person, the occupational environment, and the interaction of the person and occupational environment during occupation (Schkade & Schulz, 1992; Schultz & Schkade, 1992). It focuses on the client's experience of self in relevant occupational contexts and the use of meaningful occupations to affect the client's internal adaptation process rather than outward measures of performance (Dolecheck & Schkade, 1999; Gibson & Schkade, 1997). Desired outcomes of the occupational adaptation framework are effective, efficient, and satisfying responses to the demands posed by the environment.

The Ecology of Human Performance (EHP) framework (Dunn, Brown, & McGuigan, 1994) builds on the premise that "interaction between person and the environment, affects human behavior and performance, and that performance cannot be understood outside of context" (p.598). Context is the viewpoint from which persons perceive their work and encompasses temporal, physical, social, and cultural factors. The EHP defines person, task, performance, and context, using the "Uniform Terminology for Occupational Therapy—Third Edition" (American Occupational Therapy Association (AOTA), 1994), and describes possible relationships among the four components. In addition, five collaborative approaches to intervention (establish/restore, alter, adapt, prevent, and create) that incorporate all four components of the EHP framework are described.

In a further theoretical development of the Model of Human Occupation, Kielhofner (1995) identified the environment as influencing occupational behavior through affording and pressing. The environment affords opportunities for performance, and presses for certain types of behavior. The physical environment was conceptualized as being composed of natural and built environments and objects. The social environment consists of social groups and occupational forms—that is, rule-bound action sequences. The physical and social environments intertwine to create occupational behavior settings, or meaningful contexts for occupational performance.

A primary intent of the Person-Environment-Occupational (PEO) model (Law et al., 1996; Strong et al., 1999) was to explicate use of the environment in practice. Occupational therapy's unique view of occupational performance encompasses the intersection of person, occupation, and environment. The environment consists of cultural, socioeconomic, institutional, physical, and social domains, all of which are constantly changing. The environment can have a positive or negative influence on occupational performance, enabling or constraining it, and is more readily changed than the person.

Task analysis, which is essential to occupational therapy practice, merits recognition as an ecological framework. Task analysis defines the relationship between the person and the environment as an action (e.g., reaches) oriented toward an object (e.g., into the cupboard). As a conceptual approach, task analysis has been highly developed in human factors engineering (Militello & Hutton, 1998a, b; Pelland & McKinley, 2001; Schaafstal, Schraagen, & van Berlo, 2000; Yu, Hwang, & Huang, 1999). A human factors approach to capacity-demand models uses task analysis to divide tasks into discrete sequential steps and then defines the physiological (e.g., actions, postures, grasps), sensory (e.g., feels, sees), and cognitive (e.g., searches, scans) requirements for successful task completion (Faletti, 1984). The occupational therapy practitioner then compares the demands of each step of the task and the ambient environment (e.g., heat, light), with the capacities of the person. When the task-environmental demands are greater than the person's capacities, the specific area for intervention is targeted (Clark, Czaja, & Weber, 1990; Czaja, Weber, & Nair, 1993).

Most recently, the Occupational Therapy Practice Framework (OTPF) was introduced (AOTA, 2002) for use within the profession, with a second edition in process (AOTA, in press). The OTPF defines occupational performance as "resulting from the dynamic transaction among client, the context and the activity" (2002, p. 632). Client factors support the development of performance skills (for example, motor, process and communication) necessary for everyday occupations, and as routines are developed in the performance of those skills, performance habits emerge. As people fulfill the social roles that are expected, required, or desired by them, they combine the performance skills and habits of occupations into broader engagement in everyday life situations, known as social participation. Engagement takes place in seven areas of occupation: activities of daily living (ADL), instrumental activities of daily living (IADL), education, work, play, leisure, social participation. Within occupational areas, each activity has unique demands, associated with its complexity, properties, and use (e.g., social demands, sequencing and timing). The performance of any activity is influenced by the various contexts in which it occurs. By definition, context includes seven interrelated conditions: cultural, physical, social, personal, spiritual, temporal, and virtual. Spirituality, along with values and beliefs may be listed as a client factor in the OTPF 2nd Edition (AOTA, in press), illustrating that there is no clear distinction between client and context and that these conditions are conceptualized as within and surrounding clients. Similarly, the demand character of activity spans aspects intrinsic (e.g., required body functions and structures and actions) and extrinsic (e.g., objects, space, social demands, sequencing or timing) to clients.

Person-Environment Models in Rehabilitation and Health Care

Although occupational therapy has historically acknowledged the person-task-environment transaction, this triad emerged to the forefront of theory and practice in rehabilitation and health care in recent years in part because of disability rights advocates, who emphasized the role of the environment in causing performance problems. Hence, over the past two decades, a major shift has occurred in the way in which health policy groups have defined disability, or limitations in socially defined activities and roles. In the Institute of Medicine's (1991) initial presentation of the enabling-disabling process, the environment was named as one of three disability risk factors. However, in a subsequent expansion of the model, the environment became a key feature, with the level of support provided by the physical and social environment responsible for the severity of disability experienced by the person (Institute of Medicine, 1997).

An increased emphasis on external versus internal disability factors is also evident in the sequence of models developed by the World Health Organization. The International Classification of Impairments, Disabilities, and Handicaps (World Health Organization, 1980), which was designed to describe the functional consequences of medical conditions, did not acknowledge the environment. Nonetheless, the environment emerged into prominence in the latest model, the International Classification of Functioning, Disability and Health (ICF) (World Health Organization, 2001). The ICF portrays health as having two parts: Part 1 concerns functioning and disability, while Part 2 emphasizes contextual factors. Functioning indicates nonproblematic health states, identified as body structures and functions, activity, and participation. In the ICF, functioning is built on a foundation of health, manifested in the "functional and structural integrity" of body functions and body structures. In the health condition, activities (i.e., tasks and actions executed by a person) are not limited. When activities are carried out in a standardized environment, such as an occupational therapy clinic, it is referred to as *activity capacity.* When activities are carried out in the real-life environment, such as a client's home or workplace, it is known as *activity performance.* When discrete activities are combined to enact social roles in real-life situations, it is referred to as *participation.* Activities and participation can occur in nine categories: learning and applying knowledge, general tasks and demands, communication, mobility, self-care, domestic life, interpersonal interactions and relationships, major life areas, and social and civic life. Each component of functioning can be expressed in negative terms, resulting in a disability continuum comprised of impairments of body structures and functions, activity limitations, and participation restrictions.

In Part 2 of the ICF, contextual factors are divided into two major groups—environmental and personal. Environmental factors are classified into five categories: products and technology; natural environment and human-made changes to the environment; support and relationships; attitudes; and services, systems and policies. Factors such as gender, race, age, fitness, lifestyle, and habits are grouped under the personal label. Environmental factors account for external influences on functioning and disability, while personal factors account for internal influences.

The OTPF and the ICF

Because of the salience of the Occupational Therapy Practice Framework (OTPF; AOTA, 2002) in occupational therapy, and the International Classification of Functioning, Disability and Health (ICF; WHO, 2001) in rehabilitation and healthcare, we juxtaposed the two frameworks in Figure 46.2 to illustrate concept relationships. Although neither the OTPF nor the ICF order concepts in a hierarchy, we created a hierarchy based on increasing complexity of person-task-environment interaction, to facilitate concept comparison. Figure 46.2 is designed to illustrate concept similarity not equivalence.

In the ICF model, disability arises from disease or disorder. Disease and disorder represent two opposing explanations of disability—namely, the medical model and the social model. The medical model views disability as a consequence of factors within the person, whereas the social model views disability as a consequence of factors extrinsic to the person. Thus, disease and disorder were deliberately used in the ICF to blend the perspectives of both models into a biopsychosocial approach. When disease or disorder negatively affects a person, change or loss of body functions and structures can occur, leading to impairment. In turn, impairment can negatively influence activity capacity and performance, yielding activity limitations. When one or more discrete activities are limited, this can lead to reduced involvement in everyday life situations, or participation restrictions. Neither functioning nor disability occurs in a vacuum. Both are influenced by contextual factors. Factors internal to people with disabilities, such as low self-esteem or self-efficacy, and factors external to them, such as buildings that are not wheelchair accessible or prejudicial attitudes toward people with disabilities, can negatively influence activity and participation, and thus accentuate disability.

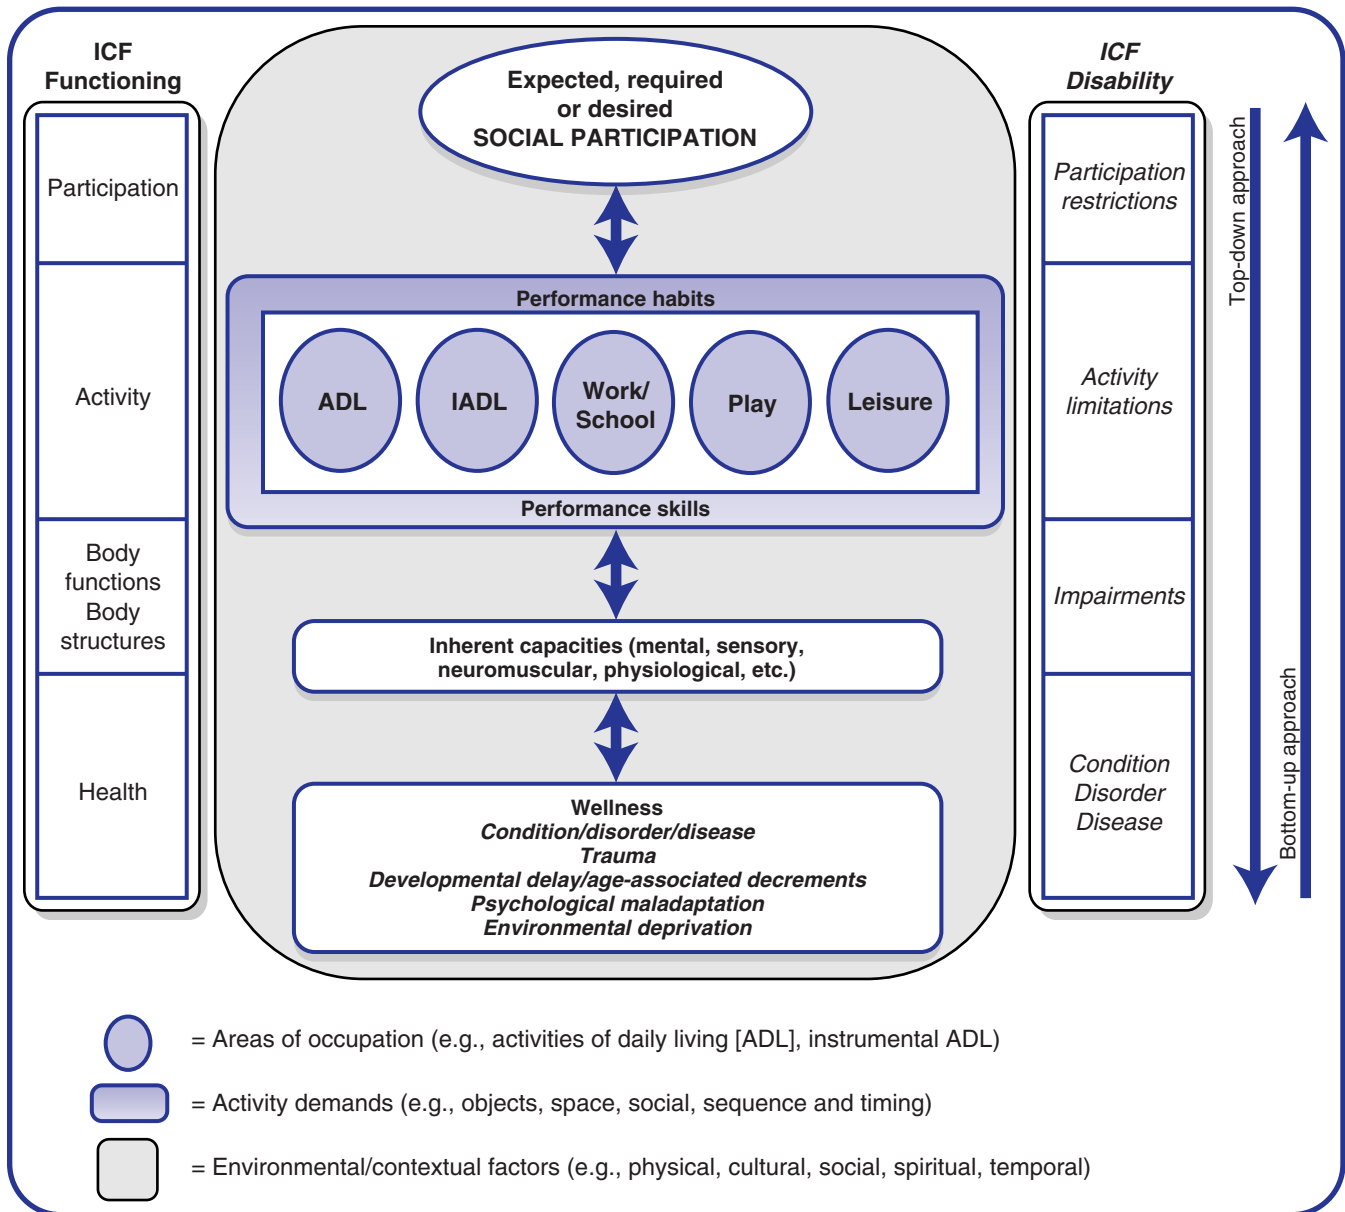
Because the OTPF is silent on disease and disorder, we incorporated the ICF biopsychosocial approach as the lowest level on the OTPF hierarchical scheme. Wellness has a positive influence, while disease or disorder (further specified as trauma, developmental delay, age-associated declines, psychological maladaptation, environmental deprivation), can have a negative effect on a client's performance capacities (e.g., mental, sensory, neuromuscular). Consequently, performance skills and habits used to carry out everyday occupations (e.g., ADL, IADL, leisure) can also be negatively affected. In turn, social participation


FIGURE 46.2   The relationship of concepts from the ICF and the OTPF.

roles may not be fulfilled adequately or at all. As part of an occupational profile, practitioners routinely evaluate clients for capacities unaffected by disease and disorder as well as unaffected skills and habits. Unaffected skills and habits constitute a client's strengths and can compensate for or replace those capacities that are dysfunctional.

Unlike the ICF, the OTPF not only recognizes the influence of context on occupational performance but also recognizes that each occupation has unique activity demands (e.g., objects, space, sequence of steps). In both models, the person-task-environment transaction becomes particularly salient at the third level of the hierarchy (i.e., activities and activity limitations, occupations), and maintains significance at the fourth level of the hierarchy

(i.e., participation and participation restriction, social participation). Hence, factors that are essential to the transaction, although external to clients, must be taken into account when intervening for disability (i.e., activity limitations, participation restriction).

Summary

This brief review of ecological models indicates that the person-task-environment transaction has been described from numerous perspectives, within and outside of occupational therapy, and with different emphases on the various factors. A common theme emerging from them is that people use their capacities to accomplish a task at a

given time, using the objects available, in a specific place. Hence, the **outcomes** of a person's performance, in terms of parameters such as task independence, safety, and adequacy, depend on the transactions between and among the capacities of the person; the demands of the task; and the cumulative demands of the various environments (e.g., cultural, physical, social, temporal) in which the task takes place.

OCCUPATIONAL THERAPY PROCESS: THEORY

The components of the occupational therapy process— evaluation, problem definition (diagnosing), intervention planning and implementation, and re-evaluation—are common to all professions as well as common to the application of all occupational therapy theories. What makes the application of these components unique to a profession is the profession's overarching view of the phenomenon that it treats or services. The phenomenon that makes occupational therapy unique is occupational performance, which is why it is essential for occupational therapy students and practitioners to understand its fundamental nature and complexity. To facilitate this understanding, we present a perspective of occupational performance that is sufficiently general that it can inform any theory.

Our perspective of occupational performance builds on the construct of the person-task-environment transaction (PTE). A performance transaction, the PTE, implies a negotiation or arrangement among three factors: person capacities (P), task demands (T), and environmental demands (E). The task, whether it is dressing, writing, driving a car, cooking a meal, or playing golf, is pivotal to the PTE. It is the task and the various environments in which it takes place that require clients to perform in defined ways to accomplish an outcome. After defining and describing each of the three factors separately, we view them in concert in the discussions of the transaction (PTE) and of performance discrepancy.

Person (Client) Capacities

Person (client) capacities include inherent generic abilities and task-specific skills. Numerous mental, sensory, and neuromuscular abilities and other bodily functions and structures underlie, support, and enable the performance of multiple tasks (AOTA, 2002). Examples of generic abilities are attention, proprioception, and joint mobility. Generic abilities coalesce into unique combinations to form task-specific performance skills and habits. Task-specific skills and habits emerge to affect performance and participation in real-life occupations, such as dressing, meal preparation, website designing, and playing wheelchair basketball. Task-specific skills are developed through training and practice—that is, through the learning and

repetition of the PTE transaction in standardized and real-life situations (Giles, Ridley, Dill, & Frye, 1997; Ma & Trombly, 1999; Mathiowetz & Wade, 1995; WHO, 2001)

Task Demands

Client capacities are challenged by the requirements of tasks, which are called **task demands** (Johnson, 2000; Seki, Ishiai, Koyama, & Sato, 1999; Steptoe, Cropley, & Joekes, 2000). Task demands are identified through **task analysis**, which is the analytic process of breaking tasks down into discrete, sequential steps (Creighton, 1992; Cynkin, 1979). Task analysis identifies the actions that clients are to perform in relation to objects. For example, to make a cup of tea, clients must perform six actions (see Table 46.1).

The actions making up task performance are highly influenced by the objects used to perform them, which include the task materials, tools, and equipment. Task objects have inherent properties that influence task demands. For instance, pancake batter presents less resistance than stiff cookie dough when stirred, a plastic garbage bag placed on a car seat provides less resistance than cloth seat covers when transferring into and out of a car, and, an overhead knit shirt stretches more easily than one with a cotton weave when donned.

When calculating the demand properties of a task, the properties of task objects must be analyzed. One method practitioners use to analyze the properties of task objects is to consider the effect the properties have on the senses. When touched, lifted, carried, pushed, or pulled, task objects can be slick, sticky, wet, dry, greasy, crumbly, hard, soft, warm, cold, sharp, scratchy, smooth, heavy, or light. When visualized, they can be large, small, colorful, bright, dull, far, or near and have distinct shapes and patterns. When listened to they can produce loud, soft, irritating, soothing, or inaudible sounds. Task objects can taste sweet, sour, salty, or bitter and emanate odors that are pleasant, noxious, or unnoticeable. The properties of objects can also be hazardous to health, such as certain chemicals, solvents, heavy metals, and radiation materials

TABLE 46.1 SIX STEP TASK ANALYSIS FOR MAKING TEA

Action	Object
1. Locate	Tea bag and drinking container
2. Place	Tea bag in drinking container
3. Obtain	Container for water
4. Obtain and heat	Water
5. Pour	Water over tea bag
6. Remove	Tea bag

(Brigham, Engelberg, & Richling, 1996). Task materials (e.g., bread, shirt, shampoo bottle), tools (e.g., fork, drill, ice-cream scoop), and equipment (e.g., computer, stove, work bench) vary based on their function, design, size, and shape (Cynkin, 1979; Demore-Taber, 1995; Hagedorn, 1995; Levine & Brayley, 1991; Rogers & Holm, 1991).

The properties of task objects can increase or decrease the demand quality of tasks for clients. For example, the task demands for making a cup of tea can vary greatly depending on the method of heating, the type of tea, and the drinking container. Heating water for a cup of tea can be accomplished by placing a pan or teapot on the stovetop, heating a cup of water in a microwave oven, plugging in an electric kettle, or inserting an electric heating element into the cup. The tea leaves can be loose in a can, contained in a tea bag, or ground into powder for instant tea. The tea can be served in a ceramic mug, a plastic mug, a china cup, or the lid of a Thermos™. Thus, the task steps, and the inherent properties and design of specific task objects used to perform a task, have a strong influence on the task demands and performance outcomes.

In the example of making tea, task demands exerted their influence through the client's manipulation of task objects. However, the demands of tasks may also be brought to bear on clients when they perform in relation to objects. When executing transfers, for example, clients perform in relation to chairs, commodes, beds, and cars and the specific features of these objects have a direct influence on task performance.

Environmental Demands

In addition to the demands inherent in tasks, task performance is also influenced by the environment surrounding the task (AOTA, 2002; Christiansen, 1991; Dunn et al., 1994; Iwarsson, Isacsson, & Lanke, 1998; Law et al., 1996; Letts et al., 1994; Rogers, 1982). This influence is called **environmental demands**. Although environment is a multifaceted construct (e.g., physical, social, cultural, temporal), for the purposes of illustration, we will discuss only its physical and social features.

The properties of the physical environment usually include space, arrangement of equipment and objects, equipment controls, surface heights, lighting, temperature, noise, humidity, vibration, and ventilation (Demore-Tabor, 1995; Hagedorn, 1995; Jacobs, 1999; Raschko, 1991). Each of these properties has been further delineated in architectural (Raschko, 1991; Stamps, 2000), anthropometric (Baker, 1999; Diffrient, Tilley, & Bardagjy, 1974; Pheasant, 1998), ergonomic (Jacobs, 1999; Kroemer & Grandjean, 1997; Rice, 1998), or occupational health and safety literature (Brigham et al., 1996; Carson, 1994; Kroemer & Grandjean, 1997; Moore & Garg, 1995). Not only are there static aspects of the physical environment to consider but there are also dynamic aspects: machines that have moving parts, temperatures that fluctuate, noise levels that rise and fall, humidity that rises and falls, and ventilation that fluctuates.

The demands of the physical environment may compound those of the task. If a toilet is on the second floor of a two-story house and a client cannot climb stairs, the client will not be able to get to the toilet to use it. A portable toilet may need to be purchased or rented and installed in a first-floor bedroom or closet to reduce the demands of physical structures. Furthermore, if space in the bedroom is restricted, or if there is no lighting in the closet, the safety of toilet transfers may be compromised, and adaptations may need to be made to reduce the negative effect of environmental demand.

Often environmental demand is viewed solely in terms of the physical environment. However, task performance is also surrounded by a social environment (Woodward, Hales, Litidamu, Phillips, & Martin, 2000). The social environment includes more than the mere number of people in the home, school, or workplace. The knowledge, skills, habits, expectations, values, attitudes, and motivations of these people create a social climate that fosters or hinders task performance (MacDonald, Karasek, Punnett, & Scharf, 2001; Seki et al., 1999; Walker, Goodwin, & Warren, 1995). Cultural beliefs, norms, customs, and practices also influence the social environment (Hagedorn, 1995). Moreover, people arrange their temporal environment as well as their physical and social environments. For example, they establish daily schedules and the pacing of tasks (MacDonald et al., 2001), in addition to selecting and placing task objects, and organizing and governing social groups. In so doing, people set the overall level of stimulation (e.g., too much, just right, too little) surrounding them during task performance (Christiansen, 1991; Gerdner, Hall, & Buckwalter, 1996; Keuter, Byrne, Voell, & Larson, 2000). At any given time, a person can have numerous roles (e.g., worker, parent, husband, grandparent, co-worker, volunteer, client, and social activist), each of which has unique task demands that occur in separate or overlapping physical and social contexts.

The Transaction

Clients are not passive recipients of the effects of their environments. Rather, they act on, as well as are acted on, by task and environmental forces. This creates a transactional relationship that is characterized as an interdependence between person capacities, task demands and environmental demands (Dunn et al., 1994; Law et al., 1996; Lawton, 1982; Rogers, 1982). For example, a client who is unable to get up the stairs to the bathtub may build a shower on the first floor of the home, install a stair lift to the second level, or bathe at the kitchen sink. Each of these decisions changes the task objects and the task environment, and, in turn, these environmental changes alter the PTE transaction.

Performance Discrepancy: Demands Exceed Capacities

When the capacities of a client are sufficient to manage the demands of the task and the surrounding environment, the client's performance and the level of performance that is expected, required, or desired are congruent. However, when demands (task and/or environmental) exceed capacities, task performance is compromised, and there is a **performance discrepancy** between actual performance and the performance skills or habits that are expected, required, or desired (Lawton, 1982; Mager & Pipe, 1984; Mangino, 2000). The performance discrepancy can be reduced, eliminated, or prevented by establishing or restoring capacities, reducing task demands, reducing environmental demands, or by using a combination of these three methods (Holm, Santangelo, Fromuth, Brown, & Walter, 2000; Law et al., 1996; Mathiowetz & Matuska, 1998; Rogers et al., 1999; Rogers et al., 2000; van Heugten et al., 1998). With the diminishment of their capacities through impairment, trauma, developmental delay, age-related decrements, psychological maladaptation, or environmental deprivation, clients become more susceptible to environmental influences. They have fewer internal resources and less energy to resist external forces or to devise adaptive strategies to counteract them (Lawton, 1982). By designing a therapeutic environment to accommodate diminished capacity, practitioners may be able to improve task performance (Close et al., 1999; Cummings et al., 1999; Mee & Sumsion, 2001; Rogers et al., 1999, 2000).

OT PROCESS: EVALUATION

The theory of occupational performance selected by the occupational therapy practitioner permeates the entire occupational therapy process, but is initially applied to **evaluation**. Evaluate means to examine and form an opinion about. Examination involves the systematic gathering of information about a client's occupational performance. Opinion formation involves combining the information gathered with professional knowledge and judgment to: describe the client's occupational profile, define client's performance problems (discrepancies), hypothesize about the causes of these problems, establish the occupational outcome(s) to be achieved through intervention, and, determine the "best" intervention to bring about the stated outcomes.

Evaluation Protocols: What Combination Is Appropriate—PTE, PT, P?

Practitioners use one of three person-task-environment (PTE) protocols, alone or in combination, to evaluate the transaction. Recognizing the combined influence of task and environmental demands on clients' capacities, the optimal protocol (PTE) is to evaluate all three components directly and simultaneously in the actual, real-life task situation. Accordingly, clients perform targeted tasks in their usual manner, with familiar task objects and equipment, in the setting or settings in which they typically perform these tasks. When performance discrepancies emerge, the relative contribution of person capacities, task demands, and environmental demands to their development can be readily determined. Practitioners working in home care, long-term care facilities, school systems, or work environments have the opportunity to implement the optimal PTE protocol, because evaluation and intervention occur in the real-life situation.

In most other practice settings, such as hospitals, rehabilitation facilities, and outpatient clinics, evaluations are conducted in clinic environments. Clients' performance capacities are evaluated under laboratory rather than real-life conditions. Laboratory conditions may place very different demands on clients' capacities because task objects and equipment are usually not identical to those in the real-life situation. Executing bed transfers may be easier in the clinic than in a client's home because the bed is lower in the clinic. The clinic (task objects and environment) may facilitate performance, because of its enabling, prosthetic features that reduce disability (e.g., wheelchair accessibility) or it may hinder performance, because task objects and equipment are unfamiliar (e.g., cooking with an electric rather than a gas range). In the second PTE protocol (PT), unless clients bring in their own task materials to use during the evaluation (e.g., clothing, medications), their capacities are evaluated with unfamiliar task materials and equipment. The extent to which unfamiliarity has a positive, neutral, or negative influence on task performance is largely unknown. Research suggests that this influence is task dependent (Raina, Rogers, & Holm, 2007). When clients' performance is tested in clinic environments, every effort should be made to approximate the real-life situation to elicit a "true" baseline performance profile. Under the laboratory conditions of clinics, the influence of the environment can be known only indirectly through client or proxy report. Hence, practitioners must use their therapeutic judgment to infer real-life performance from laboratory performance to identify appropriate performance problems, interventions, and outcomes.

While the first PTE protocol accounts directly for person, task, and environment (PTE), and the second protocol accounts for the person and the task (PT), the third protocol (P) accounts only for the person. Hence, it requires an even greater reliance on therapeutic judgment than the person-task (PT) protocol because only person capacities are directly evaluated. Data gleaned from the evaluation are matched to the practitioner's knowledge of task and environmental demands and a judgment is made about tasks clients will and will not be able to performance based on this match. For example, knowing that shoulder

COMMENTARY ON THE EVIDENCE

Occupational Therapy and Evidence Related to the Occupational Therapy Process

Evidence related to the occupational therapy process can be found in the literature on problem-solving/ information processing, clinical reasoning, therapeutic reasoning and evidence-based practice. One thrust of the problem-solving/information processing and clinical reasoning literature has been the differences between novices and experts, or students and experienced practitioners. Most occupational therapy literature on this topic has been position papers, reviews of related literature, books, and studies with small samples (Higgs & Jones, 2000; Line, 1969; Robertson, 1996, Rogers, 1983). Research evidence from quasi-experimental, pre-post designs has shown that using a structure, such as the occupational therapy process, provides novices with a way to organize current knowledge (client evaluation data; didactic knowledge) and it also provides experts with a way to organize and use both current knowledge and prior knowledge (previous experience) (Griffin, 1975; Neistadt, 1987, 1992, 1998, Rogers & Masagatani, 1982).

More recently, research has shifted from the teaching of therapeutic reasoning to using research evidence in critical thinking and making well-reasoned decisions by practitioners (Gambrill, 2005). Although the research literature confirming the effectiveness and efficacy of occupational therapy interventions has increased exponentially in the last ten years (see Commentaries on the Evidence throughout this text), unfortunately, evidence on the use of that research by practitioners is not encouraging at this time. Surveys, reviews, interviews, and pre-post evidence-based practice interventions primarily revealed a focus on barriers that impeded use of research evidence, including time, knowledge of research methods, access to research literature, and feelings of inadequacy associated with not understanding research (Dubouloz, Egan, Vallerand, & Von Zweck, 1999; Dysart, & Tomlin, 2002; Koch, Cook, Tankersley, & Rumrill, 2006; McKenna, Bennett, Dierselhuis, Hoffmann, Tooth, & Mc-Cluskey, 2005). Of even greater concern, however, are the findings of a moderately robust pre-post evidence-based practice intervention study which found that although practitioners' knowledge of evidence-based practice improved significantly, even with continuous support their use of research evidence in practice did not change (McCluskey & Lovarini, 2005).

Moreover, in a study examining the use of research evidence by a sample of 131 registered therapists and members of the American Occupational Therapy Association, the findings indicated that as the educational level of the respondents increased the view of the importance of research decreased, and as the years of practice increased, the use of evidence for therapeutic decision-making decreased (Cameron et al., 2005).

ETHICAL DILEMMA

Ethics, Education, and Intervention

Although the current AOTA Code of Ethics (AOTA, 2005) specifically addresses intervention, a major component of the occupational therapy process, it is silent in regard to evaluation, another major component of the occupational therapy process. Because intervention is based on evaluation, does this present an ethical dilemma?

external rotation is needed to brush hair on the back of the head, and having ascertained that a client is unable to perform this action, the practitioner may infer from this range of motion restriction that the client is dependent in hair combing. Hair combing is not "tested," only the range of motion needed to comb hair. Research has shown that this protocol is most discrepant from the PTE protocol and often leads to inaccurate inferences about occupational performance (Rogers et al., 2003).

Regardless of the specific conceptualization or theory of occupational performance, data collection is systematic, that is, it is guided by that conceptualization or theory and follows a logical sequence. Just as the primary care physician methodically reviews body systems during the annual physical, so too the occupational therapy practitioner systematically evaluates the PTE transaction and its components. The advantage of collecting data systematically was demonstrated by Edwards and colleagues (2006) in a study of post-stroke patients. Two methods were used to identify cognitive and sensory impairments in 53 patients hospitalized for acute stroke. The first method applied a research protocol that followed the Clinical Practice Guidelines for Post-Stroke Rehabilitation recommended by the Agency for Healthcare Research and Quality, while the second method obtained data from a review of the patient's medical chart. The first method, that is, the research protocol, identified significantly more impairments than the chart review regarding memory, visuospatial neglect, and depression. These results suggest that without structured evaluation procedures numerous impairments may not be identified, and therefore may go untreated.

Methods of PTE Evaluation: How Should Data Be Gathered?

There are three primary methods for practitioners to obtain data about clients' occupational performance:

1. Asking questions about performance using structured or open-ended interviews or questionnaires.
2. Observing performance, in a laboratory (i.e., clinical) or natural (i.e., home, school, workplace) context, using structured or unstructured assessments.
3. Testing performance, using norm-referenced or criterion-referenced assessments.

Practitioners may also obtain data from medical records or case conferences, however, data obtained from these sources were initially collected through questioning, observing, or testing.

Each data-gathering method has advantages and disadvantages. The questioning method is more subjective than observing or testing, and this subjectivity may reduce reliability. Questioning is also less expensive and labor intensive. Interviews and questionnaires can be administered by less costly personnel than observational instruments and tests, because they require less skilled judgment.

Moreover, clients are not placed at physical risk for injury when they talk about their occupational performance, as they may be when they actually perform tasks. Hence, performance observation requires skilled personnel to manage risk during evaluation.

Through observation and testing, practitioners objectively rate task performance. Questioning yields subjective ratings of task performance. When observation is structured, reliability is improved because task items must be operationalized to be performed. Thus, the ambiguity associated with questioning (e.g., Can you perform heavy housework?) is removed (i.e., heavy housework is operationalized as using an upright vacuum cleaner to vacuum a room). Increased reliability, in turn, facilitates detecting changes in performance, which is an essential psychometric property for evaluating the effectiveness of an intervention (Guralnik, Branch, Cummings, & Curb, 1989). Structured observation and testing are similar in their standardization, but testing allows practitioners to compare their clients' performance outcomes to that of peer reference groups (norm-referenced testing) or performance standards (criterion-referenced testing). Practitioners may use a norm-referenced test, for example, when they want to know how a child's social skills compare to those of children the same age or if an older adult is able to react as quickly as a younger person. In contrast, they may use a criterion-referenced test to ascertain if an adolescent can perform all essential functions of a short-order cook or an older adult, who is legally blind, can perform the tasks required to live independently and safely in the community. The disadvantages of observation and testing over questioning are that they are more costly in terms of personnel skill and time, as well as space, and equipment (Rogers et al., 2003).

Although no data-gathering method is intrinsically superior, one method may be preferred over others for some evaluative purposes. For example, questioning is preferred for evaluating how often a task is performed, or performance habits, because observing or testing habits would require repeated evaluation over time and would be extremely costly. Similarly, questioning is the method of choice for evaluating occupational role, that is, the unique configuration of tasks that comprise various roles (personal care, worker, parent, etc.) for a client, because "role" is an abstract construct that needs to be operationalized to be observed. Conversely, observation or testing is preferred for evaluating the reason(s) for a performance discrepancy because clients may not be aware of why they are having a performance problem or these methods may be needed to provide precise measurement (e.g., degrees of range of motion restriction).

The selection of a data-gathering method, or combination of methods, is largely determined by the overall purpose for conducting the evaluation in conjunction with practicalities, such as the time allowed for the evaluation and the equipment available. Some instruments,

the Handicap Assessment and Resource Tool (HART) (Vertesi, Darzins, Lowe, McEvoy, & Edwards, 2000) being an example, permit collecting data from several sources. Practitioners need to be aware, however, that different data-gathering methods do not necessarily yield the same findings in regard to the same task. Clients may perceive themselves as independent in bathing, while practitioners may rate their performance as partially dependent because of their need for physical support while entering and exiting the bathtub (Rogers & Holm, 2000; Rogers et al., 2003; Sager et al., 1992).

PTE Content: What Occupational Areas Should Be Evaluated?

When planning an evaluation, decisions must be made about the areas of occupations and the specific tasks to be evaluated as well as the parameters of tasks to be evaluated. What tasks are of concern to the client? Dressing? Computer use? Getting to work? The occupational therapy process should revolve around tasks that have meaning to clients. Decisions about the tasks to evaluate are based on the client's values. Clients' problems may occur in one or several areas of occupation—activities of daily living (ADL), instrumental activities of daily living (IADL), education, work, play, leisure, or social participation. Each of these seven occupational areas contains an array of individual tasks (AOTA, 2002). Education, for example, consists of formal educational participation, exploration of informal personal educational needs or interests, and informal personal education participation and, in turn, each of these activities consists of individual tasks. Early in the occupational therapy process the tasks that clients need to perform or want to perform or are problematic to perform or are becoming problematic to perform are identified. Typically, priorities and problems are initially identified through structured or unstructured interviews or questionnaires administered to clients or their advocates, if clients are not able to respond on their own behalf. Assessments such as the Role Checklist (Oakley, Kielhofner, Barris, & Reichler, 1986) and the Canadian Occupational Performance Measure (COPM) (Law et al., 2005) are examples of tools that serve this purpose.

Value reflects the relative importance that various occupational areas and tasks have for clients. When energy is limited, humans typically establish priorities for how they want to use their energy. Hence, clients may choose to have a spouse dress them, rather than dress themselves, so that they can save the energy that they would expend dressing to go to a theater or restaurant. Because motivation for occupational engagement is influenced by personal values, ascertaining the relative value that various occupational areas and tasks have for clients is useful for establishing intervention priorities.

Individual tasks are sequenced together to form personalized daily living routines and habits as well as socially defined roles. One person's daily living routine, for example, moves from arising from sleep in the morning, showering, dressing and simultaneously eating cold cereal and reading the newspaper, while another person's routine calls for arising, cooking and eating breakfast and then dressing, leaving bathing for the evening. These daily living routines are incorporated into the "personal care role" which requires adults to perform the occupations necessary to fill their need for food, clothing, and shelter. The personal care role, in turn, supports other roles such as those of student, worker, homemaker, and spouse. Appraising the extent to which problems in valued tasks disrupt the performance of routines, habits, and roles places these problems in the context of normal living, and thus provides an essential facet of the client's emerging occupational profile.

PTE Parameters: What Do We Want to Know about Occupational Performance?

In addition to ascertaining the occupational areas and specific tasks to be evaluated, practitioners need to decide what they want to know about occupational performance. Key questions about occupational performance to be answered through the evaluation are: Can clients perform the task by themselves? Can they perform it safely and can they do it adequately? What explains or accounts for the performance discrepancy? Each question requires practitioners to use a different measurement parameter or yardstick (see Box 46.1).

Independence

The most common parameter used to measure occupational performance is the level of **independence** clients exhibit when performing a task. Ratings of independent or able mean that clients can perform a task, without assistance from another person, although they may use assistive technology. Conversely, dependent or unable implies that help from another person is required. When performance is not totally dependent, it may be rated using the percentage of the task completed independently (e.g., 75%, 50%, 25%) or the quantity of help needed (e.g., no, minimal, moderate, maximal).

When assistance is required to complete a task, the type of assistance may also be added to the rating scale. Three general types of assistance are recognized and are rank ordered from least to most assistive as: assistive technology, nonphysical assistance, and physical assistance (see Box 46.1). Assistive technology qualifies as the least assistive type of assistance when it enables task performance to be adaptive but independent. The performance of clients feeding themselves using utensils with enlarged or elongated handles fits this definition.

A client who requires nonphysical assistance is considered to be less dependent than one who needs physical, hands-on help. Nonphysical assistance takes into account multiple techniques, including task setup, supervision,

Yes ☐   Task Experience   ☐ No

Yes ☐   Resources   ☐ No

standby assistance, and verbal and nonverbal cues to give encouragement or instruction. Examples of task setup are opening milk cartons and arranging clothing on a chair in the sequence in which items are to be donned. Supervision means that the caregiver may not be consistently present, but is available to monitor task performance and to intervene if problems arise. Standby assistance requires the caregiver to be physically present and near the client at all times. A caregiver who checks to see if the fried eggs are sufficiently cooked is an example of supervision; one who walks alongside a client who is climbing stairs is an example of standby assistance. Verbal cuing means using spoken or written words to motivate or instruct clients about task performance. Putting a sign saying "toilet" on a bathroom door to aid the wayfinding of a client with dementia is an example of a verbal cue. In nonverbal cuing, communication is accomplished through demonstration or gestures.

Physical assistance involves physically guiding clients to do a task or part of a task and doing the task for them. With physical guidance, clients are expected to participate actively in the task, whereas with physical assistance, clients are expected to cooperate with caregiving. Positioning a client's hands on a walker illustrates physical guidance, while lifting a client from a chair illustrates physical assistance.

The Functional Independence Measure (FIM) (UDSMR, 1997) and the Inpatient Rehabilitation Facility Patient Assessment Instrument (IRF-PAI) (www.resdac.umn.edu/IRF-PAI; accessed August 13, 2007) are examples of measures using independence as the measurement parameter.

Perceived self-efficacy, or clients' beliefs about their ability to perform tasks independently, is another facet of task independence. If the distance between the bed and the wheelchair looks like the Grand Canyon to clients and they believe that they do not have the ability to perform the transfer, it is unlikely that they will perform the transfer. Self-perceptions of performance ability influence performance as significantly as actual abilities (Gage, Noh, Polatajko, & Kaspar, 1994). Perceived self-efficacy is specific to individual tasks. Thus, clients do not perceive themselves as able or unable but rather as being able to do some tasks but not others. The Perceived Self-Efficacy Scale for People with Arthritis (Lorig, Chastain, Ung, Shoor, & Holman, 1989) and the Self-Efficacy Gauge (Gage, Noh, Polatajko, & Kaspar, 1994) are examples of self-efficacy measures.

Safety

Safety is the risk incurred by clients or to the environment when clients perform tasks. Safety is not a quality of the environment per se, but rather is a characteristic of the person-task-environment transaction. Although a bathtub safety rail is a safety feature, its presence in the bathroom will not improve clients' safety unless it is actually used, and used correctly, when bathtub transfers are executed.

However, unsafe features of a home may indicate unsafe task performance or increased risk. A can of bacon grease on the stove or an electrical cord traversing a sink suggests that the client, or someone else in the home, has unsafe daily living habits.

Commonly, risk connotes physical risk as occurs when there is concern that clients may cut themselves while preparing food or may sustain a fracture if they trip over an uneven carpet. Safety risks may also involve poor judgment, for example, forgetting to extinguish a burning candle, taking too much or too little prescribed medication, or flashing $50 bills around the bus station. Safety is rated by the absence, presence, or extent of risk.

Although safety has always been recognized as a critical evaluation parameter in occupational therapy, it has usually been rated as a part of task independence. However, humans can perform independently but unsafely and instruments such as the Performance Assessment of Self-Care Skills (PASS) (Rogers & Holm, 1994b) and the Safety Assessment of Function and the Environment for Rehabilitation—Health Outcome Measurement and Evaluation (SAFER-HOME) (Letts & Marshall, 1995) account for this in their scoring. When working with clients, it is often difficult to know where the line between safe and unsafe performance should be drawn and to determine when task performance is sufficiently unsafe that independence should be restricted. As occupational therapy moves more into clients' homes; interfaces more with the legal system for the purposes of guardianship, conservatorship, and involuntary commitment; and, becomes more oriented toward prevention and health promotion, safety will increasingly shift to the forefront of evaluation technology.

Adequacy

Adequacy refers to the *efficiency* of performing tasks as well as the *acceptability* of the outcome of performance. For example, when dressing, movement may be fluid or uneven (efficiency) and when dressing is completed, the person may look neat or disheveled (acceptability). Similarly, when clients with essential tremor write checks, their hands may shake and their signature may be readable or unreadable.

EFFICIENCY.   Efficiency of task performance implies a minimum of unnecessary effort. Common parameters emphasizing the efficiency of action or process are: difficulty, pain, fatigue and dyspnea, and duration.

DIFFICULTY.   Difficulty is the perceived ease with which a task is accomplished. Rehabilitation theorist Verbrugge (1990) argued that difficulty is the most appropriate way to measure activity limitations because ratings of difficulty come from clients, whereas ratings of the amount of assistance required to complete tasks come from clients'

caregivers. Caregiver ratings of assistance may be more reflective of the assistance given than of the assistance that is actually needed. The Functional Status Index (FSI), an activity limitation measure designed for use with adults with arthritis, uses a four-point scale of no, mild, moderate, and severe difficulty (Jette, 1980). The Health Assessment Questionnaire (HAQ), another activity instrument designed for clients with arthritis, also employs a four-point scale. The HAQ scale considers without any difficulty, with some difficulty, with much difficulty, and unable to do (Fries, Spitz, Kraines, & Holman, 1980).

The level of difficulty experienced during task performance is increasingly being viewed as a marker of preclinical disability—that is, as a symptom that indicates that the individual is at risk for decline in function even though the decline is not yet apparent (Fried, Herdman, Kuhn, Rubin, & Turano, 1991). Unless the onset of pathology is sudden, such as that arising from a car accident or stroke, it is likely that clients will find it harder to perform tasks before they are unable to perform them at all. Along similar lines, an increase in perceived difficulty or the spread of difficulty from more difficult (e.g., heavy housework) to easier (e.g., oral hygiene) tasks may signal the progression of occult disability.

PAIN.   Pain is the discomfort or sensation of hurting that is experienced during task performance and may continue after performance has stopped (Jette, 1980). In relation to task performance, the component of pain that is of most concern is the extent to which it interferes with performance. Interference may be ascertained in relation to specific tasks, such as walking or cooking a meal, or may be gauged more globally in reference to clients' overall activity level (McDowell & Newell, 1996). Because of pain, tasks may be modified, done at a slower pace, done less often or less adequately, or eliminated from one's daily routine. In addition to interference with tasks, it may be useful to note the presence or absence of pain, the location and distribution of pain, the intensity of pain (none, mild, moderate, severe), and/or the character of the pain experienced (shooting, burning, dull). The Functional Status Index (Jette, 1980) examines pain in relation to activity performance.

FATIGUE AND DYSPNEA.   Fatigue is the discomfort or sensation of tiredness, weariness, or exhaustion that is experienced during or after task performance (Hart & Freel, 1982; Tack, 1991). When fatigued, clients describe themselves as tired and needing to rest (Freal, Kraft, & Coryell, 1984). Fatigue and dyspnea often occur together. Dyspnea is a sensation of difficult or labored breathing (Gift, 1987). Clients describe their symptoms of dyspnea as feeling short of breathe, not getting enough air, chest tightness, and finding it hard to move air (Janson-Bjerklie, Carrieri, & Hudes, 1986). Fatigue and dyspnea may interfere with the ability to do tasks and may be exacerbated by physical activity. Similar to pain, they may lead to modifications in the manner in which tasks are done, including a slower pace, decreases in participation, and the transfer of responsibility to others. An interesting aspect of fatigue and dyspnea is that they can result from too much (e.g., strenuous housework) as well as too little (e.g., sedentary lifestyle) physical activity (Gift & Pugh, 1993). They may be a component of both physical (e.g., chronic lung disease) and mental (e.g., anxiety) illness. As with pain, the fatigue/dyspnea–activity limitation relationship is generally approached by ascertaining the extent of interference with specific tasks and usual activity level. Scales may also record the presence or absence, the amount (none, a lot), and the severity (mild, severe) of the fatigue or dyspnea (McDowell & Newell, 1996). A subscale of the Multidimensional Assessment of Fatigue (MAF) (Tack, 1991) asks respondents to rate the degree to which fatigue has interfered with their ability to engage in routine activities. The Multidimensional Assessment of Fatigue (MAF) (Tack, 1991) and the London Chest Activity of Daily Living Scale (LCADL) (Garrod, Bestall, Paul, Wedzicha, & Jones, 2000) are examples of instrument that rate activity interference secondary to fatigue and shortness of breathe, respectively.

DURATION.   The duration of task performance—that is, the time needed to complete a task—is often used as a measure of efficiency. Less time is interpreted as increased efficiency. In essence, time gives a measure of the speed of performance. Some functional assessment instruments include a time criterion in the definition of independence. The Functional Independence Measure™ specifies, for example, that activities must be completed in "reasonable time" (UDSMR, 1997). Practitioners often comment on tasks being completed "within normal limits." It is interesting that neither the average length of time adults take nor the minimum time they need to perform various daily living tasks has been calculated.

Although time to task completion provides a ratio scale for measuring task performance, it is cumbersome data to collect in the therapeutic situation, because it requires the use of a stopwatch and the designation of precise beginning and ending points for each task. Furthermore, the time needed to complete tasks depends on the reason for engaging in the task. Dressing to do housecleaning is likely to take less time than dressing to go out to work. Time is also a poor marker of efficiency for clients who are impulsive or manic, because they may rush through tasks with little consideration for safety or adequacy. Although such individuals may prepare a meal in record time, for example, the food may be unappetizing and the kitchen cluttered with pots and cooking utensils when they are finished.

ACCEPTABILITY.   Regardless of the efficiency with which a task is performed, the acceptability of the outcome of that performance is a critical criterion of occupational

performance. To evaluate acceptability, however, a performance standard is required. Measurement parameters emphasizing the acceptability of the outcome or product of the action are: societal standards, satisfaction, experience, aberrant activity.

SOCIETAL STANDARDS.   One approach to evaluating the acceptability of task outcomes or products is to evaluate those results against the normative expectations of society. The degree of difference or deviation from the 'normal' is the performance standard. For example, humans are expected to maintain personal cleanliness and not to overdraw their checking accounts. Although there may be a wide, rather than a narrow, line between what is acceptable and unacceptable, task performance that consistently goes outside the line will be labeled unacceptable, inappropriate, or inadequate according to societal standards. In applying normative standards, practitioners must be careful to make allowance for cultural diversity as this is expressed in occupational performance (Purnell & Paulanka, 2005).

SATISFACTION.   A second parameter of acceptability of task outcomes or products is satisfaction. Satisfaction refers to the experience of pleasure and contentment with one's performance (Yerxa, Burnett-Beaulieu, Stocking, & Azen, 1988; Pincus, Summey, Soraci, Wallston, & Hummon, 1983). As a parameter of performance, it is likely that satisfaction interacts with an individual's willingness to engage in a task or embrace a role. If clients fail to derive satisfaction from their performance, they may restrict their participation. In relating satisfaction to performance, a dichotomous scale may be used consisting of satisfied or dissatisfied. Alternatively, satisfaction may be rated according to the proportion of time that clients experienced satisfaction (e.g., 100%, 75%, and so on) as is done on the Satisfaction with Performance Scaled Questionnaire (SPSQ) (Yerxa et al., 1988) or on a Likert-type scale (e.g., not at all satisfied to extremely satisfied) as is done on the Canadian Occupational Performance Measure (COPM) (Law et al., 2005). Caregivers of clients may also be asked to rate the extent to which they are satisfied with the care recipient's task performance. This procedure has the potential for providing practitioners with information about the normative expectations for task performance within a social unit (e.g., family, cultural group), as previously discussed under societal standards.

ABERRANT TASK BEHAVIORS.   The task analyses used on measures are based on the way in which tasks are normally performed—that is, the way in which they are usually performed by individuals without disabilities. However, individuals with cognitive impairments, such as those associated with dementia, traumatic brain injury, schizophrenia, and mental retardation, may exhibit behaviors that are aberrant or abnormal. For example, they may pocket food in their cheeks or spit food out. Clothing items may be put on the wrong body parts. In contrast to the subtasks derived from task analyses, which are to be encouraged during intervention, aberrant behaviors are to be extinguished or reduced in frequency. These behaviors are not well represented on available instruments measuring activities of daily living, with the exception of the Routine Task Inventory, an instrument specifically devised for use with a psychiatric population (Allen, 1985).

PTE Explanatory Factors for Performance Discrepancies

When performance is problematic, whether performance is dependent, unsafe, inefficient or unacceptable, practitioners seek to identify factors that contribute to the loss of performance ability. In other words, they seek to explain what accounts for the performance discrepancy. Salient explanations for a performance discrepancy are: a deficit in one or more of the components of the PTE transaction and a lack of experience.

PTE Deficit

Breakdown of the PTE transaction may account for a performance discrepancy. When performing any task, clients must have the affective capacity to motivate them to perform the task; the cognitive capability to plan, execute, monitor, and terminate the task; the motoric capacity to perform the task; a task consonant with their competence level, and, lastly, an environment that supports performance. If any of the required affective, cognitive, motoric, task, or environmental factors is lacking or deficient, task performance will be dysfunctional. Ascertaining the most likely explanation for a performance discrepancy provides critical information for planning interventions. If the hypothesized explanation for a dressing dysfunction is a deficit in active range of motion (e.g., stiff joints), the intervention will be different than if the explanation is apraxia (e.g., problems in executing planned movement), apathy (e.g., lack of responsiveness or initiative), a task that is too complex (e.g., buying stocks and bonds for someone with dementia), or, environmental (e.g., a closet that is not wheelchair accessible). Similarly, the appropriate intervention for a skill deficit would be different from that for a habit deficit. A skill deficit would be approached by practicing the skill under supervised conditions to prompt improvement. However, if clients possess the needed skill but fail to use it routinely—that is have a habit deficit—a motivational intervention plan, to increase the frequency of using the skill, would be in order.

When a performance discrepancy is identified, practitioners may reason that it can be explained by one or more of the transactional components—person, task, and/or environment. Hence, they may undertake a more thorough or detailed evaluation of one or more of these factors *in isolation* to shed insight on the performance discrepancy.

PERSON CAPACITIES.   In reference to the person, affective, cognitive, and motoric capacities are measured with capacity-specific assessments. For affective function, a depression assessment might be used; for cognitive capacity, a mental status examination; and for motoric capacity, an active range of motion measure. Measurement parameters previously discussed, such as pain or discomfort, fatigue, and dyspnea, may also explain dependent, unsafe and inadequate behavior. Data from capacity assessments typically indicate the extent of deviation from a standard. For example, a client may obtain a score of 6 of 30 on the Mini-Mental State Examination (Folstein, Folstein, & McHugh, 1975). On this test, 24 or above is interpreted as within normal limits. The client's score of 6 deviates 18 points from 24 (normalcy), and is indicative of severe cognitive impairment.

TASK DEMANDS.   To enhance understanding of task demands, a detailed analysis is done of task requirements. For example, the action of entering and exiting a bathtub might be expanded to 5 steps: enter tub; lower self to a seated position on tub bottom; sit on tub bottom; raise self from tub bottom; and exit tub. Measurement of task demands would account for the number of steps clients could complete independently, safely, and adequately. By observing clients perform each step, practitioners learn the point of task breakdown, which is one explanation of a performance discrepancy. Assessments based on task analysis include the Performance Assessment of Self-Care Skills (PASS) (Rogers & Holm, 1994b) and the Klein-Bell Activities of Daily Living Scale (Klein & Bell, 1982).

PHYSICAL ENVIRONMENT.   Recent attention to the environment as an explanatory factor for performance discrepancies is slowly filtering into assessment technologies. The physical environment figures most prominently, with assessment focused on functionality and safety demands. However, facilitating function and safety is interpreted differently for different impairment groups. Curb cuts, for example, assist those in wheelchairs, but pose a hazard for those who are blind or have low vision. Thus, environmental assessments tend to be impairment group specific. They center on accommodations in space and equipment for people in wheelchairs; the use of textures and sound to promote wayfinding for those with visual impairment; the absence of tripping hazards, for those who fall; and, the presence of barriers to prevent access to spaces and objects that may be used in a harmful way (e.g., put excess salt on a tomato), for those who are cognitively impaired. Historically, environmental assessments have been of the "garden variety," with each occupational therapy setting devising its own assessments. "Scoring" has been qualitative with the recording of factors that facilitate and hinder function. These setting specific instruments became more standardized and universal over time. The Checklist for Readily Achievable Barrier Removal (http://

www.usdoj.gov/crt/ada/checkweb.htm; accessed August 13, 2007) and Safety for Older Consumers Home Safety Checklist (http://www.cpsc.gov/CPSCPUB/PREREL/prhtml87/87026.html; accessed August 13, 2007) are illustrative of this trend. More recently, rather than assessing environments in isolation from the person and using descriptive recording, newer instruments favor assessing the person-in-environments, using numerical recording, and establishing the psychometric properties of instruments. The Functioning Everyday with a Wheelchair (FEW; previously titled Functional Evaluation in a Wheelchair) is an example of a person-task-environment instrument (Mills et al., 2002).

SOCIAL ENVIRONMENT.   People and their perspectives expressed in the attitudes that they express and the policies and procedures that they formulate can cause performance discrepancies as readily as the physical barriers that they construct! For instance, if nursing home regulations specify that residents cannot bathe themselves, residents become dependent in bathing. Historically, assessment of social environments has been limited to recording who (people) and what (services) are available to clients. Clients' resources must be taken into account in addition to their capacities and skills when determining the severity of performance discrepancies. Consider, for example, Ms. Cross and Ms. Lum, who are unable to use the range and oven safely to prepare hot food. Ms. Cross has a niece who lives on the same city block as she does and is willing to assist her in preparing hot meals. Ms. Lum lives in a rural community, which does not have a Meals-on-Wheels program, and her neighbors are elderly themselves and unable to assist her. Although the meal preparation skills of both of these clients are the same, Ms. Lum is at greater risk for adverse outcomes than Ms. Cross because she has less supportive living resources available to her. Thus, the evaluation of occupational performance becomes meaningful only when deficits are linked to resources and this linkage is particularly important when evaluation is a part of discharge planning. The Assessment of Living Skills and Resources (ALSAR) links person capacities with environmental resources—resources that are available and those that are needed (Williams et al., 1991).

Experience

One reason that clients may not be able to perform a task is because they never learned how to do it at all or how to do it adequately. Experience is the direct participation in a task that a person has accumulated. Experience provides the opportunity for practice and for perfecting performance and outcomes. All humans generally learn functional mobility and personal care tasks during childhood and adolescence. As tasks basic to and essential for daily living, they are practiced regularly over adulthood. Possi-

ble exceptions to this norm include hair care that is done by beauticians, fingernail care that is done by manicurists, and toenail care that is done by podiatrists. Nonetheless, the societal expectation is that all adults have a wide range of experience with these tasks and perform them adequately. However, a similar expectation does not hold for other types of tasks, for which humans have more options. Some clients may have no experience in preparing meals, doing the laundry, or managing finances. Similarly, work and leisure tasks are very individualized. Clients' task performance history is essential for understanding their current performance level.

In addition to past experience, recent or current experience must also be evaluated. When tasks are not performed regularly, the proficiency needed to do them can fall into disuse or become obsolete with technological advances. Inquiries about recency and frequency of task experience are generally approached by ascertaining clients' skills and habits (Rogers & Holm, 1991). Skill refers to the capability to do a task, whereas habit refers to usual or routine task performance. In their repertoires, all humans have tasks that they usually do not perform but that they could perform if situations arise where they have to do them or want to do them. For example, you may know how to cook but prefer to let your spouse cook on a daily basis. However, if your spouse goes away on a business trip, you are able to cook dinner for yourself. When using questioning to evaluate task skills and habits, inquiries about task skills are generally phrased as, "Can you [name the task]?," while those referring to habits use "Do you [name the task]?"

OCCUPATIONAL THERAPY PROCESS: PROBLEM DEFINITION

Data about clients, their task priorities, and environments obtained through evaluation are synthesized. In addition to a profile of clients' abilities and disabilities, the synthesis yields a **problem definition** or several definitions—the occupational diagnosis (Rogers & Holm, 1989; Rogers, 2004). The problem statement has four distinct

but related parts. Each part will be illustrated through Mr. Martin, an older client with Alzheimer's type dementia (see Table 46.2).

The first part of the problem statement is a descriptive phrase that identifies the problematic task and the measurement parameter defining the problem. In Table 46.2, for example, "unable to get out of the bathtub" is the problematic task and independence is the measurement parameter that defines the problem. In this case task independence was measured in terms of caregiver assistance. As depicted in Box 46.1, there are options in the ways in which performance independence, safety, and adequacy can be measured. However, practitioners typically evaluate these parameters regardless of the specific tasks evaluated. These performance characteristics are essential to competent occupational performance. Performance that is not independent indicates a need for assistance from technology or humans. Performance that is independent but unsafe places clients at risk. Performance that is independent but inadequate restricts clients' role performance and may also place them at risk. As is also apparent from Box 46.1, there is more variability in the measurement parameters for task adequacy than there is for independence and safety. For each client, practitioners select the adequacy parameters that are most applicable for the client's condition or task environment. The extent to which pain interferes with performance, for instance, would be appropriate to rate in clients with fibromyalgia or rheumatoid arthritis, but would likely not be appropriate for those with Parkinson's disease or bipolar disorder (decision based on condition). Similarly, inadequate hygiene may be admissible at home but may be offensive in the classroom or workplace (decision based on task environment).

The second part of the problem statement is the explanatory phrase, which indicates the practitioner's explanation for the identified problem. The explanatory phrase is followed by the cue phrase which records the data, obtained through observing, questioning, or testing, that the practitioner used to identify the problem. For Mr. Martin, the practitioner hypothesized that the bathtub transfer problem was related to apraxia, which was exhibited in several observable cues: ineffective positioning for

TABLE 46.2.   STRUCTURE OF THE PROBLEM STATEMENT

Descriptive Phrase	Explanatory Phrase	Cue Phrase	Pathologic Phrase
Unable to get out of the bathtub (problematic tasks) without physical assistance (parameter of concern)	*Related to* apraxia	*As evidenced by* client placing himself in positions that prevent desired motion; required instructional cues for task completion; does not integrate upper and lower extremity motions for task accomplishment	*Due to* Alzheimer's dementia

action, incoordination of upper and lower extremities, and the need for instruction. The selection of the explanatory factor or factors to evaluate emanates from the practitioner's hypothesis about the reason for the performance problem, and this in turn, is guided by the theory the practitioner has applied to the occupational therapy process.

The last part of the problem statement identifies the medical condition or health problem, that is the secondary or remote explanation for the performance problem. Although Mr. Martin's need for assistance in transferring can be explained by dementia, apraxia is given as the primary reason and dementia as the secondary reason. Occupational therapy practitioners treat the consequences of disease (apraxia), while physicians treat the disease (dementia).

Hence, apraxia is the primary explanation for the problem that is the object of occupational therapy interventions. Nonetheless, recognizing that the apraxia is secondary to Alzheimer's dementia—a progressive, degenerative disease—informs the practitioner of the likely etiology of apraxia and limits the theoretic options available for occupational therapy interventions (e.g. a curative approach would be inappropriate).

Defining a performance discrepancy involves more than merely 'finding' a problem. A well formulated problem statement clarifies the performance problem as well as provides information useful for guiding problem solution, that is, intervention. As we have seen, problem definition embodies two levels of evaluation: evaluation of the performance problem and of the etiology of the performance problem. Problem definition stands at the interface between evaluation and intervention.

OT PROCESS: INTERVENTION PLANNING AND IMPLEMENTATION

Once an occupational performance problem has been defined, practitioners search for a solution to the problem, decide on a plan, and implement the plan. Evaluative data are blended with occupational therapy knowledge to create a future profile of the client—a profile that will be achieved through occupational therapy intervention(s).

Performance discrepancies occur because of a misfit between a client's performance capacities, the task demands, and the environmental demands. To achieve a better or optimal person-task-environment fit, person capacities may be changed, task demands may be modified, or environmental demands may be modified. Several types of outcomes may emerge from occupational therapy interventions (Rogers & Holm, 1994a).

1. One possible outcome is the *development* of a capacity, task skill, or habit that did not previously exist. Development is typically the therapeutic goal for infants and young children who are not developing normally, but it is also appropriate for adults who need to or want to learn new skills or healthy lifestyle habits. For example, the development of crawling might be appropriate for a developmentally delayed, non-ambulatory child. Similarly, a widower, who never learned to cook, may need to develop cooking skills following the death of his wife. An adolescent, who uses a wheelchair for mobility and is obese, may wish to develop healthier leisure time habits to promote weight control.

2. Another possible outcome is the *restoration* of occupational performance. Restoration interventions are directed at person capacities that were lost or became impaired as a result of a health condition. They may be curative or compensatory. Constraint induced movement therapy for clients with stroke is a curative intervention intended to cure paralysis of the upper extremity so that the extremity returns to its pre-morbid, non-paralyzed state and functions normally again (Taub et al., 1993). In the same clients, use of the non-paralyzed upper extremity to perform actions and skills previously done with the paralyzed upper extremity, is an example of a compensatory intervention.

3. A third possible outcome is the *stabilization* of occupational performance. When the overall course of a medical condition is downward, for example with Alzheimer disease or multiple sclerosis, intervention to stabilize or maintain a function for as long as possible is appropriate. By delaying the onset or slowing the rate of functional decline, clients continue a higher level of functioning for a longer time.

4. A fourth possible outcome is *prevention*. To prevent a performance problem from occurring, practitioners must predict the occurrence of a negative event from the present situation. We know, for example, that in clients with C5-C6 spinal cord injury, pressure ulcers will likely develop on the ischial tuberosities unless pressure on the buttocks is relieved. To prevent the occurrence of pressure ulcers, risk reduction interventions would be instituted. These might include a Roho™ seat cushion, and training clients to perform periodic pressure relief push ups to relieve pressure on the tissue over the ischial tuberosities.

5. Lastly, the therapeutic outcome may be *palliation*. When clients' health status is progressively deteriorating, interventions directed toward support and comfort are appropriate. Occupational therapy practitioners working in hospice or end-of-life-care, for example, may assist caregivers to manage effectively clients' personal care. Using ergonomically correct postures for feeding care recipients or procedures for transfers might be critical skills for caregivers to master.

In addition to stipulating the desired outcomes of intervention, practitioners make a functional prognosis, that is, a judgment of the chances that the desired outcome will be achieved. In the case of clients with spinal

cord injury, for example, the prognosis for preventing pressure ulcers depends on clients' willingness to perform periodic push-ups during each hour of sitting. Clients who develop this habit would have a good prognosis, while those who do not would have a poor prognosis.

Simultaneous with deciding the specific kind of intervention(s) to administer, practitioners also need to make decisions about the duration (e.g., how long will occupational therapy be needed?), frequency (e.g., How often does intervention need to occur?), and intensity (e.g., How long will each occupational therapy session be?). Should the intervention be administered for 1 hour, 3 times per week for 4 weeks? Or, is it preferable to administer it for ½ hour, 5 times per week for 2 weeks? In inpatient settings, these decisions may be established through clinical guidelines, whereas in other settings practitioners may need to exercise more judgment. In either case, decisions should be based on scientific evidence about the best schedule for eliciting change in occupational performance.

These decisions involve prognostic judgment. In other words, taking into account the client's medical diagnosis (or other health condition) as it is manifested in 'this' client, in concert with occupational therapy knowledge of the likely functional course of the condition, practitioners foretell (prognosticate) clients' future occupational profile with the proposed course of occupational therapy. As occupational therapy science accumulates, more knowledge will become available to practitioners to aid in making these decisions.

Case Scenarios for Intervention

In the following discussion, intervention strategies directed toward person capacities, task demands or environmental demands are defined and then illustrated with case scenarios involving skill and habit deficits. Although we present each intervention strategy separately, they are typically used in combination. Thus, for a client who has had a stroke, a practitioner may simultaneously or sequentially apply a person-oriented strategy (e.g., restore an extremity affected by stroke), a task-oriented strategy (e.g., provide an enlarged handled spoon to enhance grip) and an environmentally-oriented strategy [install ramps for a wheelchair (e.g., physical environment); educate the spouse (social environment)].

Change Person Capacities

When implementing the develop or restore intervention strategy, occupational therapy practitioners focus on the person component of the PTE transaction with the goal of establishing, (initially developing), or restoring (returning to its former state) a specific capacity or several capacities (Dunn et al., 1994). Following the establishment or restoration of capacities, it is assumed that performance discrepancies in tasks that require these capacities will be resolved and performance will be normalized. The four

case scenarios for skill deficits illustrate *developing* coordination and strength through functional activities (Chelsea) and coping skills through training in daily problem-solving (Mrs. Vocelli) and *restoring* upper extremity function through functional activities (Merilee) and hearing through adaptive technology (Reverend Tengesdal). Two cases highlight habit *development* and employ a cognitive prosthesis (checklist) as a reminding aid (Mrs. Vocelli) and splinting and exercise routines to alleviate the symptoms of sensory impairment in the hands (Cara).

CASE EXAMPLES: DEVELOP/RESTORE PERSON SKILL FOR PERFORMANCE IN ANY ENVIRONMENT

♦ Chelsea is a 5-year-old female with cerebral palsy and upper limb spasticity. Prior to beginning kindergarten, her physician suggested Botulinum Toxin A injections in the biceps, pronator teres, flexor carpi radialis, flexor carpi ulnaris, and thenar muscles. In addition, she was referred to occupational therapy to improve upper extremity function in preparation for handwriting and other fine motor skills associated with school (Friedman, Diamond, Johnston, & Daffner, 2000). Her occupational therapy program focused on using everyday activities to improve strength and coordination, and to establish a functional hand grasp for handwriting. After 1 month, Chelsea achieved improved range and strength at the wrist, and a functional hand grasp.

♦ Mrs. Vocelli is a 72-year-old female with osteoarthritis who was widowed one year ago. Although her family believed initially that her apathy and withdrawal from her favorite activities over the past year was due to grief, her primary care physician referred her to a geriatric psychiatrist, who diagnosed her with major depression. In addition to anti-depressant medication, Mrs. Vocelli was referred to outpatient occupational therapy. According to the occupational therapy referral, Mrs. Vocelli was accustomed to having her husband make all decisions and do everyday problem-solving. He also "lifted, carried, pushed and pulled" when Mrs. Vocelli's arthritis was painful. Consequently, Mrs. Vocelli felt ill-equipped for surviving by herself, which in turn contributed to her depressed mood. Mrs. Vocelli joined the functional problem-solving therapy (PST) group run by an occupational therapy practitioner. Each week, group members, including Mrs. Vocelli, brought examples of recent problems that "got them down." At the beginning of each session the occupational therapy practitioner reviewed the seven PST steps, namely, define the problem, choose realistic goals for resolving the problem, generate multiple solutions, implement decision-making guidelines, evaluate and choose preferred solution(s), implement preferred solutions, and evaluate the outcome (Jang, Haley, Small, & Mortimer, 2002; Oxman & Hull, 2001). The group then applied the PST steps to the problems previously vocalized by its members. Solutions were tried out over the following week. With repetition

of the PST process, and assistance from the group, Mrs. Vocelli established problem-solving skills that helped equip her for solving everyday functional problems (Lin et al., 2003).

◆ Merilee is a 46-year-old female who sustained a right hemisphere ischemic stroke 3 months ago. She completed a 2-week rehabilitation program, and is now seen as an outpatient twice a week. Although she has made significant gains, she still has difficulty with right-sided upper extremity forward flexion, wrist extension, and grasp. Merilee's occupational therapy practitioner suggested that Merilee put her plastic glasses into the sink and practice picking them up and placing them on the counter 3 times per day. The practitioner made the suggestion based on the evidence indicating that the use of functional objects for practicing reach and grasp to restore function yields significantly better outcomes than just practicing reach and grasp in isolation (Dromerick, Edwards & Hahn, 2000; Platz et al., 2001; Wu, Trombly, Lin, & Tickle-Degnen, 1998, 2000).

◆ The Reverend Tengesdal is 83 years old and has profound deafness, which is corrected slightly with a hearing aid. He is the visiting pastor of a large church and is having difficulty hearing his wife and some of the frail home-bound parishioners he routinely visits. Recently, he began removing himself from conversations with more than one person because he could no longer hear. His daughter, an occupational therapy practitioner, recommended a Pocket Talker with a magnetic loop to enhance his hearing aids and an attached microphone (Fig. 46.3). The Pocket Talker allows him to hear clearly the voice of his bride of 50 years, as well as those of his parishioners—individually or in groups.

FIGURE 46.3   The Pocket Talker has a magnetic loop that the user wears around the neck to enhance the magnification of the sound in the hearing aid, which allows easier communication with those in the social environment.

Case Examples: Develop/Restore Person Habits for Performance in any Environment

◆ Mrs. Vocelli is a 72-year-old female with osteoarthritis who was widowed one year ago. One year after her husband's death, she was diagnosed with major depression, and referred to outpatient occupational therapy. In occupational therapy, she joined a functional problem solving therapy (PST) group to develop skills in everyday problem-solving. As her depression resolved and she began to re-engage in some of her former activities, she developed anxiety attacks. She was prescribed an anti-anxiety medication and again referred to the outpatient problem solving therapy (PST) group. Mrs. Vocelli reported that the more she went out into the community, the more she worried about whether she left the stove or iron on, the water running, or the space heater too near the drapes. After reviewing the seven steps in the PST process, the solution arrived at by the group was for Mrs. Vocelli to make a checklist of the items she needed to check before she went out. She was encouraged to make a habit of going through the checklist before she left her house, dating it, and then putting it in her purse so that she could refer to the list if she became anxious. The group suggested that she also make a habit of making checklists for other activities that made her anxious, for example, taking the bus. The bus checklist could include: bringing the bus schedule, checking to make sure she had her Senior Citizen Pass, asking for a transfer, and telling the bus driver where she wants to get off the bus. Mrs. Vocelli was seen once a month for the next 6 months to maintain the habits that she had begun to put into place. She reported that the checklists worked and her anxiety was under control.

◆ Cara is a 24-year-old doctoral student who was referred to an occupational therapy practitioner with expertise in hand therapy because of numbness and tingling in her hands. She reported that she used a computer for her doctoral work in history as well as in her part-time job as a research assistant. In addition to bilateral neutral wrist splints to be worn at night (Burke, Burke, Stewart, & Cambre, 1994; Sevim et al., 2004), the occupational therapy practitioner emphasized the necessity of developing habits to interrupt static postures, promote motion, and increase blood flow to the wrist and hands. The practitioner taught Cara exercises (stretching and relaxation) for the hand, wrist and shoulders that she needed to implement routinely, provided her with handouts illustrating these exercises, and suggested that Cara make a habit of setting a timer each hour to carry out the exercises. Three months later Cara reported that her "healthy hand habits" were in place. She no longer had numbness or tingling and she continued to wear her splints at night.

Modify Task Demands to Enable or Improve Performance

When modifying a task, practitioners alter the properties of the task to achieve a desired outcome, which may be to facilitate performance that is functional or hinder performance that is dysfunctional. (Dunn et al., 1994). One task modification strategy involves adapting equipment to compensate for impairments, for example, replacing foot controls with hand controls (Keenan). A second strategy involves enhancing task properties to facilitate function, as was accomplished for Mrs. Rogers when lighting was improved to facilitate seeing. A third strategy relies on assistive technology, which ranges from low 'tech' assistive devices (e.g., a raised toilet seat) to high end products (Mr. Ibrahim's bathtub bench; Mr. Jakke's adapted car). When adaptive equipment is not commercially available, practitioners may fabricate it (Matt). Under habits, the case of Ms. Desai illustrates the use of an audiocassette player to replace a disturbing habit (screaming) with a non-disturbing one (listening to music), while that of Gary emphasizes use of the same equipment to develop a habit (sitting upright). Gary's case also exemplifies the value of task breakdown for adapting tasks (use of nails for sorting). Unlike Mrs. Vocelli, who was able to internalize a reminding strategy by using checklists, Mark was unable to do this and hence an automatic reminding system was prescribed.

CASE EXAMPLES: MODIFY TASK DEMANDS FOR SKILL DEFICIT

◆ Keenan is a 3-year-old boy with a closed head injury, seizures, and lower extremity paralysis. His occupational therapy practitioner adapted Bigfoot (a motorized ride-on vehicle) with hand controls, to replace the foot controls. This modification allows him to move around his yard and neighborhood (Fig. 46.4).

◆ Mrs. Rogers is an 83-year-old female with a 5-year history of macular degeneration, resulting in loss of central vision and fluctuating acuity in her peripheral vision. She has always enjoyed sewing items for craft fairs, but she can no longer see to thread the needle on her sewing machine, even when she uses a wire needle threader. She also cannot see the tension and stitch settings on the machine, and therefore leaves them on the same settings, which is not always appropriate for what she wants to sew. Without assistance, she is unable to pursue her hobby. The occupational therapy practitioner suggested a lighted magnifier, which enables Mrs. Rogers to use her sewing machine and continue a meaningful pastime (Fig. 46.5).

◆ Mr. Ibrahim is a 72-year-old male with a 30-year history of rheumatoid arthritis and a 10-year history of type 2 diabetes who has incurred a mild, right cerebral vascular accident. His wife is concerned about how she

FIGURE 46.4   Adapted motorized vehicles, such as this Bigfoot, enable functional mobility and exploration capacities for children with motor impairments (Vehicles adapted by S. Shores, Good Samaritan Hospital, Puyallup, WA.).

will manage him during bathtub transfers. Mr. Ibrahim likes to soak twice a day in the bathtub to relieve his arthritis pain. The home health occupational therapy practitioner recommended a spring-loaded mechanical bathtub seat that allows Mr. Ibrahim to transfer safely into the bathtub, move down to and up from the bottom of the bathtub, and transfer out of the bathtub, thus preventing falls (Fig. 46.6).

◆ Mr. Jakke is a 48-year-old male with a 10-year history of multiple sclerosis, resulting in bilateral lower extremity weakness and numbness, decreased balance,

FIGURE 46.5   A lighted magnifier used to adapt a sewing task.

FIGURE 46.6 The mechanical tub seat is spring loaded and raises from the tub bottom with a weight shift and a simultaneous pushing up on the tub edges.

and decreased sensation in his hands. Since the last exacerbation of symptoms, Mr. Jakke has been unable to transfer independently into his car, and decided to invest in a car that will suit his needs. The occupational therapy practitioner recommended a van with a remote control and hand controls and referred him to a company that specializes in adapting vehicles. The remote control operates the van door and positions the driver's seat, thus enabling Mr. Jakke to transfer easily in and out of the van (Fig. 46.7). The hand controls provide him with better vehicle control of his lower extremity spasticity. These adaptations enable Mr. Jakke to transport his children to and from school and social activities. He can also take himself to therapy and support groups, while his wife is at work.

◆ Matt is a 7-year-old boy with multiple pterygium syndrome and arthrogryposis. These medical conditions have resulted in severe limitations in all joints and contractures and deformities. He was referred to occupational therapy because his ability to perform transfers is restricted. The occupational therapy practitioner designed a custom ramp (mounted on a rolling library stool) that allows him to access areas that he cannot get up to, such as the couch, bed, tub, dining room chair, or toilet (Fig. 46.8).

FIGURE 46.7 This adapted van allows the driver to open the door with a remote control and then enter the van via a ramp. The ramp folds into the door when it closes, and the driver transfers into the bucket seat and engages the hand controls.

CASE EXAMPLES: MODIFY TASK DEMANDS FOR HABIT DEFICIT

◆ Ms. Desai is a 26-year-old female who is confined to bed and has an organic brain disorder secondary to a brain tumor. Unable to communicate her wants and needs, she learned to scream to get assistance from the nursing home staff. Eventually, she began to scream all the time when left alone. Because of her screaming, other residents avoided her and the staff placed her in her room with the door shut to reduce the disturbance to others. The occupational therapy practitioner suggested using an audiocassette tape player and headset

FIGURE 46.8 A custom ramp mounted on a rolling library stool enables access to the toilet as well as the couch, bed, tub, and chairs. (Built by S. Shores, Good Samaritan Hospital, Puyallup, WA.).

and playing tapes of her favorite music to engage her attention (Casby & Holm, 1994). Her family brought in her tape collection, and within 1 week, Ms. Desai's screaming habit was reduced to only one or two cycles a day.

◆ Gary is a 17-year-old male with cerebral palsy (hemiplegia) and moderate mental retardation. As part of his individualized vocational plan, he spends 3 hours each day in a work program. He is assigned to the lawn decorations assembly crew to develop work habits. The special education teacher notified the occupational therapy practitioner that Gary does not maintain a good posture while working and that he has difficulty assembling the pinwheel pieces in the correct order. The occupational therapy practitioner modified the assembly task by breaking it down into several additional steps that Gary can manage. She put nails in a board so that Gary can sort the pinwheel pieces in the basket by color in the correct sequence for assembly, then pick up the pieces from the nail board in correct sequence and assemble them onto a jig for the next student to continue the assembly. In regard to posture, the occupational therapy practitioner observed that once Gary becomes engaged in his tasks, he forgets about his posture. To solve this problem, a tape player with one of Gary's favorite tapes was attached to a switch plate (Fig. 46.9). To trigger the switch plate, Gary has to have most of his hand on the switch. To achieve this position, he must develop the habit of sitting upright instead of listing to the left with his shoulder protracted, elbow flexed, and wrist flexed.

◆ Mark is an 18-year-old male whose diagnosis is undifferentiated schizophrenia. An occupational therapy practitioner has seen him as an outpatient as part of a supported employment program. Mark is being placed in a fast-food restaurant and is assigned to work in the supply room and on the grill. To develop appropriate work habits, Mark is supplied with a NeuroPage System
FIGURE 46.9   A switch plate adapted to trigger a tape player when the student's hand is placed firmly on the switch.

(Hersh & Treadgold, 1994) that is programmed to activate to cue him to: wake up in the morning, gather items needed for work (e.g., lunch), and take his medications as prescribed (e.g., time, name). The target outcome is to decrease Mark's reliance on the paging system.

Modify the Environment to Enable or Improve Performance

The environment can be visualized as a series of increasingly larger concentric circles with clients at the center. The client's immediate environment consists of the people (e.g. immediate family) and physical structures (e.g., private homes or apartments, workstations) surrounding the task. Broader circles encompass extended family members, friends, co-workers, peers, politicians, policies and procedures, cultures, private and public buildings, neighborhoods and communities and so on. Although all levels exert an influence on task performance, this chapter deals with the occupational therapy process as it is applied at the individual level. Hence, discussion of the environment is confined to the immediate environment.

Occupational therapy practitioners implement two basic strategies for modifying environmental demands. The first strategy is to modify the present environment. As demonstrated in the case of Mrs. Hill, the installation of a ladder was a relatively minor home modification but it allowed her to meet her goal of staying at home by herself. In contrast, major modifications were required in Mr. Jakke's blueprints for his new home to accommodate wheeled mobility as well as in his yard for him to continue his leisure activity of gardening. Interventions to promote safe mobility and wayfinding are exemplified in the cases of Ms. Yi-Sun and Mrs. Kochinski, respectively. Modifications targeted at the social environment are key in effective management of Mrs. Prescott's skill deficits secondary to her dementia.

The second environmental strategy practitioners employ is to recommend a different environment. For Mr. Bitner, for example, the practitioner recommended enrollment in adult day care, which provided a limited change of environment. For Andrew, the characteristics of his study space were dramatically altered to create an environment to reduce distraction and facilitate studying.

CASE EXAMPLES: MODIFY ENVIRONMENTAL DEMANDS FOR SKILL DEFICITS

◆ Mrs. Hill is a 63-year-old female with a 20-year history of multiple sclerosis that resulted in bilateral numbness and weakness below the hips, decreased sensation in the hands, and low back pain with prolonged sitting. Because of several recent falls from her wheelchair when transferring, her family members want her to have an attendant while her husband is at work. She adamantly rejects their suggestion. Because Mrs. Hill used a ladder successfully in the physical therapy clinic to get

back into her chair, the occupational therapy practitioner recommended that a similar ladder be installed in the home. A suitable site for the ladder was located, and when Mrs. Hill slips to the floor during a transfer from bed to wheelchair, she is able to crawl to the ladder, pushing her wheelchair ahead of her, and use the ladder to get back in her chair (Fig. 46.10).

◆ Before Mr. Jakke and his family moved into their new home, several alterations were made to accommodate a wheelchair. Mr. Jakke (a contractor) reviewed the relevant dimensions (Fig. 46.11). and made several alterations to the physical structure. The plumbing was recessed under the bathroom sink to allow Mr. Jakke to roll under the sink without worrying about burning his insensate lower extremities on the pipes, and two drawers were made into one deep drawer so that items could be obtained and stored easily from a seated position (Fig. 46.12). The standard 15-in. high toilet was replaced with an 18-in. high toilet for easier transfers. Oak grab bars were installed next to the toilet and doubled as an assistive device for standing pivot transfers and as a towel rack (Fig. 46.13). In the kitchen, static shelves were replaced with pull-out drawers for easier

FIGURE 46.10   A wall ladder designed to blend in with the decor of the home environment.

access to items (Fig. 46.14). The microwave oven was positioned by the cutting board to facilitate transferring hot dishes to the table (Fig. 46.15). This setup allows Mr. Jakke, who has weakness and some loss of sensation in his hands, to move a hot dish from the microwave to the counter, reposition it, move it from the counter to the cutting board, reposition it, and then move it from the cutting board to the table. Finally, a counter was built in the laundry room to enable Mr. Jakke to fold laundry while seated in his wheelchair (Fig. 46.16).

◆ Ms. Yi-Sun is the occupational therapy practitioner at Vintage Long Term Care Facility. She is asked by the administration to create an environment that will be safe for residents with dementia to wander and pace when they become anxious (Hall & Buckwalter, 1987). With the assistance of students from the nearby educational program for occupational therapy assistants, she designs stations in a hallway where residents can stop and wind pocket watches, fold towels, sort and stack heavy plastic dishes, watch fish in an eye-level aquarium, and pick up finger foods. Outside, in the fenced-in patio area, they build raised plant boxes that can be tended without bending and place fencing around areas where the ground is uneven or there are tripping hazards that could place residents at risk for falls (Fig. 46.17). All the staff and residents enjoy the patio on nice days, creating a positive environment for everyone.

◆ Mrs. Kochinski is an 86-year-old female with multi-infarct dementia, who currently resides in an assisted living center. Because she is having difficulty locating her room after meals and other activities, the occupational therapy practitioner helped her put some favorite pictures of herself and her husband (circa 1940) on her door and then cued her to find the door with her pictures after each meal and activity session (Fig 46.18). In 3 days, her way-finding skills were established in her new environment.

◆ Mrs. Prescott is 51-years old and has a rapidly progressing dementing illness of unknown origin. She was hospitalized in a psychiatric unit after she lost 30 lb in 2 months, exhibited apraxia during everyday tasks, and became extremely labile. At discharge, she is unable to dress herself, cannot remember how to use silverware, and is incontinent. Her family wants to care for her at home and has hired a live-in attendant. The occupational therapy practitioner met with the family and the attendant to demonstrate a hierarchy of assists that are available to them to maintain the skills Mrs. Prescott retains and provide the necessary support as her capacities decline. The occupational therapy practitioner showed the caregivers a videotape made while Mrs. Prescott prepared a meal during therapy. As they watched the tape, the practitioner identified lower-level verbal cues, middle-level gestural cues, and higher-level physical assists (physical guidance and total assistance) as each was given. Using lower-level assists before
FIGURE 46.11   Basic measurements and proportions can be used when planning home modifications. Measurements are given in inches and centimeters. (Adapted from Diffrient, Tilley, & Bardagly, 1974).

higher-level assists, varying the type of assists from day-to-day as Mrs. Prescott's performance fluctuates, and increasing the use of high-level assists as dementia progresses were discussed with the caregivers. The practitioner gave each caregiver a list of the types of assists that Mrs. Prescott required for personal care tasks, explaining each one and then responding to questions. Although Mrs. Prescott's progressive deterioration cannot be prevented, the appropriate level of assists from the social environment can prevent a faster rate of skill deterioration (Rogers et al., 2000).

CASE EXAMPLES: MODIFY ENVIRONMENTAL DEMANDS FOR HABIT DEFICITS

◆ Mr. Bitner is a 68-year-old male with dementia of the Alzheimer type. He is a retired pharmaceutical company executive, and he and his wife, Anne, enjoy entertaining family and friends in their home. Mr. Bitner's current stage of dementia is manifested in continuous repetitive questioning of Mrs. Bitner, difficulty concentrating, loss of interest in activities, withdrawal from social activities, and constant pacing. Even though Mrs. Bitner had

rearranged furniture to accommodate her husband's new habit of pacing, 2 weeks ago Mr. Bitner sustained bilateral Colles' fractures, when he tripped over a coffee table in the family room. After assisting Mrs. Bitner with suggestions for her husband's personal care, the occupational therapy practitioner gave her information about adult day-care programs for persons with dementia. Adult day care has benefits for both the care recipient and the caregiver, with Mr. Bitner receiving needed stimulation and appropriate supervision and Mrs. Bitner receiving respite from Mr. Bitner's repetitive question and pacing habits.

◆ Andrew is a 13-year old male who has a diagnosis of attention deficit disorder. He has his own room with a desk for studying, but he becomes distracted and rarely completes his homework. Andrew's psychologist works with an occupational therapy practitioner consultant, whom he asked to evaluate Andrew and make recommendations. The therapist recommended the following: *Organize all items on Andrew's desk so that there is a clear system for accessing materials. Move posters from the walls surrounding his desk to another place in his*

FIGURE 46.12 Recessed plumbing and double-deep drawers allow easy access to the sink area from a seated position.

FIGURE 46.13 The oak grab bars also serve as a towel rack and the extra-high toilet enables an easy side-to-side transfer from a wheelchair.

FIGURE 46.14 Shallow drawers on gliders make all goods accessible from a seated position.

FIGURE 46.15 The placement of the microwave enables hot items to be stepped down to the cutting board and then transferred to the table with ease.

FIGURE 46.16 The laundry table is angled to allow a clear pathway for the wheelchair, and the counter height is 32 in. for ease of use when seated, with clear access underneath.

room. When he gets ready to study, have Andrew pull only items necessary for a particular assignment onto his desk. To decrease visual stimuli, the only light in Andrew's room should be his desk lamp. In addition, have Andrew take frequent study breaks. Andrew should study at the same time every evening, and go through the same routines to set up his study area until habit patterns are established and maintained.

   The intervention was successful.

FIGURE 46.18   Familiar cues in a new environment help assisted living center residents find their way home.

◆ Mr. Jakke has always liked being outdoors. Several years ago he took up gardening and his daily routine involved spending about 2 hours each morning tending his vegetables, flowers, and bonsai trees. Previously, he used a portable kneeler/bench to support kneeling or sitting. However, he is no longer able to use this device because of increased lower extremity spasticity. Hence, his morning gardening routine has come to a halt. The occupational therapy practitioner suggested raised gardens for his vegetables and flowers (Fig. 46.19) and a fence with shelves to tend and display his bonsai trees. The modifications enabled Mr. Jakke to resume his morning gardening routine.

OT PROCESS: RE-EVALUATION

The fifth component of the occupational therapy process is re-evaluation. During re-evaluation, the predicted outcomes are evaluated using the same measures as during the evaluation. The purpose of re-evaluation is to ascertain if occupational therapy interventions achieved the intended outcomes. Hence, the criteria for re-evaluation are the stated outcomes. If the stated outcome was to restore independence in feeding, at re-revaluation clients' ability to feed themselves independently would be tested under various conditions. The conditions would involve eating liquids (beverages) and solids (meat, mash potatoes), using various eating utensils. If the practitioner had hypothesized that the feeding discrepancy was related to inadequate grip strength for holding feeding utensils, and the intervention implemented to achieve feeding independence was graded functional activities to strengthen grip, the practitioner may also wish to re-test grip strength. If the desired outcome was achieved (independence in feeding) and grip strength was increased, the practitioner's hypothesis explaining the performance discrepancy would be confirmed. However, if grip strength was increased but the outcome was not achieved, the practitioner would need

FIGURE 46.19   The raised gardens enable clients to tend plants from a seated position.

to decide to: (1) continue the graded functional activities intervention (e.g., longer duration is needed to achieve change); (2) change the intervention, for example, to try an adaptive device (e.g., compensate for reduced grip strength), (3) continue the graded functional activities intervention but add another modality, or (4) revise the outcome (e.g., increased independence vs. independence). To make these decisions, practitioners draw on their book knowledge, hands-on knowledge, and their experience with "this" particular client.

The timing of re-evaluation is based on the practitioner's prediction (prognostic judgment) of how long it will take the intervention to have an effect. The following question must be addressed: Given Xx occupational therapy intervention, at Aa intensity, with Bb frequency, for Cc duration, how long will it take for the targeted outcome to be achieved? For example, given graded functional activities (intervention) for 1 hour (intensity), 3 times per week (frequency) for 4 weeks (duration), how long will it take the client to move from being dependent in feeding to being independent in feeding. Intensity, frequency, and duration of rehabilitation interventions have risen to the forefront of discussion with constraint induced movement therapy (CIMT). The original treatment protocol called for a massed practice schedule of 6 hours per day for 5 days per week for 2 weeks (Ostendorf & Wolf, 1981). The positive results seen over 2 weeks with CIMT have spurred practitioners to inquire if greater benefit would be derived from protocol variations by increasing the intensity, frequency, or duration. Significantly, a meta-analysis of studies involving different intensities of stroke rehabilitation found a statistically significant effect for activities of daily living (Kwakkel, Wagenaar, Koelman, Lankhorst, & Koetsier, 1997).

Re-evaluation then should be scheduled to coincide with the estimated time needed for change in the outcome variables to occur. Modifying the task or the environment often results in immediate improvement in occupational performance, whereas the effects of changing client capacities may take longer. For example, clients with spinal cord injury, who cannot hold a feeding utensil, can usually feed themselves immediately following application of a universal cuff to the hand with a spoon inserted into the cuff pocket. Restoring sufficient grip strength to hold the spoon may take months or may not be feasible. Practitioners often combine person-task-environment strategies in the overall intervention plan to take advantage of the 'almost' immediate results obtained when task and environmental demands are manipulated as well as the 'delayed' changes obtained with person-oriented interventions. The 'immediate' results following task and environmental interventions often motivate clients to participate fully in person-oriented interventions that require more effort. Nonetheless, the specific combination of interventions influences how soon functional outcomes can be achieved.

The risk in re-evaluating before change has had the opportunity to develop is that a successful intervention may be deemed unsuccessful. The timing of re-evaluations is often addressed in practice guidelines and by third party insurance carriers. Although practice guidelines and insurance regulations are increasingly being formulated based on evidence, this is not always the case and practitioners need to be aware of this possibility.

In addition to judging the success of occupational therapy interventions on clients' occupational performance, re-evaluation provides practitioners with the opportunity to assess their own performance. The accuracy of their therapeutic judgments about the definition and nature of performance discrepancies and the intensity, frequency, and duration of interventions can be evaluated against stated outcomes that are achieved and not achieved. Reflecting on one's therapeutic decisions and discussing them with more experienced practitioners is an excellent way of improving one's therapeutic reasoning skills (Rogers, 1983; Rogers & Holm, 1989).

The Hierarchy of Occupational Performance: Implications for Evaluation and Intervention

The hierarchy of occupational performance provides a useful perspective for delineating the major evaluation and intervention approaches for performance discrepancies used in occupational therapy. Occupational performance may be envisioned as a three-layer phenomenon—the top layer represents occupational role performance (e.g., student, home maker); the middle layer represents task performance (e.g., dressing, meal preparation, school work); the bottom layer represents capabilities (e.g., range of motion, short-term memory, motivation). These layers are arranged in a hierarchy as capabilities coalesce to make up task-performance skills, and tasks coalesce to make up occupational roles. Thus, it is salient to ask, at what level should the occupational therapy evaluation begin and how should it move forward. Similarly, at what level should occupational therapy interventions be targeted?

Trombly (1993, 1995) labeled the approach that begins with capabilities as the bottom-up approach and the approach that begins with role performance as the top-down approach. The top-down approach reflects the position delineated in the Occupational Therapy Practice Framework (AOTA, 2002). A third approach, that initially focuses on the client-in-context was delineated by Hinojosa and Kramer (1998).

Bottom-Up Approach to Performance Discrepancy

When using a *bottom-up approach,* occupational therapy practitioners focus evaluation and intervention on the client's generic abilities (i.e., body functions and structures and related impairments according to the ICF model; or client factors and performance skills using the OTPF). For Mrs. Fisher, a 63-year-old client who sustained a right cerebrovascular accident (CVA), the practitioner might

focus the evaluation on muscle tone, reflexes, postural control, visual motor integration, and short-term memory. Interventions are restorative in nature with the intent of normalizing body functions and structures lost secondary to stroke.

The rationale underlying the bottom-up approach is that body structures and functions support task performance in all occupational areas and that by restoring these abilities to their normal state, task performance, which was previously dysfunctional, automatically becomes functional, because the skills and habits needed to perform these tasks are once again intact. Once generic abilities are revitalized, some restorative interventions may be devised for task performance to reintegrate newly restored generic abilities into everyday performance of the client's personal care, home management, work, and play or leisure activities. This intervention would not need to be extensive, however, because the "cure" of impairments re-establishes the client's capacities, and task reactivation occurs rapidly, particularly for well-learned and well-practiced everyday skills. Hence, the bottom-up approach to performance discrepancy is efficient because the restoration of task abilities returns clients to their premorbid (pre-disease, pre-disorder) condition, and tasks and role participation are resumed at their prior level.

The bottom-up approach permits the occupational therapy practitioner to focus the evaluation and intervention on discrete client capacities without initially having to consider task or environmental demands. Mrs. Fisher's muscle tone, reflexes, and postural control can be evaluated on a mat table and her visual-motor integration and short-term memory can be evaluated through tests as she sits in her wheelchair. Interventions to normalize tone, and improve postural control can also be implemented with Mrs. Fisher on the mat table. Interventions to resolve problems in form constancy, visual closure, figure-ground perception, and short-term memory can be implemented through paper-and-pencil exercises done on a lapboard. For the most part, environmental interactions are limited to test and intervention objects and instructions.

The demands of real-life situations are introduced into the intervention plan once generic abilities have been restored or their improvement has stabilized. For example, because Mrs. Fisher has not achieved full voluntary control of her affected left extremities and cannot perform transfers in a typical manner, her occupational therapy practitioner practices bed and toilet transfers with her to help her integrate postural control techniques and manage abnormal tone during these procedures.

Top-Down Approach to Performance Discrepancy

The second major approach to occupational therapy evaluation and intervention—the *top-down approach*—begins by establishing performance discrepancies at the highest level—that is, the level of social role. It then moves to the

tasks necessary to sustain valued social roles—that is, to the ICF level of activities/activity limitations or to the OTPF level of occupations and related performance skills and patterns. Finally, the focus is transferred to generic abilities that support activities and social role performance, or to the OTPF level of inherent client factors or the ICF level of body functions and structures/impairments. The fundamental rationale underlying the top-down approach is that even though impairments cannot always be cured, activities and social participation can be improved through adapted performance of tasks and actions associated with these activities and social roles. The following logic undergirds this rationale (Mathiowetz, 1993; Trombly, 1993, 1995):

◆ Evaluation and intervention begin with tasks that are of value to clients (i.e., necessary for carrying out valued activities and social roles).
◆ Factors external to clients that contribute to performance discrepancies can be identified during task performance.
◆ Inferences about probable external causes of performance discrepancies can be verified by changing the task or environmental demands during task performance, thereby reducing or resolving the performance discrepancy.
◆ The contribution of capacities and impairments can be observed as they interact synergistically in the performance of real-life activities and social roles.
◆ A more focused evaluation of impairments can occur in the context of task performance to formulate appropriate intervention strategies to establish, restore, or prevent loss of generic capacities.

For Mrs. Fisher, who sustained a right CVA, the occupational therapy practitioner begins by evaluating Mrs. Fisher's participation in the social roles that would most likely be restricted after a stroke. Mrs. Fisher values most her roles as a wife and homemaker. She enjoys cooking for her husband and baking for her grandchildren, who visit her every Tuesday. She is also concerned about her role as a self-carer. In addition to walking, feeding, bathing, toileting, dressing, and hygiene, Mrs. Fisher expresses concern about medication management and emergency communication when her husband is not home.

Once the most salient tasks comprising each social role have been identified, performance-based evaluation is initiated to identify task performance that is unaffected as well as task limitations. In-depth evaluations are needed to identify the specific point in a task sequence where breakdown occurs, as well as the task demands, and to develop therapeutic hypotheses about the impairments responsible for this breakdown. Intervention strategies to reduce task and environmental demands involving compensatory methods of task performance, the use of adaptive equipment, and modification of the ambient physical and social environmental may be implemented. These compensatory strategies may resolve performance discrepancies relatively

quickly, and they may be temporary or permanent solutions to performance discrepancies. If temporary solutions, they are usually implemented to enable adapted task performance while capacity (impairment)-oriented interventions are instituted later to restore person abilities.

The top-down approach to performance discrepancies permits the occupational therapy practitioner initially to focus evaluation and intervention on the social roles and responsibilities that define a client's participation in the home and community. Knowledge of task demands and the physical and social environment are integral to the occupational therapy process from the beginning.

Mrs. Fisher, for example, indicated that her present concerns center on her roles as self-carer, wife, grandparent, and homemaker. She is anxious about her ability to carry out these roles since her stroke. Ideally, evaluation of the critical tasks that constitute her homemaker role (e.g., meal preparation, household maintenance, clothing care) and her self-carer role (e.g., bathing, toileting, dressing) would be carried out in her home so that information obtained about the PTE transaction is accurate and valid. Under less-than-ideal conditions, these tasks are evaluated in an occupational therapy clinic. Accuracy and validity of information are increased under clinical conditions by simulating as much as possible the task and environmental demands that Mrs. Fisher will face in her home at discharge. For example, because the bathroom in the Fisher home is too narrow to allow Mrs. Fisher to turn her wheelchair around in the bathroom while she is sitting in it, the occupational therapy practitioner trained Mrs. Fisher to back her wheelchair This procedure enabled Mrs. Fisher to practice transfers to the bathtub bench as well as the toilet, toward the stronger, unaffected right side of her body. She then learned to collapse the wheelchair and reposition it in the opposite direction before transferring out of the bathtub. Turning the chair allowed her to again transfer toward her stronger, unaffected side. The space needed to turn the chair is less when she is not in the chair because her thigh length does not need to be taken into account. In addition to the compensatory approaches, neurodevelopmental interventions (i.e., restorative) to improve postural control by normalizing muscle tone and inhibiting abnormal reflex patterns would be incorporated into transfer practice exercises.

The Client-in-Context Approach to Performance Discrepancy

Unlike the bottom-up and top-down approaches, the third approach to performance discrepancies does not prescribe a specific starting point or sequence. Rather, the occupational therapy process begins with a screening evaluation, which is structured to ascertain the client's area of greatest need (Weinstock-Zlotnick & Hinojosa, 2004). The practitioner seeks to understand why the client came or was referred to occupational therapy. Data from the screening

evaluation directs the subsequent comprehensive evaluation. If the problem is situated in a body structure or function, this structure or function is then evaluated more comprehensively. If the problem resides in the task or environment, the task or environment is examined in detail. The client's presenting problem is the trigger for future actions.

During the screening evaluation, Mrs. Fisher clarifies that her greatest concerns are her ability to transfer to the toilet, manage her medications, and communicate in an emergency when her husband is at work or away from the home. Therefore, during the comprehensive evaluation, the practitioner observes Mrs. Fisher perform a toilet transfer, sort several medications onto a daily schedule according to the directions on the prescription containers, and make a 911 call from the floor (as if she had fallen) by pulling the telephone to the floor using the cord. Additionally, she assessed Mrs. Fisher's motor control after observing the toilet transfer and floor mobility. Intervention focused on management and use of the wheelchair during toilet transfers, sorting medications for the next week by day and time, and subscription to a medical alert system for assistance in case of a fall or an emergency. Mrs. Fisher was also scheduled for outpatient rehabilitation to focus on normalizing the tone in her affected side, as well as improving postural control.

Advantages and Disadvantages of the Approaches to PTE Transaction Discrepancies

The Bottom-Up Approach

An advantage of the bottom-up approach to PTE discrepancies is that intervention aimed at developing or restoring generic abilities may benefit many tasks. For example, increasing muscle strength or range of motion in the upper extremities will facilitate all tasks for which these abilities were deficient. Similarly, reducing apathy will foster re-engagement in previously neglected occupational areas. Likewise, correcting visual-sequencing deficits will enhance the performance of all tasks negatively affected by this impairment. Thus, potentially, by remediating neuromuscular, mental, or psychological impairments, multiple task disabilities can be treated simultaneously.

Because the bottom-up approach emphasizes performance factors that are internal to clients, consideration of external, environmental factors is extremely limited. Therefore, the approach is economical to administer because occupational therapy practitioners do not need to assess or manage the demands of tasks and the surrounding physical and social environment, or how they impinge on the client's abilities.

Nonetheless, an inherent disadvantage of the bottom-up approach is that improvements in generic abilities may not generalize to specific tasks (e.g., dressing, medication

management) or actions (e.g., buttoning, sorting medications). Generalization may not occur for several reasons. First, abilities-oriented interventions concentrate on the body functions and structures that are common to many tasks. However, task performance requires the application of these abilities to the unique demands of specific tasks. Improvements in visual figure-ground perception demonstrated on paper-and-pencil tests, using black-and-white stimulus materials, may not enable clients to identify hazards, such as water spills, on a multicolored and patterned vinyl floor surface. Second, when abilities are exercised in isolation from tasks, they are not integrated with the other abilities that are also needed to perform these tasks (Ma & Trombly, 1999; Trombly & Wu, 1999). In other words, discrete abilities-oriented interventions do not acknowledge either the interaction between task-related abilities or their coalescence in the PTE transaction in which the discrete abilities will be used. Perceiving a water spill on the floor must be accompanied by the cognitive capacity to motor plan to avoid the spill and the neuromuscular strength and endurance to execute walking around it. Finally, generalization may not occur because although abilities may be improved, they may not be improved sufficiently to meet task demands. An increase in range of motion of 10° at the shoulder joint is still inadequate for grooming if 25° more motion is needed to comb the hair on the back of the head.

The bottom-up approach may also result in the identification and treatment of impairments that may not actually be causing performance dysfunctions. A deficit score on a test of visual figure-ground perception may not translate into performance deficits on well-learned daily living skills. Without assessing the PTE transaction during tasks, the meaning of impairments for performance is vague.

The bottom-up approach is generally initiated with the intent to switch to the top-down approach if full recovery does not occur or once maximum benefit is obtained from restorative interventions. The danger in this tactic is that too much intervention time may be spent on remediating impairments. At the outset of intervention, it is difficult to predict if full recovery will be achieved, and occupational therapy practitioners are prone to persist in restorative interventions as long as gains are being made. Unfortunately, if full recovery is not achieved, there may be little 'reimbursable' intervention time left for addressing activity limitations or participation restrictions. Clients may then be deprived of independent, safe, and adequate task performance that could have been achieved—or achieved more readily— through compensatory interventions. The risk of clients being discharged from therapy before maximum improvement in task performance has been achieved has been intensified by managed care and reduced time allocations for rehabilitation (Angelelli, Wilber, & Myrtle, 2000; Banja & DeJong, 2000; Cope & Sundance, 1995; Eastwood, 1999).

Another disadvantage of the bottom-up approach is that clients may not see the connection between interventions aimed at discrete impairments (e.g., motor control exercises, visual-scanning programs on a computer, stacking cones) and improvement of their daily living activities and social participation. Hence, they may be less motivated to participate in occupational therapy. However, by educating clients and their families about the connection between impairment reduction and task improvement, this disadvantage may be overcome or minimized.

Top-Down Approach

A primary advantage of the top-down approach is that evaluation and intervention center on social role participation and task performance that are meaningful to clients, yet are discrepant with the levels of performance that are expected, required, or desired (Trombly, 1993). Consistent with this advantage are two additional benefits. First, because the occupational therapy process focuses on social role participation and activity performance that are meaningful to clients, the relevance of therapy for improving daily life is readily apparent to clients (Trombly, 1993). Thus motivation to participate in therapy is heightened. Second, social role and task performance are influenced directly by the intervention. Real-life performance is both the medium and the outcome of therapy (Dirette & Hinojosa, 1999; Dolecheck & Schkade, 1999; van Heugten et al., 1998).

The top-down approach also has the advantage of reinforcing and expediting an approach that people often implement naturally when problems are experienced in task performance (Fried, Herdman, Kuhn, Rubin, & Turano, 1991; Yakobina, Yakobina, & Tallant, 1997). When difficulties are encountered in doing tasks, people tend to seek the assistance of others, use a tool to help themselves, or try a different way of performing the task. These compensatory procedures foster task completion. Because the top-down approach enhances processes that people turn to naturally when problems are encountered, it is familiar to clients, and hence it is likely to be accepted by them.

The top-down approach provides a further advantage at the point at which intervention switches from a social role participation or task focus to an impairment orientation. The top-down approach facilitates the identification of impairments in the context of social roles and the tasks embodied in these roles; consequently, the relevance of impairments for social roles and their tasks is clear to clients. In contrast, in the bottom-up approach, by which impairments are evaluated in isolation, their relevance for social roles and tasks can only be inferred. The visual-perceptual impairments identified through a paper-and-pencil test may or may not impair social roles and activities. The identification of role and task-related impairments, in turn, enables a more targeted evaluation

of impairments as well as more precisely directed restorative interventions.

The disadvantage of the top-down approach is that evaluation and intervention are social role and task specific, and there may be little transfer from one task to another. Moreover, for intervention to be maximally effective, it must occur in the occupational context in which the client lives, works, or plays, which may be difficult to arrange and may not be reimbursable. Thus the approach requires the occupational therapy practitioner to take into account the complexity of environmental factors that impinge on performance.

Rogers and Holm stressed the salience of the top-down approach as well as compensatory interventions for maximizing performance gains (Holm & Rogers, 1989, 1991; Rogers & Holm, 1989; Rogers et al., 1997). Research shows that the correlation between task abilities and task performance although positive is low. Mathiowetz (1993), in a discussion of neuromuscular capacity evaluation and intervention for function, noted that it is possible for some clients to have grip or pinch strength within normal limits but not be able to accomplish necessary functional tasks and for others to have grip or pinch strength below normal limits and yet be able to accomplish all their functional tasks. He further pointed out that the kinesiology literature suggests that motor learning is task specific, with little carryover to other tasks, and thus the best way to improve motor function is to practice the task for which it is required. According to Trombly (1993), "we have no definitive study in occupational therapy that indicates that a person's occupational functioning is better as a result of restorative therapy rather than adaptive therapy" (p. 255), and Wood (1996) summarized concerns about a singular use of the bottom-up approach to PTE transaction discrepancies (Humphrey, Jewell, & Rosenberger, 1995; Neistadt, 1994a, 1994b; Trombly, 1995) by noting that there "has been increasing evidence that improvements in performance components do not necessarily translate into competent functioning in everyday life" (p. 631).

Additional compelling arguments for the top-down approach have come from health insurance companies because they define acceptable outcomes of therapy through their reimbursement practices. For example, Blue Cross of California defined a meaningful outcome of therapy as "one in which the activity level achieved by the patient . . . is that level necessary for the patient to function most effectively at home or at work" (Stewart & Abeln, 1993, p. 213). Another parameter of acceptability, a utilitarian outcome of therapy, is defined as a functional outcome that is economically and efficiently achieved (Eastwood, 1999; Stewart & Abeln, 1993).

Finally, the disability rights movement has also promoted the top-down approach and compensatory interventions by focusing on task and environmental adaptations. When using compensatory interventions, practitioners probe to identify how task and environmental demands affect role and task performance and then seek to work around problems or capitalize on assets (Dunn et al., 1994; Verbrugge, 1990). Thus, compensatory interventions do not assume that there is something wrong with the person with a disability that needs to be fixed or changed. It is the task or the environment that needs to be changed to accommodate the person's abilities. As Verbrugge (1990) noted, the request of advocacy groups for persons with disabilities is: "Change the milieu, not me" (p. 68).

The Client-in-Context Approach

The client is the pivotal point in the client-in-context approach. A major advantage of this approach is that the territory of inquiry for evaluation is immediately and efficiently narrowed. Furthermore, it is narrowed to a primary concern of the client, thus peaking the client's interest in therapy and facilitating cooperation. A client presents with a diagnosis of carpel tunnel syndrome of moderate severity reporting pain and weakness that interfere with daily living tasks. The practitioner responds by fabricating a night splint that keeps the wrist and metacarpophalangeal joints in a neutral position and teaching tendon and nerve gliding exercises (Brininger et al., 2007). The pain and weakness resolve over 3 weeks and the performance of daily activities is no longer problematic.

The advantages provided by an occupational therapy process that is highly focused and efficient and that builds on problems identified by clients are offset by several disadvantages. First, for clients to identify problems amenable to occupational therapy interventions, they must have a clear understanding of occupational therapy. Unfortunately, occupational therapy is poorly understood by the public and health care professionals alike (Ahlstrand, 1989; Chakravorty, 1993; Jamnadas, Burns, & Paul, 2001; Kane, Robinson, & Leicht, 2005; McAvoy, 1999; Patel & Shriber, 2000; Royeen, Zardetto-Smith, Duncan, & Mu, 2001). Hence, clients may need to be coached about occupational therapy before they are able to articulate performance problems.

Second, clients with cognitive impairments may not be able to identify their performance problems. Clients with dementia, for example, may deny that they have problems in caring for themselves or their homes. Similarly, those with mental retardation may want to live in a group home but may not be aware of the daily living skills required by these residences. Clients may also be unaware of their problems, may refuse to report them, or may exaggerate them, as often occurs for clients with mental health diagnoses (e.g., schizophrenia, depression, bipolar disorder) (Branch & Meyers, 1987; Pearson, 2000).

Third, clients may be reluctant to state their problems. Older adults, for example, may hesitate to acknowledge dependencies fearing that this may be interpreted as an inability to continue to reside independently in the community.

THE OCCUPATIONAL THERAPY PROCESS REVISITED

Occupational performance is the human behavior addressed by occupational therapy practitioners. Performance—'doing'—is one of the defining characteristics of our profession and in the therapeutic situation practitioners are often anxious to move quickly to the 'doing.' The six components of the occupational therapy process serve as a cognitive assistive device to remind practitioners to 'think before they act.' Although we have discussed theory, evaluation, problem definition, intervention planning and implementation, and re-evaluation separately, in the practice situation, the process shuffles back and forth among components. Practitioners do not collect 'all' evaluative data and then organize it to define problems. Rather, they move back and forth between theory, evaluation, and problem definition almost simultaneously theorizing, evaluating, defining, and intervening.

Some occupational therapy interventions particularly lend themselves to an 'evaluation-intervention-re-evaluation' mode of operation. For instance, suppose that a practitioner ascertains, through performance <u>evaluation</u>, that a client is dependent in transferring out of the bathtub. Further, suppose that the practitioner reasons that this dependency is secondary to apraxia—an inability to problem solve how to get out of the tub. Because the client cannot be left seated in the tub, the practitioner initiates interventions to facilitate exiting the tub. The client is instructed (<u>intervention</u>) to position the feet under the body to rise from the tub bottom and then exit the tub. The intervention is successful and the client exits the tub (<u>re-evaluation</u>). Hence, the practitioner's hypothesis about the reasons for the performance deficiency is at least partially confirmed, and the practitioner has gained new information about the client's capacity (e.g., the client can follow verbal instructions) that can be used in therapy. The 'evaluation-intervention-re-evaluation' mode is referred to as a dynamic or interactive assessment process (Rogers, Holm, & Stone, 1997) and it encapsulates all components of the occupational therapy process.

Evaluation plays a key role in understanding the performance problems experienced by clients. However, to be optimally serviceable, evaluation must yield data useful for selecting interventions and outcomes as well as defining problems. Outcomes stipulate the results that are to be achieved through occupational therapy interventions (Rogers & Holm, 1994a). As pointed out by the wisdom of the Cheshire Cat, in the following dialogue, outcomes determine methods.

> Alice: Oh, no, no. I was just wondering if you could help me find my way
> Cheshire Cat: Well that depends on where you want to get to.
> Alice: Oh, it really doesn't matter, as long as...
> Cheshire Cat: Then it really doesn't matter which way you go.

Practitioners plan interventions with an outcome in mind, thus forging the link between re-evaluation and intervention.

CONCLUSION

The occupational therapy process is theory-based and data-driven. It is the therapeutic problem solving process used by practitioners to respond to their clients' occupational performance needs. The occupational therapy process is first driven by theory, and then consists of five additional major components—evaluation, problem definition, intervention planning, intervention implementation, and re-evaluation. Each component was presented and its therapeutic utility discussed. In this chapter, we chose to elucidate the occupational therapy process using the construct of the person-task-environment transaction (PTE), rather than choosing a specific theoretical approach. The PTE transaction implies a negotiation or arrangement among three factors: person capacities (P), task demands (T), and environmental demands (E). Finally, we provided numerous case examples that combined aspects of the occupational therapy process, and the PTE transaction.

PROVOCATIVE QUESTIONS

1. When all factors of the Person-Task-Environment transaction are not taken into consideration during an evaluation, what possible impacts could this have on intervention choices and client outcomes?
2. Structuring a problem statement stands at the interface between evaluation and intervention, and provides information useful for guiding problem solution. For Mrs. Rogers, found under "Case Examples: Modify Task Demands for Skill Deficit," structure a problem statement. Also try to structure problem statements for other Case Examples.

Critiquing Assessments

JANICE MILLER POLGAR

Learning Objectives

After reading this chapter, you will be able to:

1. Describe a format for critiquing assessments in occupational therapy and apply it in practice
2. Describe the process of construction of a standardized test
3. Describe five benefits of a standardized test over a nonstandardized test
4. Define reliability and critique evidence of reliability relevant to a specific assessment
5. Define validity and critique evidence for it relevant to a specific assessment
6. Describe issues related to fair testing practices and apply them in practice

Evaluation has two main purposes in the practice of occupational therapy: as part of the therapy process to aid the determination of occupational performance issues (Townsend et al., 2002) and to provide support for the evidence base of our profession (Hamer & Collinson, 1999; Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000). When a standardized assessment is used, it is crucial that the occupational therapist has critiqued it to determine its appropriateness for the individual or group to be evaluated as well as the purpose of the evaluation. As part of an occupational therapy practice process, it is important to review the underlying theoretical construct of the test to establish its congruence with the frame of reference that is guiding intervention (Townsend et al., 2002). The occupational therapist must ensure that the method of test development, standardization, development of norms, and **psychometric properties** meet an acceptable standard when determining the test's **clinical utility**. This chapter provides an understanding of why it is important to critically appraise these assessments and discuss each component of a thorough appraisal.

The primary purpose of this chapter is to inform occupational therapists of the purposes of **evaluation** and the necessity of critiquing the assessments we use in our practice. A framework will be presented to organize the critique. Issues of test development and standardization, reliability and validity, and the influence of age, culture, and disabilities on test use will be presented. This chapter is meant to provide sufficient information to enable an adequate appraisal of assessments used in occupational therapy. It is not meant to provide a detailed discussion of the various statistical analyses that are involved in test development or establishment of psychometric properties. Sources for

more detailed information are identified at the end of the chapter. In the literature, various labels are used to identify a measurement tool, including *test, instrument, evaluation, measurement,* and *assessment.* Either *assessment, instrument,* or *test* will be used in this chapter. *Evaluation* in this chapter refers not to a test instrument but to the whole process of assessing a client.

MEASUREMENT

Measurement is the process of assigning numbers to represent quantities of a trait, attribute, or characteristic, or to classify objects (Nunnally & Bernstein, 1994). It enables therapists to understand aspects of clients' function, abilities, or personal characteristics. An important distinction here is that measurement enables therapists to quantify attributes of individuals but not individuals themselves (Nunnally & Bernstein). It provides a means to operationally define behaviors and, by quantifying these behaviors, to make comparisons between individuals or to compare the same person at two different times (Dunn, 2001).

Some fundamental assumptions of measurement are critical to an understanding of the properties of psychometrically sound instruments (Dunn, 2001). The definition of measurement presented in the foregoing paragraph assumes that psychological, sociological, and biological functions are observable and thus measurable. A second assumption is that what is observable and quantifiable corresponds to aspects of human behavior. Third, it is assumed that these attributes have a normal distribution in the population, a concept that will be discussed later. Finally, it is assumed that some traits are relatively stable across time while others are expected to change.

PURPOSES OF EVALUATION IN OCCUPATIONAL THERAPY

Tests are used in different ways, depending on the purpose of a given evaluation. Three main purposes have been identified for evaluation (Jackowski & Guyatt, 2003). The first purpose is discriminative. When the occupational therapist's intent is to describe individuals within a group or to discriminate between members of a group, an instrument should be chosen that measures the desired attribute comprehensively (Law, 1987). For example, if an occupational therapist is interested in describing a child's ability to operate a powered wheelchair, the instrument should measure all components that are considered necessary for this task.

A second purpose is to predict either future function or function in a related area (Jackowski & Guyatt, 2003). The occupational therapist might be interested in understanding the relationship between performance on a measure of motor skills in infancy and subsequent performance

on a test of fine motor skills at the age of 5 years. Alternatively, the therapist might be interested in determining the relationship between achievement of a certain score on a vocational test and function on the job site.

Finally, occupational therapists use measurement to evaluate outcomes of therapeutic intervention. In this instance, it is important to use an instrument that will detect change that has occurred (Jackowski & Guyatt, 2003). Two situations are important here. In the first, evaluation of intervention with a single client helps to determine the client's response to treatment. In the second, cumulative evidence of the outcome of intervention provides support for occupational therapy practice.

Whether an instrument is used for discriminative purposes, to predict function, or to evaluate outcome, the results of testing are used to guide decisions (Dunn, 2001). For example, we determine a person's suitability for returning to work or to his or her community, whether a person should receive assistive technology, or whether a person is safe to continue to drive or not. We also make decisions about the efficacy of our practice. These decisions have important implications for the lives of our clients and our practice. Because of the importance of our decisions, it is crucial that occupational therapists critique assessments to confirm that they are selecting an appropriate test.

CRITIQUING ASSESSMENTS

An outline to guide the critique of an instrument can be seen in Box 47.1.

Theoretical Context of Assessment

Some theoretical perspective guides each occupational therapist's approach to intervention, whether it is explicit or tacit. In selecting an assessment, it is important to consider whether the theoretical foundation of the assessment is congruent with that of the therapist. Subsequent sections will describe the process of test development in which one step is to describe the construct to be measured by the test and the related domain of concern. This information provides the user with an understanding of the test developer's theoretical perspective.

Why is it important to determine a test's underlying construct and the evidence that the scores are indeed reflective of that construct? Let's consider a situation in which a therapist is assessing a child with a motor problem. The therapist's frame of reference views motor planning, an executive function, as the foundation of the motor problem. An available test of motor function is based on the premise that motor difficulties are due to a lack of opportunity to engage in physical activities, including factors such as parental involvement in sport and the existence of organized activity programs within the community, to choose an extreme example. The resulting scores on the

A FRAMEWORK FOR CRITIQUING ASSESSMENTS

1. Is the purpose of the assessment to:
   - Describe the client's current level of function?
   - Evaluate the client's response to service delivery?
   - Predict future function?
   - Evaluate an intervention program?
2. Theoretical frame of reference
   - Is the underlying construct of the test congruent with the clinician's frame of reference?
   - What information does it provide?
   - Is the information obtained meaningful and relevant to the client population?
3. Clinical utility
   - Is the test readily available and easy to use?
   - Are specific qualifications required to administer the test?
   - Can the test be administered in a reasonable amount of time?
   - Is the test difficult to learn to use?
   - What is the test format?
   - What are the test procedures?
   - What is the response format (e.g., motor or verbal response)?
   - Is the test easy to score?
4. Technical considerations
   a. Norms
      - What type of score is obtained (e.g., percentile rank, standard score)?
      - What are the characteristics of the standardization sample?
      - What were the standardization procedures?
      Reliability: What evidence exists to support?
      - Test-retest reliability?
      - Interrater reliability?
      - Alternative form reliability?
      - Internal consistency of the test?
   b. Validity: What evidence exists to support the construct relative to:
      - Content?
      - Internal structure?
      - Response processes?
      - Relationship to external variables?
5. Fair testing issues: How did the test developers address potential bias issues related to:
   - Culture?
   - Language?
   - Age?
   - Disability?
6. External review comments
   - What information is available from published evaluations of the test?
7. Summary of strengths and weaknesses of the test

---

test might lead the therapist to recommend that the parents become more involved in sport with their child or lobby for more organized physical activity programs within their community. While these outcomes are not necessarily bad, they illustrate the point that if the test does not provide information that is relevant to the frame of reference that guides the therapist, the intervention that follows will not be specific to the identified occupational performance issues, which may then lead to an unsatisfactory outcome.

Clinical Utility

Occupational therapy service delivery faces increasing demands for efficiency and economy of time management. Realistically, only tests that help the clinician to meet these demands will be used in practice. **Clinical utility** is defined as ease, efficiency, and use of a test and the clinical relevance and meaning of the information that it provides (Law,

King, & Russell, 2001; Letts et al., 1999). A framework was described to evaluate the clinical utility of a test (Barlow & Miller Polgar, 2002). It proposed six areas that should be considered with respect to clinical utility. The framework was modified for this chapter to include (1) availability of test and ease of use, (2) administration time, (3) clinician's qualifications, (4) aspects related to learning the test, (5) format, (6) test procedures, (7) response format, and (8) scoring. With the exception of the first point, all of this information should be in the test manual. It can also be found in published reviews of the test (see the end of the chapter for sources of these reviews), and a brief description should also be available from the test publisher. Discussion of each element follows.

Test Construction

The test manual should describe the manner in which the test was constructed. It should give sufficient information

for the individual who is evaluating the test to be able to determine whether it was developed in a logical, systematic, and stringent fashion.

Defining the Construct

The current *Standards for Psychological and Educational Measurement* (American Educational Research Association [AERA], American Psychological Association [APA], & National Council on Measurement in Education [NCME], 1999) define a *construct* as the concept, characteristic, or behavior that a test is designed to measure. Because there are many ways of understanding a construct, the test developers must articulate their understanding of the construct and its content domain. Furthermore, they should articulate some theoretical structure to the construct that is grounded in relevant literature (Wilson, 2005).

Item Development

Development of the test items is an involved process, detailed discussion of which is beyond the scope of this chapter. For our purposes, it is important to start with the definition of the construct, as defined by the test developer. The process of developing and selecting test items and the response format (e.g., rating scale, forced-choice response) can then be reviewed. The following should be considered: (1) item definition and selection process, (2) the process of determining the response format, (3) the method of establishing congruence of items with total test (e.g., factor analysis or investigation of internal consistency), and (4) the design of the research process for making revisions to test structure, items, and response format. These issues will be described further in subsequent sections of this chapter.

Scales of Measurement

There are four scales of measurement: nominal, ordinal, interval, and ratio (Pedhazur & Schmelkin, 1991; Portney & Watkins, 2000). The *nominal scale* involves mutually exclusive categories (e.g., female versus male, geographic location). This scale simply identifies differences with no attempt to quantify or order those differences.

A second level is the *ordinal scale.* This scale involves rank-ordering scores. The order indicates greater (or better) than, but no inference can be made about the magnitude of the difference between scores. *Interval scales* are a third level. This type of scale is the most common in measures found in occupational therapy. The intervals between scores are equal so that comparisons can be made between individuals (Pedhazur & Schmelkin, 1991). However, 0 is not an absolute point on these scales. Because 0 is arbitrary, ratio comparisons between scores cannot be made (Pedhazur & Schmelkin; Portney & Watkins, 2000). For example, if person A scores 20 on a test of self-esteem and person B scores 40 on the same test, it is not meaningful to

say that person B has twice as much self-esteem as person A. To make this comparison meaningfully, 0 would have to be a fixed point.

On *ratio scales,* 0 does have a fixed point, and ratio comparisons can be made (Pedhazur & Schmelkin, 1991). To use these scales, absence of the attribute being measured must be meaningful. In measuring volume, a score of 0 indicates the absence of liquid. In occupational therapy, range of motion can be understood as a ratio scale, as there can be absence of measurable movement around a joint, and it is meaningful to indicate that a person has gained twice as much movement between measurements.

Development of Norms

Many of the tests that occupational therapists use are norm-referenced (Anastasi & Urbina, 1997; Murphy & Davidshofer, 1998). Norms are statistics that are generated from a well-defined group that has been evaluated using the test in a standardized manner (Bolton, 2001; Salvia & Ysseldyke, 2004). Usually, but not necessarily, norms are measures of the average performance of this reference group. These statistics are used to make comparisons between the individual who is being tested and this reference group (i.e., the norms provide a point of reference for comparison of the individual's score).

It is crucial to understand that the norms provided in the manual are not *the* definitive norms (Murphy & Davidshofer, 1998). They represent the performance of the individuals who were tested for the development of the norms. The usefulness of the norms for making a meaningful interpretation of an individual's score is dependent on the information that is given about the characteristics of the **sample** used to create the norms, the method of recruiting the sample, and the degree to which the sample represents the test's target **population**.

At some point in the development of the test, a target population is identified (Murphy & Davidshofer, 1998; Salvia & Ysseldyke, 2004). The population defines the group for whom the test is intended. The test manual should clearly state the intended target population. Before using a test, the therapist must determine that it is intended to evaluate people with characteristics similar to those of the client.

Salvia and Ysseldyke (2004) describe three main issues that are relevant in determining the usefulness of the norms related to the target population: They should be representative, relevant, and recent. The sample *represents* the target population when the distribution of critical characteristics of the population is reflected in the sample. A test that is targeted for national (or international) use must demonstrate that the norms were developed to represent the distribution of region, urban or rural living, gender, ethnicity, and any other relevant characteristics of the national or international population (Murphy & Davidshofer, 1998; Salvia & Ysseldyke, 2004). A test that is intended to provide infor-

mation about performance at different ages must use a sample including individuals of each age.

The test manual should include clear information about the selection of the normative sample (AERA, APA, & NCME, 1999). Random-sampling procedures should be used that involve selection based on the distribution of the characteristics of the population identified, not convenience (Salvia & Ysseldyke, 2004). The sample size should be sufficient to minimize measurement errors and to maximize the confidence the test user has in the norms provided.

The normative sample should be *relevant* to the target population (Salvia & Ysseldyke, 2004). It should have characteristics similar to the population. For example, norms that have been developed from the motor performance of adults are of little use in providing a meaningful interpretation of the motor performance of preschoolers.

Finally, norms should be *recent* (Salvia & Ysseldyke, 2004). Test material can become dated. For example, consider a picture vocabulary test. It is unlikely that children today will correctly identify a picture of a typewriter—not because they do not have the vocabulary to give a correct response but because a typewriter is no longer a common object and it is not within the children's experience to recognize it. Over time, performance or attributes may change in the population. Twenty years ago, many executives had little or no keyboarding skills and so would have performed poorly on tests measuring this ability. Now, with the pervasive use of computers, the ability to input keystrokes is a more universal skill.

Standardized Scores

Raw scores are usually converted into another form to facilitate comparison and a meaningful interpretation. These forms include percentiles, *z*-scores, *t*-scores, stanines, and age- or grade-equivalent scores (Murphy & Davidshofer, 1998; Salvia & Ysseldyke, 2004). These will be discussed below, but first, some basic statistical concepts related to test scores will be reviewed briefly. There are three measures of central tendency: mean, median, and mode. The *mean* is the arithmetic average of the cumulative measures (Murphy & Davidshofer, 1998; Portney & Watkins, 2000). The *median* is the point in the distribution of the scores that divides the scores in half (i.e., 50% are above the median and 50% are below it). The *mode* is the most frequently occurring score (Portney & Watkins, 2000). It is important to know which of these measures of central tendency is being reported.

For a given population, scores are considered to be distributed normally. In the *normal distribution*, the bulk of the scores are at the center of the range, with fewer scores found at the extremes of the range (Portney & Watkins, 2000). The *range* of the distribution is the span between the lowest score and the highest score (Portney & Watkins, 2000). The *variance* indicates the dispersion of the scores

(Portney & Watkins, 2000). *Standard deviation* (SD) is the square root of the variance and is the most common method of dividing the normal distribution. It represents the spread of the scores in the same units as the test score (Salvia & Ysseldyke, 2004). Approximately 68% of the scores fall within −1.0 and +1.0 SD, 95% fall within −2.0 and +2.0 SD, and 99% fall within −3.0 and +3.0 SD (Portney & Watkins, 2000).

Standard scores use the standard deviation to obtain a scale with equal intervals. There are several forms of standard scores. A *z*-score has a mean of 0 and a standard deviation of 1 and is used to plot the area under the curve of the normal distribution (Hogan, 2003); *t*-scores are standardized scores with a mean of 50 and a standard deviation of 10 (Hogan, 2003). The *percentile rank* is expressed as a whole number between 1 and 99. The number represents the percentage of test takers who scored at or below a given score (Portney & Watkins, 2000; Salvia & Ysseldyke, 2004). An individual whose score is at the 75th percentile performed as well as or better than 75% of those tested. Percentile rank is an ordinal scale so the intervals between the ranks are not equal (Salvia & Ysseldyke, 2004). It is considered to have a normal distribution, with the majority of the scores falling around the 50th percentile (Portney & Watkins, 2000).

Stanine is an abbreviated form of the term *standard-nine* (Salvia & Ysseldyke, 2004). This method of standardizing scores divides the normal distribution into nine components, each making up one half of a standard deviation to provide equal units of measure. It minimizes a tendency to overinterpret small differences in scores, but it might not be sufficiently sensitive to detect small changes (Salvia & Ysseldyke, 2004).

Age- or grade-equivalent scores relate the individual's performance on the test to that of the typical individual of a particular age or grade (Murphy & Davidshofer, 1998). It is crucial that the sample that is used to create the norms has sufficient representation of the comparison grades or ages.

Standardized Tests

In clinical practice, both standardized and nonstandardized tests are used. **Standardized tests** are assumed to have undergone a rigorous development process and are administered and scored in a prescribed manner. Of course, review of the rigor of the standardization process is critical. Nunnally and Bernstein (1994) identify five advantages of standardized tests: (1) They provide an objective means of measuring a specific construct; (2) the construct is operationally defined and can be quantified; (3) communication among professionals who use the test is enabled by a common understanding of the construct; (4) when appropriate, a therapy aide can administer a standardized assessment, reducing the cost of the administration; and (5) generalization of the results is facilitated by a well-constructed

standardized test. Without standardization, there is no assurance that it measures the construct it is intended to measure, that the scores are reliable, or that sources of variation in the derived scores are minimized.

Test Standardization

Because of the effect that decisions from test scores have on people's lives, it is important that as many extraneous factors as possible are eliminated from the method of administering, scoring, and interpreting the scores (Murphy & Davidshofer, 1998). Test standardization procedures are used to ensure the maximum level of consistency in testing situations.

The test manual should clearly describe the arrangement of the testing environment, the presentation of materials, standardized instructions, and time limits (AERA, APA, & NCME, 1999). When the test developers have made modifications to any of these areas to accommodate individuals with different abilities, these modifications should be clearly indicated so that they can be replicated in appropriate situations. Moreover, the manual should include clear guidelines for scoring the test and interpreting the scores (AERA, APA, & NCME, 1999).

It is not possible to standardize all aspects of test administration. Aspects of the environment, such as noise, or individual factors such as the examinee's mood at the time of testing are not controllable. Because of these uncontrollable factors, which can affect the reliability of the test score, it is important to follow the standardized instructions of the test exactly. Failure to do so will influence the reliability of the test scores (AERA, APA, & NCME, 1999). It is also important to ensure that the test user is adequately trained or prepared to administer the test. Many tests indicate the type of training that is necessary for administration. Indeed, some tests are not available except to people who hold the necessary qualifications.

RELIABILITY

Definition of Reliability

First, let's consider the general definition of reliability. A standardized test used to evaluate the performance of an individual or to measure the existence of a specified trait yields a score. It is important to demonstrate that the score resulting from the use of a test is consistent and repeatable. Consistency and repeatability are aspects of **reliability**, defined as "the consistency of . . . measurements when the testing procedure is repeated on a population of individuals or groups" (AERA, APA, & NCME, 1999, p. 25). Reliability is based on the correlation coefficient and referred to as a reliability coefficient. The reliability coefficient can range from 0 to +1, with 0 indicating no consistency and +1 indicating perfect consistency.

Theoretical Perspectives of Reliability

Two theoretical perspectives concerning reliability will be considered here: classical test theory and generalizability theory (Thompson, 2003). Classical test theory suggests that a test score has two components—the true score and measurement error—and that while there are many sources of error, only one is estimated with any given study. Generalizability theory also recognizes different sources of error and attempts to quantify the error from those various sources. A third perspective, item response theory, is not considered in this chapter.

Both generalizability theory and classical test theory assume that each person has a true score (Hogan, 2003). In classical test theory, this true score is assumed to be stable across various situations; that is, the true score is independent of the testing context (Portney & Watkins, 2000). In contrast, generalizability theory assumes that the true score and testing conditions are not independent and that certain factors (called *facets*) influence the true score. In other words, the variation across test administrations is not considered to be solely random error from a generalizability perspective.

Classical Test Theory

A test score is considered to be reliable when similar results are achieved under various situations, such as repeated administrations, different raters, and when there is consistency among the items on a test. Classical test theory assumes that a test score consists of three components: (1) the obtained scored; (2) the true score variance, considered to be a hypothetical, unobservable quantity of the specific attribute under consideration (Portney & Watkins, 2000); and (3) random error. The relationship between these components is expressed as follows:

$$\text{obtained score} = \text{true score variance} + \text{random error}$$

In other words, every obtained score is made up of two components: a portion of the score that reflects the "true" quantity of an attribute and random errors that contribute to inconsistency in the measurement (Murphy & Davidshofer, 1998). It is assumed that no relationship exists between true scores and the error component (Murphy & Davidshofer, 1998). Reliability is high when the proportion of the obtained score due to measurement error is low.

Generalizability Theory

Cronbach, Gleser, Nanda, and Rajaratnum (1972) introduced generalizability theory, which recognizes a variety of sources of error variance and provides a means to estimate these in a single study. Generalizability theory assumes that the derived test score is one of a number of possibilities

within a universe of scores obtained under equivalent testing conditions and specifies these testing conditions.

Interclass correlation (ICC) is used to estimate the variance from a variety of sources with a single administration using analysis of variance. With this analysis, it is possible to calculate variance due to specified facets as well as the interaction between these facets. Identification of the facet of interest is crucial when conducting this analysis. Different models are used to determine the ICC, and it is important to understand the structure of these models and to determine whether they were applied appropriately in a reliability study. A full discussion of ICC is beyond the scope of this chapter; however, Portney and Watkins (2000) provide an excellent discussion of this topic.

Sources of Error Variance

Thorndike (2001) identified six sources of variation that can contribute to measurement error. *Lasting general characteristics* are individual characteristics that are expected to be stable over a time that are not specific to the construct being measured, such as literacy or fluency. *Lasting specific characteristics* are personal attributes, stable over a long period of time, that are specific to the construct being measured, such as previously acquired knowledge or skills such as ability to respond to multiple choice items (Murphy & Davidshofer, 1998). These affect performance on the test as a whole or on specific subsets of a test. *Temporary general characteristics* are nonspecific personal aspects that are present in the short term, such as fatigue or emotional state (Murphy & Davidshofer, 1998; Thorndike, 2001). *Temporary specific characteristics* are short-term qualities that are specific to a test, such as recognition of a pattern of correct responses or response to unintentional clues in the test format (Thorndike, 2001).

Administration and appraisal of test performance sources stem from issues related to the assessor, such as familiarity or training and adherence to test standardization; issues related to the testing environment, such as distractions, time limits, or length of assessment; and issues related to the standardization and construction of the test. *Chance variance* derives from factors that are not systematic, such as incorrectly recording the examinee's response on a data collection form (Murphy & Davidshofer, 1998; Thorndike, 2001).

Types of Reliability

The reliability of a test score is important in three different situations: when the test is administered on more than one occasion, when comparable tasks are involved, and when the test is administered and scored by different raters. These forms of reliability are test-retest, alternative forms, and interrater reliability, respectively. A further form of reliability is referred to as *internal consistency,* which examines the structure or consistency of the items that compose a test.

Test-Retest Reliability

Test-retest reliability is a measure of the consistency of an assessment over time. It has also been termed *stability* (Salvia & Ysseldyke, 2004), as it estimates the stability of the measurement over time. This form of reliability is determined by administering an evaluation on two occasions separated by a time interval. Nunnally and Bernstein (1994) suggest that a desirable separation is two weeks. With a shorter time period, the examinee might remember the test items; with a longer time period, actual changes might occur (Hogan, 2003). A correlation approaching +1.0 suggests that a test is stable across time.

Test-retest reliability or stability is meaningful only when the trait that is being measured is expected to be stable over the testing interval (AERA, APA, & NCME, 1999). An evaluation of mood, for example, is not expected to yield consistent results over a period of weeks, for mood is considered to fluctuate. Alternatively, a trait such as height is stable and should yield little variability in the obtained scores over repeated measurements. Many attributes that are measured in occupational therapy are not as clearly consistent or inconsistent as the examples just given. In each case, individuals considering the test must compare their understanding of the construct or attribute being measured with that described in the test manual to assess whether that attribute is stable and whether an indication of stability is essential.

Alternative Form Reliability

The establishment of reliability using alternative forms has some similarities to test-retest reliability, since it is estimated by testing the same group of people on two separate occasions (Hogan, 2003). However, it differs from test-retest reliability estimation with its use of two distinct but parallel forms of a test (Hogan, 2003). When estimating alternative form reliability, the test administration should occur about two weeks apart to account for day-to-day fluctuations in performance (Nunnally & Bernstein, 1994).

Occasionally, in occupational therapy treatment, a client's performance in a specific area must be evaluated repeatedly. Repeated administrations of the same instrument causes problems because the person might remember test items or practice them. Thus, repeated exposure to the same test might artificially inflate the obtained score. The use of parallel forms minimizes the influence that memory or practice can have on inflating the estimated reliability. These two forms should not differ in a substantive manner (Hogan, 2003).

Interrater Reliability

This form of reliability can be considered to be the consistency between scores assigned by different raters when using the same assessment at the same time or when observing the same behavior (Auerbach, Heft La Porte, &

Caputo, 2004). It is important to have confidence in the consistency between raters for both assessment and outcome evaluation of clinical practice.

The method of estimating interrater reliability is an important consideration in choosing a specific assessment. Simply calculating the correlation between scores assigned by different raters might overestimate reliability if the raters differ in a consistent manner (Auerbach et al., 2004). Cohen's kappa and the ICC are more appropriate statistical analyses (Portney & Watkins, 2000). Cohen's kappa measures the degree of agreement between raters by comparing the number of items for which agreement is found between raters with the number of items for which agreement is expected (Auerbach et al., 2004). Cohen's Kappa ranges from −1 to 1, with 1 indicating perfect agreement and 0 indicating agreement that occurs at the chance level. Application of the ICC here would specify "rater" as the facet of interest.

Internal Consistency

Internal consistency is an estimation of the homogeneity of the structure of a test. One that is intended to measure a single construct should have a high degree of internal consistency; that is, all test items should be highly correlated to each other. The simplest and crudest type of internal consistency is split-half reliability (Nunnally & Bernstein, 1994; Pedhazur & Schmelkin, 1991), in which reliability is determined by dividing the test items in half and obtaining the correlation between these two halves. The split-half method of estimating reliability is limited by the variety of ways of dividing the items that can result in different reliability coefficients (Hogan, 2003).

More sophisticated methods of estimating internal consistency take into account the correlation of each item with every other item as well as with the total score (Hogan, 2003; Nunnally & Bernstein, 1994; Pedhazur & Schmelkin, 1991). These inter-item and item-total correlations provide an estimate of how consistent the items are with each other. Items that do not correlate highly with other items or with the total test might measure a different construct.

The most common ways to estimate the internal consistency are through the use of Cronbach's alpha (Cronbach, 1951) or the Kuder-Richardson formulas (Kuder & Richardson, 1937). Cronbach's alpha is computed when the items are scored in a nondichotomous manner. When the scoring is dichotomous, the Kuder-Richardson formulas are used. For further information on the theory and calculations of internal consistency, refer to one of the books marked with an asterisk in the references at the end of this chapter.

Standard Error of Measurement

In instances when the therapist would like to understand how close the obtained score is to the true score for an individual, the estimates from group data can be used to calculate the standard error of measurement (SEM). The SEM indicates how much variability in the test scores can be attributed to error (Murphy & Davidshofer, 1998). As can be seen from the following equation, as reliability increases, the standard error of measurement decreases:

$$\text{SEM} = \text{SD}\sqrt{1 - r_{xx}}$$

In this equation, SD refers to the standard deviation of the group from which the reliability is calculated.

Once the SEM has been calculated, a confidence interval can be constructed around the obtained score. A *confidence interval* is defined as the range into which it can be stated with a specified degree of confidence that a certain score would fall (Portney & Watkins, 2000). The degree of confidence is determined from the properties of the normal distribution. To calculate a confidence interval, the precise SD that corresponds to 95% of the distribution, for example, must be used. Thus, from the normal distribution, 95% of the scores fall within −1.96 and +1.96 SD from the mean, and 99% fall within −2.54 to +2.54 SD from the mean (Anastasi & Urbina, 1997). To construct a 95% confidence interval, the SEM is multiplied by 1.96 (Murphy & Davidshofer, 1998). Thus, the true score is known, with 95% confidence, to fall between [obtained score −1.96(SEM)] and [obtained score +1.96(SEM)].

How High Should the Reliability Coefficient Be?

The question "How high should the reliability coefficient be?" does not have a ready answer. The purpose of the test should be considered when deciding whether the reliability reported is acceptable (Salvia & Ysseldyke, 2004). Tests that are used to make decisions about a person, such as determining whether he or she is capable of returning to work, should have a higher level of reliability than tests that are intended to serve as screening or descriptive instruments (Hogan, 2003; Murphy & Davidshofer, 1998; Salvia & Ysseldyke, 2004). Similarly, the instruments that attempt to categorize people, such as a test that is used to assign cognitive levels, should have a high degree of reliability (Murphy & Davidshofer, 1998).

The following minimal levels of reliability should be considered as guidelines. Generally, a reliability coefficient of .90 is considered to be high, 0.80 moderate, 0.70 low, and 0.60 generally unacceptable for clinical use (Murphy & Davidshofer, 1998). It is recommended that when a test score is to be used to make significant decisions about an individual, such as placement decisions, a minimum level of reliability of 0.90 should be reported (Salvia & Ysseldyke, 2004); Nunnally and Bernstein (1994) suggest .95 as desirable. If the test has been administered to a group and the data are reported for the group as a whole, a

minimum level of 0.60 has been suggested (Salvia & Ysseldyke, 2004).

It should be clear from this discussion that reliability estimates are not fixed entities. When examining reliability during the decision to use a particular assessment, it is important to remember that the reliability reported reflects the specific situation and the sample used to collect the data. The potential test users must ensure that they understand the type of reliability that has been reported, the appropriate means of establishing that specific reliability, and its applicability for the purpose of the test. Table 47.1 summarizes this information.

VALIDITY

Definition of Validity

Contemporary understanding of validity is that it is a unitary concept and that the establishment of validity is the process of accumulating evidence to support the underlying construct that an evaluation is considered to measure (Cronbach, 1988; Messick, 1988, 1989, 1995). This notion is relevant not only to the interpretation of the test score but also to the social consequences of that interpretation. The current edition of *Standards for Educational and Psychological Testing* (AERA, APA, & NCME, 1999) defines **validity** as "the degree to which evidence and theory support the interpretations of test scores entailed by proposed uses of tests" (p. 9). Messick adds that validity is the "appropriateness, meaningfulness, and useful-

ness of inferences and actions based on test scores" (Messick, 1988, p. 33). Further, evidence for validity is concerned with the relevance and utility of scores for particular persons or groups and the significance of the value attributed to the score or underlying construct as they relate to the social consequences for the individual or group (Messick, 1988).

What conclusions can we draw from these defining statements? First, let's consider the ideas of appropriateness, meaningfulness, and usefulness, which are relevant to how the test is used and the consequences of the inferences made from interpretation of the scores. Appropriateness refers to the question of whether the construct and elements of the test are suitable for the target population and the context and purpose of the evaluation. Meaningfulness is associated with the articulation of the underlying construct and how it explains or describes the trait being measured. Finally, usefulness is concerned with the utility of the test in terms of the information that is gained from the test results in consideration of the effort required to undertake the test. Evidence of validity, as it provides support for the underlying construct, is necessary to justify a particular test with a specific population in a given context.

These statements are very clear that it is not the test that has validity. Rather, validity relates to the interpretations and actions derived from the resulting scores (Messick, 1988, 1989, 1995). Both empirical and theoretical evidence of validity are required to provide support for these interpretations and actions. Thus, an assessment must be based on a well-founded or articulated theoreti-

---

TABLE 47.1 A SUMMARY OF THE TYPES OF RELIABILITY, THEIR APPLICATION, AND SOURCES OF VARIABILITY RELATED TO EACH

Type of Reliability	Provides Evidence For	Sources of Variability
Test-retest	Stability	Length of time between testing stability of trait measured Memory of test items Actual change in trait measured
Alternative form	Equivalence of parallel forms (equivalence and stability if forms are administered at two times)	Ability to generate parallel forms
Interrater	Consistency across raters	Adherence of tester to scoring Adequacy of description of scoring criteria
Internal Consistency: Split-half	Homogeneity of items	Method of splitting items Length of test Consistency of content of test
Cronbach's alpha Kuder-Richardson	Homogeneity of items	Consistency of content of test

cal construct, and there should be empirical evidence to support the hypotheses derived from the theory. Otherwise, the inferences made from the test scores are without meaning and are not justifiable.

Further, these definitions suggest a variety of uses of the test results. Consequently, evidence of validity must be provided for each of the intended uses. When first using an assessment, the occupational therapist must be very clear on its intended use. How will the test score be interpreted and how will that interpretation affect the client's life? Is the therapist's intended use of the assessment congruent with that articulated by the test developers? Is the therapist's theoretical approach to intervention congruent with the theoretical foundation of the test? The answers to these questions will influence the appropriateness, meaningfulness, and usefulness of inferences made from the test scores.

Before a discussion of sources of validity evidence, two threats to validity will be described. These are construct underrepresentation and construct irrelevance (AERA, APA, & NCME, 1999: Messick, 1989, 1995). *Construct underrepresentation* refers to an inadequate sampling of the construct domain in the test items; that is, content is missing (AERA, APA, & NCME, 1999; Messick, 1989, 1995). The resulting interpretation of the score is not comprehensive, because the test did not tap some content, underlying processes, or response means that are important to the understanding of the construct.

Construct irrelevance is present when test scores are influenced by processes or abilities that are not pertinent to the construct (AERA, APA, & NCME, 1999; Messick, 1988, 1995). Here, the person who is being evaluated must have a certain level of ability, skill, or knowledge, extraneous to the construct being measured, in order to make a response or achieve a satisfactory score. A valid interpretation of a low score cannot be made because it cannot be determined whether the score reflects performance on the construct or some other ability. An example of this type of variance is a test of arithmetic ability that requires reading comprehension to complete the problems satisfactorily.

Evidence of validity comes from examination of different aspects of the test and performance in different situations. Synthesis and analysis of available studies related to each of the following dimensions helps the test user to construct an argument concerning relevant validity.

Evidence of Validity

Evidence of Validity Derived from Content

The current *Standards for Educational and Psychological Testing* refer to content as themes, wording, item format, response method, and guidelines for procedures for administration and scoring (AERA, APA, & NCME, 1999). In other words, not only does the actual content of the test items provide important evidence, but so do the processes that underlie the respondent's interpretation of the items and the response format. Construct representativeness is interpreted here as how well the content of the evaluation represents the hypothesized content domain and structure. Construct relevancy considers how relevant the content, means of interpretation, and response format are to the construct.

Validation of the content of a test begins at the test development stage. As was described previously, the initial stages of test construction begin with a clear articulation of the theory underlying the construct. Theoretical ideas operationally define the construct, that is, what behaviors are considered to be indicators of the construct (Pedhazur & Schmelkin, 1991), and hypothesize the structure and elements of the construct and the relationship among them (Messick, 1988, 1989). From here, a table of specifications is developed to guide the content, the item difficulty, and the proportions of the test that represent particular dimensions of the theoretical construct to be represented on the test.

Validation of the content is derived from consideration of the sampling of the construct domain, that is, that all aspects of the domain are adequately covered, content is relevant to the construct, and the underlying processes necessary for satisfactory interpretation of test items and response are also relevant (AERA, APA, & NCME, 1999; Messick, 1988, 1989). One means of gathering this evidence is through the examination of the content by a panel of experts to determine relevance and representativeness. For example, consider an instrument that is designed to measure performance in activities of daily living (ADL). The test developers articulate their understanding of the construct of ADL, create items that are considered to measure ADL performance, and assemble these in an assessment. A panel of occupational therapists who are considered experts review the assessment. Their analysis provides evidence for content representativeness and relevance.

When a test is used with a population that is different from the one for which it was originally intended or for a different purpose, the test user must examine the content to determine that it is appropriate for that population or purpose. In particular here, issues of relevance are important. The test user must determine whether any aspects of test administration, item interpretation, or response format are a source of bias for their purpose or population (AERA, APA, & NCME, 1999; Messick, 1988, 1989, 1995).

Inferences of low scores that are based on content can only suggest that the respondent was not competent in taking the test. The interpretation that the individual is incompetent on the underlying skill or has inadequate knowledge cannot be made. Other sources of variance might have contributed to this low score (Messick, 1989).

Evidence from Test Structure

To compile evidence from the structure of the test, it is necessary to examine the relationship of the hypothesized structure of the construct to the structure of the assess-

ment (AERA, APA, & NCME, 1999; Messick, 1989). This examination is completed through empirical analysis of the relationship between the items (interitem) and to the total score (AERA, APA, & NCME, 1999). If the conceptual framework suggests that the underlying construct is unidimensional, then analysis of the relationship between the items should reveal a single dimension. Alternatively, if a multidimensional structure is hypothesized, then analysis should support this structure with multiple dimensions of content that are distinct from each other and congruent with the structure that was hypothesized from the theory. More simply put, if the construct is hypothesized to have three dimensions, analysis should reveal three factors. Items that load on those factors should have content that is congruent to articulation of the construct. Additionally, the scoring structure should reflect the theorized dimensionality of the construct (Messick, 1989).

Evidence from Response Processes

Part of the hypotheses of the construct includes the underlying processes that are necessary for indicating the intended response (AERA, APA, & NCME, 1999). Examination of how respondents arrive at a response provides evidence for this element of the validity argument. For example, a professional certification examination might be hypothesized to require clinical reasoning to achieve a correct response. It is only through examination of an individual's approach to answering questions on this examination that evidence is provided to support or refute this hypothesis.

The issue of construct irrelevance is important here. As was indicated previously, evidence must be provided that the means of deriving an answer and indicating a response are relevant to the construct. This evidence is important during test construction, but, more important for occupational therapists, it is necessary when considering a test that was not developed for the population or purpose for which the therapist intends. Evidence must be provided that these elements of validity are not a source of bias for our clients.

Evidence from the Relationship to External Variables

When examining the relationship to other variables, we are considering the "extent to which the test's relationship with other tests and nontest behavior reflects the expected high, low and interactive relations implied in the theory of the construct being assessed" (Messick, 1989, p. 45). Here, we are looking for convergent evidence (i.e., the test is highly related to other tests or nontest behavior that is theoretically related to the construct) or divergent evidence (i.e., the test is not related to other tests or nontest behavior that is theoretically not related to the construct). Both convergent and divergent evidence provide necessary information for our understanding of the theoretical construct and our ability to measure it. This evidence is derived from empirical studies.

Historically, there are two types of studies that are important here (AERA, APA, & NCME, 1999): predictor and concurrent studies. Predictor studies provide evidence that performance on the test predicts performance on a criterion later in time. Clinically, such evidence is useful to guide decisions on who will benefit from a given intervention. Concurrent studies provide evidence of the relationship between the test and a given criterion at the same point in time. Such studies are useful when examining different methods for measuring the same construct or when analyzing a client's behavior or abilities (AERA, APA, & NCME, 1999).

Examination of the relationship to other variables provides information about group differences. It may support predicted differences between groups with different characteristics, suggesting that the meaning of the score is different for members of different groups (AERA, APA, & NCME, 1999). It is important to provide evidence that the differences are congruent with hypotheses derived from the construct and not due to some source of construct irrelevance.

Another construct that is important when considering evidence of validity is responsiveness. When a measure is used to evaluate outcomes, either individually or cumulatively, evidence of responsiveness is important (Guyatt, Walter, & Norman, 1987). *Responsiveness* is defined as the ability of a test to detect a change that is considered to be clinically meaningful and important relative to a client's function following intervention (Guyatt et al., 1987; Jackowski & Guyatt, 2003; Liang, 2000; Patrick & Chiang, 2000). What specifically constitutes a clinically meaningful and important change can be difficult to determine. Liang (2000) suggested that gathering the perspectives of the client, significant others, and the clinician is important in the determination of a clinically meaningful change.

Social Consequences

There is some debate as to whether consideration of the social consequences of inferences and actions based on a test score are relevant to the validity argument (Lees-Haley, 1996; Messick, 1988, 1989, 1995; Zimiles, 1996). However, both Messick (1988, 1989, 1995) and the current *Standards for Educational and Psychological Testing* (AERA, APA, & NCME, 1999) make a compelling argument that these consequences need to be considered in the evaluation process, although they do not, in and of themselves, provide evidence for the validity argument. Social consequences refer to the implications that inferences that are made and actions that are taken from the test score have for the life of the individual who is being tested. High-stakes testing (Haertel, 1999) involves assessment in which the results have significant implications for the life of the individual, such as access to education, treatment, or a career; the value associated with a labeling derived

from the score; and costs that result from actions based on the score. How are these important for occupational therapists?

When we assess a client, we do so from a particular theoretical framework, tacit or otherwise. This framework guides what we measure, the meaning given to a score, and the interpretation. Furthermore, it influences the label that results; for example, performance on certain measures of motor performance result in the child being labeled as having developmental coordination disorder. It is important to recognize the value associated with a label and whether the value has positive or negative connotations in the lives of our clients.

Results of our assessment guide who will receive intervention and the theoretical ideas of change resulting from therapy guide indicators of when therapy should cease. There are implications here for costs, both actual and in time and effort, for the therapist and client. Given the economic state of many health care systems, the evidence to support decisions related to where therapy efforts will be directed, in what manner, and for how long is crucial.

Constructing the Validity Argument

The preceding discussion of various sources of evidence concerning the validity of inferences and actions based on test scores suggests a dynamic and continuing process. An initial argument to support the use and interpretation of test scores is constructed from the available evidence. However, subsequent studies could provide information that weakens the initial argument when hypothesized relationships are not supported or new sources of construct irrelevance are uncovered. This fluidity underscores the importance for occupational therapists of examining evidence to determine that the proposed use of the test is appropriate and that the interpretation of the scores can be made with some degree of confidence. Table 47.2 identifies different elements that contribute to the validity argument, the information they provide and methods used to build evidence for statements about validity.

FAIR TESTING PRACTICES

It is the responsibility of the test user to take whatever measures are possible to minimize bias in testing for particular groups. Because the outcome of occupational therapy evaluation has implications not only for the lives of our clients but also for the distribution of scarce health care dollars, we must seriously consider whether an assessment is fair for our clients and what extraneous variables might influence their scores. The *Standards for Educational and Psychological Testing* (AERA, APA, & NCME, 1999) describes four aspects of **fair testing**, reflecting the idea that testing does not need to be identical for all groups but that there should be evidence that interpretation of the score is valid, without undue influence of construct underrepresentation or irrelevance (AERA, APA, & NCME, 1999). Sources of bias should be identified and eliminated, where feasible, so that they do not alter the meaning of scores obtained by our clients. When bias cannot be removed satisfactorily, the assessment should not be used. All clients should be treated in an equitable manner with respect to the context and purpose of the test and the way in which the test scores are used and should have a reasonable opportunity or means to demonstrate their competence on

---

TABLE 47.2   SUMMARY OF THE EVIDENCE FOR VALIDITY RELATED TO DIFFERENT ASPECTS OF TEST CONTENT, RESPONSE PROCESSES, STRUCTURE, AND RELATIONSHIP TO EXTERNAL VARIABLES

Evidence	Information	Method of Determination
Content	Content adequately samples the domains of the construct and reflects the hypothesized structure	Support for content is found in the literature and expert opinion
Response processes	The means of deriving and indicating a response are congruent with construct hypotheses	Examination of how the respondent forms and indicates a response
Test structure	Structure of the test, e.g., dimensions or scores congruent with that of underlying construct	Examination of relationship of items to each other and with total test
Relationship to external variables	Test scores relate to other measures or nontest behaviors as predicted by theoretical construct	Empirical studies of hypothesized relationships

the construct measured. Differences in outcomes across groups do not necessarily mean that one group is disadvantaged relative to another. However, such differences need to be examined to determine whether such a situation is present. Finally, all groups should have a similar opportunity to learn or practice knowledge or behaviors measured by the test (AERA, APA, & NCME, 1999). For our purposes, three specific instances of fair testing practices will be considered: culture, seniors, and people with disabilities.

When discussing changes to a test that are intended to enhance fair testing practice, a distinction is made in some sources concerning accommodation versus modification of assessments (Education Accountability Act, 2000; Individuals with Disabilities Education Act Amendments, 1997). Accommodations are considered to be changes that enable a person to participate in an assessment but do not alter content, performance requirements, response method, reliability, or validity (Ministry of Education, 2000). Modifications, by contrast, are more significant changes to the assessment and do have implications for reliability, validity, and subsequent inferences made from obtained scores.

Culturally Fair Evaluation

In many countries, cultural diversity is increasing. Occupational therapists may be required to assess an individual whose first language is not the official language of the country. There are two main issues here: the influence of a native language other than English on interpretation of and response to test items and the influence of cultural expectations, behaviors, and values on test performance (AERA, APA, & NCME, 1999; Padilla, 2001).

Even within North America, among people whose first language is English, there is a disparity of culture (Padilla, 2001). The life experience of people living in remote areas of the Arctic is vastly different from that of individuals living in urban areas, and both are different from the experiences of many people of color.

Language can significantly confound the results that are obtained on an assessment. When the assessment requires a verbal response or when the test items contain a substantial verbal component, the test may measure language ability more than the underlying construct (AERA, APA, & NCME, 1999). The intelligibility of the test items and instructions for individuals whose first language is not English must be determined (Springer, Abell, & Hudson, 2002).

One seemingly obvious means to minimize the language issue is to directly translate the test. However, this approach is not as useful as it would appear, as language is dynamic, filled with cultural and historical context (Hambleton & Patsula, 1998). Many words or phrases do not have the same meaning when translated from one language to another. For example, in French, *poser un lapin à quelqu'un* means "to stand someone up." This phrase translates in English as "to lay a rabbit on someone," which

creates quite a different visual image than the French meaning. The naming of common objects differs, even among English-speaking cultures. For example, in Britain, *nappy, petrol,* and *bonnet* refer to a diaper, gasoline, and the hood of a car, respectively. Similarly, concepts may differ between cultures.

Behavioral expectations vary from one culture to another (AERA, APA, & NCME, 1999). Children in one culture might be discouraged from responding directly to an adult or from engaging in a detailed conversation, as it is considered rude (Salvia & Ysseldyke, 2004). If the assessment requires expression of ideas, children of this culture are likely to perform poorly, not because their ideas are ill-formed but because of their cultural expectations.

People from cultures in which speed is not emphasized, as it is in North America, will not perform as well on a timed test. The actual test situation might be unfamiliar for people from some cultures (Hambleton & Patsula, 1998). The very act of placing people into a testing situation can put them at a disadvantage. Similarly, some people might not be familiar with completion of computer-marked response cards, so the means of indicating a response in this situation requires skills or exposure to media that are not universal.

The foregoing discussion illustrates the complexity of the issue of performing assessments with individuals of a culture different from the one for which the instrument was standardized. The *Standards for Educational and Psychological Testing* (AERA, APA, & NCME, 1999) present several standards to minimize the potential disadvantage to individuals of a diverse culture. These standards and the recommendations from other writers that follow recognize that it is not generally feasible to create a test that can be considered free of cultural bias. It is the ethical responsibility of the examiner to ensure that measures have been taken to minimize the cultural bias (AERA, APA, & NCME, 1999).

The *Standards for Educational and Psychological Testing* recommend that tests and their use for non-English speakers or for people who speak certain English dialects "should be designed to reduce threats to the reliability and validity of test score inferences that may arise from language differences" (AERA, APA, & NCME, 1999, p. 97). The ability of non-English speakers to understand the test items or instructions should be ascertained, perhaps through the administration of practice items (Hambleton & Patsula, 1998). When language or other modifications have been made to tests that were originally developed in English, information should be provided in the test manual to document those modifications and their influence on the psychometric properties of the test.

Critiquing Assessments for Older Adults

Little attention has been paid in the psychometric literature to the issues related to assessment of older adults. Yet

this group is a growing segment of our population, with estimates suggesting that over 21% of Canadians will be over the age of 65 years by 2026 (Statistics Canada, 2001) and 78 million Americans will be over this age by 2050 (Rosenbloom, 2004). This group represents a significant proportion of the clients for whom occupational therapists provide service.

First, let's consider some of the personal issues that will influence an older adult's performance on a standardized test. Many of these issues are well documented in the literature, so they will simply be identified here. Changes in physical function and the incidence of physical disabilities increase with age. A survey of physical limitations identified that people 75 years of age and older were the most likely to report the presence of three or more disabilities (Statistics Canada, 2002). Vision changes include difficulty in low-light situations, loss of visual acuity, and slowed visual scanning, along with impairments such as cataracts, glaucoma, and macular degeneration (Owsley, 2004). Cognitive issues include loss of memory, attentional difficulties, and dementia. Affective concerns include anxiety related to the testing situation and depression.

World views, life experiences, and goals may differ between the client and the clinician or test developer (Mouton & Esparza, 2003). These have the potential to affect the client's interpretation of the purpose of the test and the specific items that make up the test. Issues that were identified previously about response to testing and interpretation of test items, based on culture and life experience, are relevant to this discussion.

A final personal issue is one that is perhaps less recognized. The issue of social consequences was discussed earlier in reference to validity. With older adults, social consequences refer to decisions that significantly affect their lifestyle. Two situations illustrate this point. The outcome of a driving assessment might be the loss of the legal right to drive, leading to negative consequences for the driver and family (Suen & Sen, 2004). Similarly, results of a functional or competency assessment may influence whether a senior can remain in his or her own home or must give up that independence and enter supported living. It is very obvious, then, that seniors facing assessment might bring fears to the situation about the consequences to their lifestyle and the meaning of those consequences to their self-concept.

Issues related to the test itself can be inferred from the previous discussion. When selecting an assessment to use with a senior, the clinician should appraise its appropriateness for this age group (e.g., did the normative sample include seniors?). The content should be examined for bias related to expected knowledge and literacy level. Consideration of the response format should include whether it is reasonable to expect that the client will have sufficient recent experience to provide an answer. Cultural issues also need to be examined. Physical issues of test such as font and layout can affect performance. Time constraints may be a source of anxiety.

The testing situation can also be a source of bias. It is important to ensure that sufficient lighting is available and that the client is comfortably positioned. The test administrator should ensure that the testing environment is as supportive as possible.

Issues in the Evaluation of People with Disabilities

Because of the nature of our profession, the clients whom we assess typically have some form of disability. As with the use of tests with people of diverse cultures and older adults, the issues here are complex, and the solutions are often incomplete. Individuals with disabilities may have impairments that affect their ability to perceive test instructions or materials, process information related to formation of a response, or indicate a response through verbal or motor means (Hacker & Porter, 1987; Salvia & Ysseldyke, 2004; Taylor, Sternberg, & Richards, 1995). Further, a mental health issue might limit the client's ability to engage in the testing situation (Taylor et al., 1995).

The *Standards for Educational and Psychological Testing* (AERA, APA, & NCME, 1999), recommend that people who modify any test for use with an individual with a disability do so with the assistance of an individual who is an expert in psychometrics. Furthermore, the test user should have knowledge about the manner in which the disability might affect the reliability and validity of the inferences of the test score. As always, these changes should be reported in the test manual.

When conducting assessments with children with disabilities in the school system, occupational therapists must know the regulations that govern such assessment. Two examples of these regulations will be described: Individuals with Disabilities Education Act Amendment of 1997 (P.L. 105-17) and the Education Accountability Act in the province of Ontario, Canada. Both pieces of legislation require that students with disabilities be afforded the opportunity to participate in provincial or state standardized testing. Assessment must be conducted in such a way that the score can be meaningfully interpreted to reflect the child's performance on the underlying construct and not be biased by some variable, irrelevant to the construct, such as language or motor ability (Education Accountability Act, 2000; IDEA, 1997).

Both IDEA (1997) and the Education Accountability Act (2000) indicate that modifications or accommodations are to be used as appropriate, provided that there is evidence of reliability and validity with the specific modifications. Specific modifications include changes to time requirements, format of administration or response, language, setting, and individual or group administration. Specific accommodations include alteration of test administration (e.g., large print, Braille translation, interpreter

for the hearing impaired, multiple sessions) response method (e.g., oral response, use of computer access devices), and setting (e.g., segregated area) (*Federal Register,* 1999; Ministry of Education, 2000).

This discussion of the challenges of evaluating clients in a fair manner underlines the responsibility of the therapist. Satisfactory validity evidence must be present to support the intended purpose of the test, interpretation of the scores, and actions that arise from that interpretation. Particularly when the outcome of the evaluation has the potential to influence education, employment, or living situation, the therapist must be able to demonstrate the validity of the inferences that are made from the score.

SOURCES OF INFORMATION ON PUBLISHED TESTS

This chapter has provided an overview of issues with which an occupational therapist must be familiar to critique an assessment. A number of sources are available that provide reviews of published tests. The *Mental Measurements Yearbooks* provide reviews of most commercially available tests. Test reviews are available online at http://burros.unl.edu/buros/jsp/search.jsp. *Tests in Print* (e.g., Murphy, Plake, Impara, & Spies, 2002) provides descriptive information and bibliographies. An excellent source of test information that is specific to occupational therapy is *Measuring Occupational Performance: Supporting Best Practice in Occupational Therapy* (Law, Baum, & Dunn, 2001)

This chapter was meant to be an overview of the critical concerns in the critique of assessments. It was not intended to include a detailed discussion of the various aspects, formulas, or calculations of test construction, item analysis, reliability, and validity. For further information, the books on the reference list marked with asterisks (*) provide more detailed information and, frequently, reviews of assessments commonly used in occupational therapy.

CASE STUDY: *Application of Critiquing Assessments Framework to the FIM™ Instrument*

Note: This review of the FIM™ instrument is for illustrative purposes only and is not intended to be an exhaustive review of the literature related to this test.

Purpose of the Test

The FIM™ instrument is a measure of function and disability based on the concept of burden of care (Hamilton, Granger, Sherwin, Zielezny, & Tashman 1987). It is used to describe current function, predict future function and discharge destination, and evaluate a client's response to intervention (Timbeck & Spaulding, 2003). It is part of the Uniform Data System for Medical Rehabilitation (USDMR) (Deutsch, Fiedler, Granger, & Russell, 2002).

Theoretical Frame of Reference

The FIM™ instrument is based on the concept of burden of care. Disability is rated according to how much assistance a person requires to perform daily activities (Hamilton et al., 1987). It is intended for an adult rehabilitation population and provides information on motor and social aspects of function.

Clinical Utility

Information: Information about the FIM™ instrument is available from the Uniform Data System for Medical Rehabilitation: www.udsmr.org.

Qualifications: Facilities that wish to be part of the (USDMR) must be accredited. Clinicians who administer the FIM™ instrument within an accredited facility must take a training course and pass a test.

Support for learning: Workshops are available for clinicians who will administer the test within an accredited facility. For others, training materials, including videos, are available.

Test format: The FIM™ instrument has 18 items in six areas: self-care, sphincter control, mobility, locomotion, communication, and social cognition. Individual items are rated from 1 (total dependence) to 7 (full independence) with a total score range of 18–126. The first four areas form the motor subscale, and the last two form the cognitive subscale.

Test procedures: Information is obtained through direct observation, interview, or chart review.

Administration time: The FIM™ instrument takes approximately 30 minutes to administer.

Response format: Both motor and verbal responses are required.

Scoring: Score derived from observation of performance, interview, or chart review. Guidelines, case studies, and decision trees are available to support determination of rating.

Technical Considerations

Norms: No norms are available, but performance profiles can be obtained (Letts & Bosch, 2001)

Continued

CASE STUDY: *Application of Critiquing Assessments Framework to the FIM™ Instrument* *Continued*

Reliability: Analysis of 11 studies investigating reliability found high interrater reliability with stronger correlations for motor subscales than for cognitive subscales. Correlations were strong for test-retest and equivalent forms reliability (Ottenbacher, Hsu, Granger, & Fiedler, 1996). Examination of internal consistency supports the structure of the FIM™ instrument (Hobart et al., 2001; Hsueh, Lin, Jeng, & Hsieh, 2002).

Validity: Research consistently supports a strong relationship with the Barthel Index (Deutsch et al., 2002; Hobart et al., 2001; Hsueh et al., 2002). The FIM™ instrument is consistently found to be responsive to change in functional status for a CVA in-patient rehabilitation population (Desrosier et al., 2003; Dromerick, Edwards, & Diringer, 2003; Hseuh et al., 2002). The admission FIM™ instrument score was found to be a strong predictor of discharge FIM™ instrument score, disability rating, discharge rating, and discharge location (MacNeill & Lichtenberg, 1998; Timbeck & Spaulding, 2003).

Fair-Testing Issues

Observation of required activities can occur in a variety of settings or conditions, allowing for administration of the FIM™ instrument in an environment that is supportive for the client. The instrument can be administered to any rehabilitation client regardless of age or disability. Individuals who use assistive technology to complete daily activities cannot receive a maximum score whether they require assistance from another person or not (Minkel, 2002).

Reviewer's Comments

The FIM™ instrument is a widely used tool that is excellent for program evaluation in a rehabilitation setting. The psychometric properties are strong, making it a good first choice as an outcome measure in a variety of settings (Letts & Bosch, 2001)

Activities of Daily Living and Instrumental Activities of Daily Living

ANNE BIRGE JAMES

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the purposes of an occupational therapy ADL and IADL evaluation.
2. Given a client case, identify client and contextual factors that would influence the evaluation plan.
3. Develop individualized client goals that will drive the intervention process.
4. Describe contextual considerations that influence goal development.
5. Explain the most common approaches to ADL and IADL intervention.
6. Describe the role of client and caregiver education in treatment of ADL and IADL deficits.
7. Grade treatment activities to progress clients toward increased participation in ADLs and IADLs.

This section focuses on the evaluation and treatment of areas of occupation that are classified as activities of daily living (ADLs) and instrumental activities of daily living (IADLs) in the Occupational Therapy Practice Framework (OTPF) (American Occupational Therapy Association, 2002). Dysfunctions in ADLs and IADLs are termed *activity limitations* in the International Classification of Functioning, Disability, and Health (World Health Organization, 2001) framework. Evaluation and treatment of ADL and IADL dysfunction are central to individuals' participation in meaningful occupation. Individuals may value ADLs and IADLs as meaningful in and of themselves and as prerequisite tasks to meaningful engagement in education, work, play, leisure, and social participation.

DEFINITION OF ADL AND IADL

Conceptually, the term *activities of daily living* (ADLs) could apply to all activities that individuals perform routinely. In the OTPF, however, ADLs are defined more narrowly as "activities that are oriented toward taking care of one's own body" (AOTA, 2002, p. 620), which include 11 activity categories: bathing/showering, bowel and bladder management, dressing, eating, feeding, functional mobility, personal device care, personal hygiene and grooming, sexual activity, sleep/rest, and toilet hygiene. IADLs are defined as "activities that are oriented toward interacting with the environment and that are often complex in nature" (AOTA, 2002, p. 620). IADLs also include 11 activity categories: care of others, care of pets, child rearing, communication device use, community mobility, financial management, health and maintenance, home establishment and management, meal preparation and clean up, safety procedures and emergency responses, and shopping. Although both ADLs and IADLs include essential occupational performance tasks, IADLs are typically easier to delegate to another person (AOTA, 2002).

The OTPF (AOTA, 2002) provides a nomenclature and organizational scheme for occupational therapy practitioners in the United States. The OTPF's definitions of ADLs and IADLs are consistent with those of the National Center for Health Statistics (2007); however, other health care and social services practitioners or occupational therapists outside the United States might use other terms to refer to these same ADL and IADL concepts or use the same terms but define them differently. The term *ADL* is typically restricted to activities involving functional mobility (ambulation, wheelchair mobility, bed mobility, and transfers) and personal care (feeding, hygiene, toileting, bathing, and dressing), consistent with the OTPF, although some practitioners define *ADL* more broadly, referring to all activities that are performed in daily life. Other terms that are used to refer specifically to functional mobility and personal care are *basic ADL* and *personal ADL* respectively (AOTA, 2002). The term *IADL* appears outside the occupational therapy literature in a less consistent way. Measures of IADL vary considerably according to the activities that are included in the scales (Chong, 1995); for example, the Nottingham Extended Activities of Daily Living Scale includes leisure activities and feeding (Nouri & Lincoln, 1987), tasks that fall outside the OTPF definition of *IADL*. Synonyms for *IADL* are *independent living skills* and *extended ADL* (Nouri & Lincoln, 1987). More recently, the acronym AADL—for advanced activities of daily living—has come into use. The term AADL has also been used in different ways by various authors, for example, to capture activities that are more physically strenuous than IADLs (Reuben, Laliberte, Hiris, & Mor, 1990) or to refer to activities that are "volitional" rather than essential (Ashworth, Reuben, & Benton, 1994), such as hobbies, recreation, and volunteer work (Moore, Endo, & Carter, 2003); these definitions are more in line with the OTPF concept of play or leisure. The crucial point is to understand that terms that refer to daily activities are used in variable ways, so it is important, in referring to written work, to look for operational definitions of terms used by authors and, in a clinical setting, to find out the conventional language used by practitioners. Occupational therapy practitioners need to be aware of the differences in terminology and use commonly accepted terms for the context when communicating with other professionals and when selecting assessment instruments.

This chapter focuses on the evaluation and treatment of occupational performance limitations specifically related to ADLs and IADLs as defined by the OTPF. It is essential to have a fundamental understanding of the occupational therapy process before reading this chapter; the process is described in Chapter 46. The reader should be aware that ADLs and IADLs, while often a primary focus of occupational therapy practice, do not typically represent the full complement of occupational performance tasks needed for satisfying and meaningful participation in individual and societal roles. Evaluation and treatment should always begin with a comprehensive occupational profile (AOTA, 2002). Treatment should address all of the client's priorities, which will typically extend beyond ADLs and IADLs, although the rest of this chapter will focus exclusively on ADLs and IADLs.

EVALUATION OF ADLS AND IADLS

Evaluation refers to the overall process of gathering and interpreting data needed to plan intervention, including developing an evaluation plan, implementing the data collection, interpreting the data, and documenting the evaluation results (AOTA, 1995). **Assessment** refers to the specific method that is used to collect data, which is one component of the evaluation process (AOTA, 1995). Standardized assessment methods are referred to as *assessment tools* or *instruments.* The evaluation is carried out by an occupational therapist; an occupational therapy assistant may participate in selected assessments under the supervision of an occupational therapist, who is responsible for interpreting assessment data for use in intervention planning.

The ADL/IADL evaluation is discussed in two stages in this chapter: (1) planning the evaluation, which includes selecting specific assessment methods, and (2) implementing the evaluation, which includes gathering assessment data, making critical observations, hypothesis generation, and ongoing revision of the evaluation plan until adequate data have been collected. Keep in mind that ADL and IADL evaluation is only one part of a more comprehensive occupational therapy evaluation, which should address all areas of occupation that are relevant to each client.

Evaluation Planning: Selecting the Appropriate ADL and IADL Assessments

Occupational therapists can choose from a variety of ADL and IADL assessments, designed to meet the varied needs of clients and treatment settings. Selecting an appropriate assessment will facilitate optimal treatment planning and can be initiated by following these steps:

1. Identify the overall purpose(s) of the evaluation.
2. Have clients identify their needs, interests, and perceived difficulties with ADLs and/or IADLs as part of the occupational profile.
3. Further explore the client's relevant activities so that the activities are operationally defined.
4. Estimate the client factors that affect occupational performance and/or the assessment process.
5. Identify contextual features that affect assessment.
6. Consider features of assessment tools.
7. Integrate the information from steps 1–6 to select the optimal ADL and IADL assessment tools.

In practice, the experienced occupational therapist completes this process quickly, so much of the ADL and IADL evaluation is completed in the first occupational therapy session. Also, although these steps appear to follow a linear progression, in practice the steps become integrated as the occupational therapist continually blends knowledge and experience with information from and about the client. For the developing therapist, however, it is helpful to explore each step independently to examine critical factors that contribute to the complex clinical reasoning process that is employed in planning an evaluation.

Step 1: Identify the Purpose of the ADL/IADL Evaluation

ADLs and IADLs may be evaluated for different purposes. At the level of individual client care, evaluation may be done to assess activity limitations to plan occupational therapy intervention or to facilitate decision making concerning discharge environment, competency, conservatorship, and/or involuntary commitment. At the programmatic level, evaluation may be done to document the need for program development and to appraise outcomes. Before starting an evaluation, the practitioner must determine how the information will be used so that appropriate and sufficient data are obtained. The extent of data gathering depends on the specific purpose for which the evaluation is being conducted.

EVALUATION TO PLAN AND MONITOR OCCUPATIONAL THERAPY INTERVENTIONS. Before practitioners intervene to improve performance of ADLs or IADLs, they must evaluate clients' baseline performance. When an evaluation is conducted to plan occupational therapy intervention, certain types of data are needed (Rogers, Holm, & Stone, 1997). First, activities in which performance is deficient need to be identified so that intervention can focus on components that are dysfunctional while simultaneously maintaining and enhancing those that are functional. Second, data are needed about the cause or causes of the activity limitation. For example, a limitation in cooking might be caused by low vision, a wheelchair-inaccessible kitchen, or poor motivation to cook. Occupational therapy intervention for a limitation in cooking is different for each of these causes. To understand the etiology of an activity limitation, data about occupational areas (ADLs, IADLs) need to be supplemented with data about the client's performance patterns and skills, client factors, activity demands, and contexts. Third, the occupational therapy evaluation should provide data about the possibilities for modifying the client's activity performance. Information about the activity demands and context should include consideration of which aspects might be modifiable to support performance and which features cannot be changed. The potential to change performance patterns and skills or client factors must also be assessed. Interventions that involve skill acquisition are feasible for some clients, depending on the factors that are interfering with task performance. For example, a child with balance deficits secondary to cerebral palsy might have the potential to increase balance skills to support participation across several ADLs and IADLs, while a person with similar deficits from Parkinson's disease might not because the disorder is progressive. All three types of data are needed to devise adequate intervention plans.

EVALUATION TO FACILITATE DECISION MAKING ABOUT ELIGIBILITY OR DISCHARGE ENVIRONMENT. Clients may also be referred for evaluation of ADLs and IADLs to facilitate decision making about eligibility or discharge environment. The ability to care for oneself and one's home can make the difference between independent and supported or assisted living. Supported living represents a continuum of options that includes in-home services (e.g., chore services), personal care assistants, assisted living centers, foster homes, group homes, independent living centers, supervised apartments, transitional apartments, and long-term care facilities. Varied levels of support are offered within these settings to maintain or enhance daily living skills. When ADLs and IADLs are evaluated to serve eligibility or discharge decisions, the evaluation may be less comprehensive and detailed than when it is done to plan individual interventions. The primary question to be answered through the evaluation is "Does the client meet the functional criteria?" This question can generally be answered by identifying activities in which limitations are present.

A somewhat similar evaluation objective occurs when occupational therapy practitioners are asked to make recommendations regarding legal competence for independent living. This usually involves competence in caring for oneself or competence in managing one's property. Difficulties

with the first type of competence lead to legal proceedings called *guardianship,* whereas difficulties with the second type of competence involve *conservatorship*. Evaluation may also be requested in conjunction with involuntary commitments to psychiatric facilities to appraise the influence of psychiatric status on daily living. When competence is used in the legal sense, the capacity to make judicious or responsible decisions usually takes precedence over the capacity to perform activities. Individuals who have the ability to procure services and supervise caregivers in managing their personal care and living situation are viewed as competent, even though they might not be able to perform these activities themselves. Thus, occupational therapy evaluations that are conducted with guardianship, conservatorship, or involuntary commitment in mind must take into account the decisional capacities and supervisory skills needed by clients.

EVALUATION FOR PROGRAMMATIC USES. Although this chapter emphasizes evaluation for individual client care, it is important to recognize that data gathered about clients may be aggregated for programmatic purposes. For example, data about the ADL and IADL characteristics of clients who are served in an occupational therapy clinic can be used to document the extent of particular activity limitations and to support the development of new or expanded programs to manage them. In the current health care climate of cost-effectiveness and cost containment, group data are increasingly being used to evaluate the outcomes of occupational therapy programs and occupational therapy interventions. Occupational practitioners are often expected to measure and document ADL and IADL data consistently across clients so that they can be used effectively for program evaluation (Robertson & Colburn, 2000).

Step 2: Have Clients Identify Their Needs, Interests, and Perceived Difficulties with ADLs and/or IADLs

Once the purpose of the ADL/IADL evaluation has been determined, the occupational therapist must identify the specific activities to be evaluated. This is *one* component of the occupational profile, which will also encompass other aspects of occupational performance, including education, play, leisure, work, and social participation (AOTA, 2002). Developing the client's occupational profile is a crucial step in a client-centered evaluation, which enhances both the process and outcomes of occupational therapy (Law, 1998). A client-centered approach to ADL and IADL evaluation requires practitioners to begin by discovering the ADL and IADL problems of concern to the *client* (Law & Baum, 2005). Practitioners can expect the activities of concern to vary significantly for a 10-year-old elementary school student, a 29-year-old homemaker caring for three young children, and a 49-year-old business executive; and

the evaluations of these clients need to be tailored to take the clients' lifestyle differences into account. It is easy to make assumptions about a client's priorities, based on both clinical and personal experience and values; however, it is important to remember that unique circumstances may affect clients' selection of the ADLs or IADLs that they wish to address in treatment. Clients' perception of their ADL and IADL problems, needs, and goals can be gathered through a semistructured interview process or through a more formal assessment, such as the Canadian Occupational Performance Measure (COPM) (Law et al., 2005). The relative value of activities can be quantified by having clients rate the activities on a Likert scale on which, for example, 1 = "not at all important to perform effectively" and 10 = "crucial to perform." Alternatively, clients can be asked to rank a list of ADLs and IADLs in order of importance to identify priorities.

Step 3: Further Explore Clients' Relevant Activities So that the Activities Are Operationally Defined

The meanings of terms that are used for selected ADLs and IADLs can vary among individuals. Before activities can be evaluated, they must have an **operational definition**; that is, the occupational therapy practitioner and client must be clear on the precise meaning of each term. For example, meal preparation for a middle school student might consist of making cereal for breakfast and packing a lunch, whereas meal preparation for a homemaker feeding a family of five involves a much wider range of food preparation tasks and a very different set of skills. Because different assessment tools define activities differently, it is important to select an instrument that is congruent with the activities as defined by the client. For example, in using the Barthel Index to assess feeding, clients are rated "independent" if they can feed themselves, which includes cutting up food and spreading butter on bread (Mahoney & Barthel, 1965). Clients are rated as "needing assistance" if they can get food from the plate to the mouth but need help cutting food into bite-sized pieces. The Katz Index of ADLs, however, does not include preparation of food on the plate (e.g., cutting and spreading butter on bread) in the operational definition of feeding, so clients are rated independent if they can get food from the plate to the mouth, even if they cannot cut food or butter bread (Katz, Ford, Moskowitz, Jackson, & Jaffe, 1963). Many adolescents and adults would be dissatisfied with their feeding performance if their food had to be cut or their bread buttered by another person, so the Katz Index of ADL would not be an appropriate measure for individuals who consider cutting and buttering to be essential components of feeding.

The operational definitions of IADLs are more varied than those for ADLs because of their greater complexity. Consider the task of meal preparation. On the Instrumental Activities of Daily Living Scale (IADL Scale), which is

generally considered to be the prototype assessment instrument for IADLs, the highest level of competence is described as "plans, prepares, and serves adequate meals independently" (Lawton, 1972, p. 133). Comparable items on the Nottingham Extended ADL Index examine the ability to make a hot drink and hot snack alone and easily (Nouri & Lincoln, 1987). Thus, a rating of independence in cooking achieved on the Nottingham Extended ADL Index implies a lower level of competence than does a rating of independence on the IADL Scale.

Occupational therapy practitioners also need to consider relevant performance parameters when planning an evaluation. **Performance parameters**, which are described in detail in Chapter 46, include independence, safety, and adequacy. Operational definitions of acceptable ADL and IADL performance should include attention to all relevant parameters in order to establish appropriate baseline data and intervention outcomes.

LEVEL OF INDEPENDENCE. Although clients often wish to be independent in ADLs and IADLs, practitioners should not make this assumption, as some level of assistance, either verbal or physical, might be acceptable. For example, a client who has had a total hip replacement may not don shoes and socks independently without adaptive equipment for two months postoperatively while movement restrictions are in place. Some clients who live with others might prefer to have assistance with this task rather than purchasing and using the required adaptive equipment. As long as the context supports this, that is, as long as they have someone who is willing and able to assist, a goal for assisted lower extremity dressing is perfectly appropriate, and treatment may focus on making sure that the patient and caregiver can complete the task together while adhering to total hip precautions. Independence is the performance parameter that is the focus of most assessment tools, so occupational therapists can select from a variety of assessment tools that measure independence. Several other considerations, discussed later in this chapter, can help the occupational therapist to identify which of the many assessment tools is best for the situation.

SAFETY. Many assessment tools address safety indirectly by specifying that performance be completed in a safe manner in order to be rated as independent (e.g., the FIM™; U.B. Foundations Activities, 2004). Some tools do not address safety directly (e.g., the Katz Index of ADL; Katz et al., 1963), and a few rate safety separately from independence (e.g., the Performance Assessment of Self-Care Skills; Holm & Rogers, 1999; Rogers & Holm, 1994). When safety is a particular concern, for example, with clients who have cognitive deficits that impair judgment, a separate measure of safety can be more effective for documenting progress toward treatment goals. A separate safety measure also makes it clear in the occupational therapy documentation that safety has been addressed.

ADEQUACY. Clients may have criteria regarding the efficiency of task performance and the acceptability of the outcome of the performance, and these should be considered in selecting assessment tools. For example, a client might be safe and independent in lower body dressing but deem her performance inefficient because it takes her over an hour to complete the task and she is too physically exhausted after dressing to attend to work duties. Or a client might be independent and safe in feeding himself but find his performance outcome unacceptable if he drops food onto his clothing during each meal. If an assessment tool measured only independence and safety, it would be hard to justify intervention in either of the above examples because both clients were safe and independent. There are, however, occupational performance problems in both cases that might be addressed effectively through treatment, that is, reducing the time needed to complete lower body dressing or reducing the amount of food spilled on clothing during eating. Adequacy parameters that warrant consideration in the context of ADL and IADL performance include perceived difficulty, pain, fatigue, **dyspnea**, societal standards, satisfaction, aberrant behaviors, and past experience with the activity. Specific options for measuring adequacy parameters are described in Chapter 46. Practitioners must keep in mind that independence might not be the only important performance parameter to assess in the occupational therapy evaluation.

Step 4: Estimate the Client Factors That Affect ADLs/IADLs and the Assessment Process

One purpose of the ADL/IADL evaluation is to provide insight into the problems underlying occupational performance deficits. However, some estimate of these deficits prior to the assessment can help the occupational therapist to select the assessment tools that will be most effective in identifying and documenting occupational performance problems and the underlying deficits. Occupational therapists use their knowledge of pathology and how it affects occupational performance when selecting assessment tools. For example, some instruments rely on self-report, which is a very efficient way to gather information about a wide range of activities. However, if the client has significant cognitive deficits (e.g., a person with Alzheimer's disease), distorted thought functions (e.g., a person with schizophrenia), or little experience with the disorder (e.g., a teenager who sustained a spinal cord injury with quadriplegia just five days earlier), self-reported measures could be inaccurate. For many types of deficits, insight into clients' underlying problems will be enhanced by actually seeing the client attempt to perform tasks rather than relying on a description of the problem. For example, a client who has had a stroke might report that he is unable to reach items stored above chest height with his affected hand, but the occupational therapy practitioner can gain additional infor-

mation needed for treatment by observing the client while he is reaching by looking for clues as to whether the movement problem is due to limitations in movement of the scapula, glenohumeral joint, or elbow or some combination of the three. Knowledge of underlying pathology and anticipated impairments also enables occupational therapists to select appropriate assessment tools that are designed for specific diagnostic groups, focusing on activities that are more commonly problematic for that population. For example, the Arthritis Impact Measurement Scale was developed for adults with rheumatic diseases and includes not only measures of ADL and IADL performance, but also symptoms that are commonly experienced by people with arthritis during or following activities, such as pain and fatigue (Meenan, Mason, Anderson, Guccione, & Kazis, 1992).

Step 5: Identify Contextual Features That Affect Assessment

In this step, the occupational practitioner considers the intervention context and its impact on the evaluation of ADLs and IADLs. These include physical context, social context, safety, the client's experience, time constraints, the practitioner's training and experience, availability of resources, and mandates from facilities or **third-party payers**.

PHYSICAL CONTEXT. Practitioners may observe activity performance under natural or clinical conditions. Under natural conditions, performance is observed within the context in which it usually takes place or is expected to take place, including the location (e.g., home), the objects that are usually used for activities (e.g., bathtub, soap), and the routine time when activities take place, when possible. These conditions, which can often be met in long term-care settings and home-based care, provide the most accurate assessment of clients' performance (Rogers et al., 2003). When clients are seen in the hospital or outpatient clinics, observation of activity performance takes places under clinical conditions. Regardless of where an assessment takes place, the influence of the physical context on activity performance must be taken into account so that valid conclusions about performance can be drawn. Occupational therapy clinics are designed to promote function and have numerous adaptive features to compensate for impairments. These features can make it easier for clients to perform activities in the clinic than in their own homes. Conversely, performance might be more difficult for some tasks because clients are unfamiliar with the clinic setting. When an evaluation is done in the home, clients have the advantage of using their own activity objects in the confines of familiar architecture. Research in this area is limited but demonstrates the variable impact of context on performance. For example, Brown, Moore, Hemman, and Yunek (1996) found that clients with mental illness performed

similarly on a simulated purchasing task in the clinic and an actual purchasing task in a store, whereas Park, Fisher, and Velozo (1994) found that older adults' process skills during IADLs were higher in their homes than in clinic settings. More research is needed to identify the relationships among different types of client impairments and varied evaluation contexts.

SOCIAL CONTEXT. The occupational therapy evaluation also occurs in a social context. Practitioners must oversee activity performance during assessment, and their very presence can affect the manner and adequacy of the activities performed. The practitioner's presence especially affects the client's ability to initiate participation in ADLs or IADLs, since the structure of the assessment process itself prompts clients to engage in the tasks. If initiation of task performance is impaired, the practitioner must supplement performance measures from a structured therapy session. For example, the Independent Living Scale includes a subscale for initiation (Ashley, Persel, & Clark, 2001). Alternatively, family members might be asked to keep track of the number of days the client completed pet care responsibilities without being asked, for example. Clients' occupational performance might be also be impaired or enhanced in the natural environment compared to the clinic, depending on their needs and the differences in social context between clinic and natural environments. For example, a client with a spinal cord injury who must be skilled in directing a personal care attendant during ADLs might give directions effectively to a rehabilitation aide who is familiar with caring for people with similar needs but might not give detailed enough instructions for an employee in the home who has less experience. Conversely, a client who requires setup to feed herself will be more independent at home than in the clinic if she lives in a family where meals are routinely set up for the entire family by a parent who does all the cooking.

SAFETY. Occupational therapists must assess risks associated with ADLs or IADLs that have been identified as priorities by clients and might need to defer assessment of a task that they believe could be unsafe. Identifying the potential risk of a given assessment is based on occupational therapists' expertise in determining activity demands combined with their estimate of client problems, outlined in step 4 above. For example, a client who suffered a recent stroke resulting in very poor sitting balance might identify showering as an important goal; however, getting the client onto a shower chair in a wet and slippery environment for an assessment might be unsafe, given the level of assistance she needs for maintaining balance so soon after the stroke. Instead, the occupational therapist might suggest beginning with an assessment of bathing skills that can be completed at bedside and defer a shower assessment until sitting balance is improved.

THE CLIENT'S EXPERIENCE.   Clients will come with varied experience with ADLs and IADLs based on personal context. Typically, ADL practice begins in childhood, and the societal expectation is that adolescents and adults have a wide range of experience with these activities and can perform them adequately. However, a similar expectation does not hold for IADLs, for which people have more options. Therefore, clients might not have developed proficiency in all IADL activities. Some might have no experience in planning and preparing meals, doing the laundry, or managing finances. Children with developmental disabilities often experience delays in the acquisition of ADL and IADL skills and might lack experience that a typically developing child would have at a given age. Clients' activity performance history is essential for understanding their current performance level. An activity limitation is interpreted differently for a client who has had no or little prior experience performing the activity than for one who had been doing it immediately premorbidly.

TIME CONSTRAINTS.   The time that is available for occupational therapy intervention is often limited by a number of factors, including reimbursement policies, so the evaluation process must be done efficiently. For clients with a long list of ADL and IADL goals, selecting key activities could be necessary so that the intervention designed to enhance occupational performance can be initiated in a timely manner. As goals are met, additional assessments may be initiated to document baseline performance of other ADLs or IADLs and to justify additional occupational therapy goals and treatment.

THE OCCUPATIONAL THERAPY PRACTITIONER'S TRAINING AND EXPERIENCE.   An occupational therapy practitioner's experience can also affect the selection of assessment tools. Familiarity with an instrument can increase efficiency of use and effectiveness of interpreting assessment results. Some assessment tools require specialized training, so they are not options for therapists who lack the training. For example, the Assessment of Motor and Process Skills (AMPS) (Fisher, 2006a, 2006b) relies on software that can be accessed only by practitioners who have completed the training course and calibration process (Gitlin, 2005).

AVAILABILITY OF RESOURCES.   The materials that are required for ADL and IADL assessments vary, and the occupational therapist must make sure that the necessary materials are readily available. Completing a cooking assessment using a client's favorite cookie recipe might be excellent for examining the client's performance, but because of the logistics and cost of procuring the ingredients, this activity is not likely to be practical for an occupational therapy practitioner in a hospital setting, whereas a client who is being seen in home-based therapy might have the required resources readily available in the home. Some assessments require special test kits, which can be costly, and facilities might have only a few such tools available for use.

MANDATES FROM FACILITIES OR THIRD-PARTY PAYERS. Many facilities or third-party payers have assessment forms or procedures that must be completed for all clients. For example, rehabilitation facilities must use the Inpatient Rehabilitation Facilities–Patient Assessment Instrument (IRF-PAI), which includes the Functional Independence Measure (FIM™) for measuring ADLs (U.B. Foundation Activities, 2004). If a client's description of a selected ADL differs from that of the FIM™ or if the client would like to address adequacy parameters in addition to independence and safety, then the occupational therapist must use a supplemental assessment, since documentation of the FIM™ scores is required.

Step 6: Consider Features of Assessment Tools

The occupational therapist must be familiar with available assessments and consider what tasks are included in the assessment, how tasks are defined, the psychometric properties, the type of data to be collected, and the method of data collection.

TASKS ASSESSED.   Tasks that are included in an ADL or IADL assessment should be consistent with clients' priorities, and the operational definition of effective performance should fit clients' needs and address all parameters of importance. For example, many assessment instruments measure independence, but if clients would also like to complete tasks independently without experiencing shortness of breath or pain, occupational therapists might want to use a dyspnea or pain scale in conjunction with the independence measure.

STANDARDIZED VERSUS NONSTANDARDIZED ASSESSMENTS. Some assessments are not standardized; that is, the individual therapist designs the assessment and decides the type of information to gather, or practitioners in a clinic might develop their own instrument for assessment. Nonstandardized assessments lack testing of psychometric properties, such as reliability, validity, or sensitivity to change in a client's status (Lorch & Herge, 2007). Standardized assessments rely on a well-described, uniform approach. There is a lot of variability in the extent to which the psychometric properties of standardized assessments have been established. Some assessments have been extensively studied and include a wide range of psychometric statistics to support the reliability and validity of the tool. The psychometric properties of test instruments may be published in the test manual or through peer-reviewed publications, such as the *American Journal of Occupational Therapy* (AJOT). When possible, it is best to use an assessment with established psychometric properties (Lorch & Herge, 2007).

There are different types of standardized assessments, including norm-referenced tests and criterion-referenced tests. Types of evaluations are described in more detail in Chapter 47. The purpose of norm-referenced testing is to compare a client's performance on a test to that of other people on the same test (Benson & Schell, 1997). ADL and IADL assessments are not usually norm-referenced tests, which tend to be used to assess developmental levels, performance skills, or client factors, such as visual perception, grip strength, or coordination. ADL and IADL assessments are typically criterion-based, that is, tests that compare a client's performance to a performance standard (Benson & Schell, 1997). Criterion-referenced tests stress activity mastery and address questions such as "Can clients perform all activities, or procure the services, needed to live in the community on their own?" Criterion-referenced tests often incorporate activity analyses, and the degree of structure that is imposed on testing is usually more flexible than those for norm-referenced testing, allowing therapists to tailor tests appropriately. For example, a dressing assessment is typically done with clothes that the client needs to and wants to wear, which can have an impact on performance. If a patient needs to be able to manage buttoning, that should be incorporated into the assessment even if it is difficult for the patient; however, if the patient has not worn garments with buttons for many years, there is no reason to assess buttoning ability.

DESCRIPTIVE VERSUS QUANTITATIVE DATA. Some non-standardized assessments use a descriptive approach, that is, the salient characteristics of clients' activity performance are observed or obtained through client or caregiver descriptions. Clients' status is documented by simply describing their performance. Quantitative ADL and IADL measures use a scale that converts observed or reported behavior into a number. Standardized quantitative measures include instructions for the person who is completing the assessment, which makes the assessment more reliable when the tool is used for reassessment or when there are multiple therapists in a facility. For example, the term *moderate assistance* could be interpreted in a number of ways, but if it is specifically described as "The patient requires more help than touching, or expends between 50 and 74% of the effort" (U.B. Foundation, 2004, p. III-7), there is likely to be better agreement among therapists using the instrument. Reducing observed behavior to a number also makes it efficient for reporting data in documentation. However, loss of descriptive data can make it difficult for the reader to get a clear understanding of the client's limitations. Often, documentation includes quantitative assessment data that are accompanied by some descriptive data to provide a more comprehensive picture of client performance. A brief case, presented in Table 48.1, compares descriptive and quantitative data from two cases.

It is possible to use descriptive data to document a client's baseline status, which is needed to determine whether or not progress is made in treatment; however, this can be difficult and time-consuming. For example, if Melinda and David's occupational therapist had to document the status of *all* ADLs and IADLs as in Table 48.1, the evaluation report would take a great deal of time to write and to read. Additionally, the occupational therapy practitioner who is documenting descriptive data should be very careful to distinguish between *observations* and *clinical judgments* (subjective interpretations about the observations). The statements listed in Table 48.1 are observations. A statement of clinical judgment is interpretive, and several plausible interpretations could be made from the more objective observations. For example, the occupational therapy practitioner could conclude that David has weak trunk muscles that interfere with balance. This conclusion should be presented as a hypothesis, not as an observation, because David's inability to maintain balance while dressing could be due to other factors, such as impaired vestibular and proprioceptive input that interferes with his ability to detect when he is starting to fall to one side.

Quantitative methods provide a more efficient way to document progress, although it might not provide the reader with adequate information. For example, although Melinda and David have the same quantitative score on the Wee FIM™, the descriptive information enables readers to see that there are very different underlying problems. Occupational therapists can document some key descriptive data to support their evaluation and treatment plan, but most descriptive observations are simply used by therapists for planning treatment, while quantitative data are recorded in documentation. Many quantitative ADL scales are available; however, it can be difficult for occupational therapy practitioners to find standardized assessments for some IADLs, so a descriptive approach also provides a reasonable option for the assessment of selected tasks for which no quantitative measure exists.

REPORTED VERSUS OBSERVED PERFORMANCE. Data about ADL and IADL performance can be gathered by report or through direct observation. Reported data about the client's abilities and limitations in performance can be gathered from the client, the caregiver, and/or another health professional. The occupational therapy practitioner poses questions about ADL and IADL performance. The questioning method may be implemented in an oral or a written format, using interviews or questionnaires, respectively. Although the questioning is frequently done face to face, either format can be done without physical interaction. Interviews may be conducted over the telephone. Questionnaires may be completed while the client is waiting for an appointment or can be mailed out in advance of a session. Gathering data via report can be done

TABLE 48.1	COMPARISON OF DESCRIPTIVE AND QUANTITATIVE DATA FROM A DRESSING ASSESSMENT OF TWO CHILDREN	
Client Description	Melinda is an 8-year-old child who sustained a traumatic brain injury. Before her injury, she was a typically developing child who dressed herself independently.	David is an 8-year-old child with cerebral palsy affecting the right side of his body. His mother has been dressing him before this assessment.
Descriptive Data	◆ Well-coordinated and smooth movements of both upper extremities when manipulating clothing. ◆ Maintenance of appropriate posture (unsupported, sitting on the bed) for the task. ◆ Able to reach all areas of her body (reach behind, overhead, and to feet) without loss of balance or any apparent instability in maintaining her position on the bed. ◆ Frequently stopped midtask to verbally express thoughts to the occupational therapy practitioner, which were disjointed and difficult to follow. ◆ Made repeated (total of 5) attempts to get her left arm in a sleeve that was turned inside out without attempts to correct the orientation of the garment. Did not respond to verbal directions to turn the sleeve right side out. The practitioner turned the sleeve right side out for Melinda after 3 attempts at giving verbal cues and gesturing toward the sleeve. ◆ Melinda left the dressing task to go look out the window when she heard a plane passing overhead and continued to talk about the plane when asked by the practitioner to return to the dressing task. ◆ Melinda returned to the task when the practitioner physically guided her to the bed and placed one of Melinda's arms in the sleeve. Melinda then completed putting the shirt on her other arm without physical assistance or cues. ◆ When asked to button her shirt, Melinda completed 2 of 6 buttons, which were misaligned. When asked how well her shirt was buttoned, she looked down at herself and said, "It's perfect," then skipped out of the room saying that she wanted to go to the TV room.	◆ Started to put left (stronger) arm in his shirtsleeve first. Responded immediately to verbal cue to dress the right side of the body first. ◆ Wavering of trunk when both upper extremities were being used to position the shirt. Therapist steadied David's trunk to prevent him from falling forward when he pulled the shirt across his back. He could not get the shirt far enough around to reach the sleeve, and the practitioner moved the shirt so he could reach it with the left upper extremity. ◆ Left upper extremity movements were smooth and well-coordinated when manipulating clothes and fasteners. ◆ Right upper extremity movements were slower and ineffective for fine tasks, such as buttoning. Several attempts were required to complete the bottom 3 buttons, and the occupational therapy practitioner had to complete the top 3. ◆ Dressing the upper body required 25 minutes, and David reported that he felt "pretty tired" at the end of the session. Throughout the session, David worked consistently, even when his little brother ran into and out of the room several times. ◆ David followed instructions consistently and made 4 or 5 attempts to help solve problems he encountered along the way, for example, suggesting that he wear pullover shirts that do not have buttons. ◆ When asked at the end of the session which arm he will dress first when he tries the task tomorrow, David responded, "My right arm."
Quantitative Data Based on the Wee FIM™	Upper Body Dressing = 4	Upper Body Dressing = 4

informally; that is, the practitioner develops the questions to be asked and the actual data that are gathered, or through the use of a standardized instrument such as the COPM (Law et al., 2005), the Occupational Self Assessment (Baron, Kielhofner, Iyenger, Goldhammer, & Wolenski, 2002), or the Child Occupational Self Assessment (Federico & Kielhofner, 2002). Although self-report is an efficient way to measure ADLs and IADLs, it is not always consistent with actual performance (Brown et al., 1996; Hilton, Fricke, & Unsworth, 2001; Rogers et al., 2003), and the occupational therapist should do selected performance-based assessments when the client's accuracy is in question.

In some situations, clients might be unable to respond on their own behalf. For example, they might be too physically ill or depressed to participate in questioning, or they might lack insight into their problems because of cognitive deficits. In these situations, caregivers or other proxies can be asked to respond on behalf of clients. The usefulness of the information that is obtained from caregivers or proxies depends on their familiarity with the client's ADLs and IADLs. For example, if the caregiver or proxy has not actually observed a client bathing or has not done this for some time, the information that this person gives about bathing might be based more on opinion than on concrete knowledge of performance. In addition, there are known biases in the reporting tendencies of caregivers and proxies. Family proxies are prone to perceiving clients as being more disabled than clients perceive themselves to be and to perceiving clients as more disabled than do professional caregivers (Rubenstein, Schairer, Wieland, & Kane, 1984). Caregivers and proxies can readily observe evaluation parameters such as independence, safety, and aberrant activity behaviors. For some evaluation parameters, however, clients are the only appropriate respondents. For example, values, satisfaction with performance, and activity-related pain are subjective, and indices of these parameters are difficult for others to observe.

Assessments that rely on self-report or caregiver's report are particularly useful for screening for activity limitations, because a large number of activities can be queried in a short amount of time. Questioning is also the data-gathering method of choice when information is needed about daily living *habits*—that is, about what clients usually do on a daily basis—or to learn about clients' ADL and IADL experience. However, reporting is less useful in evaluating limitations for the purposes of intervention because clients might not be able to describe their limitations in sufficient detail to target the components of activities that are problematic.

Assessment data can also be gathered through direct observation of ADLs and IADLs, which gives the practitioner more information about how the client performs a task. Observation of performance, however, requires more time and material resources and is therefore more costly.

Direct observation of performance can also be done in a nonstandardized way or through use of a standardized assessment. The constraints of practice settings, often imposed by third-party payers or limited funding, can place restrictions on the time an occupational therapist has available for evaluation. Occupational therapists must be strategic in selecting ADL and IADL assessments that will provide information that is relevant to the client and can be generalized to other tasks so that the practitioner does not have to observe all meaningful ADLs and IADLs that may be addressed in treatment. For example, if a client requires assistance with cooking because of an inability to transport food and cooking equipment safely while using a walker, the occupational therapist can reasonably project, without having to observe performance, that the same client will require assistance in doing laundry, since laundry also requires the transportation of task objects.

Selected standardized ADL and IADL assessments are listed in Table 48.2. The ADL assessments that are included in Table 48.2 are readily available and either are commonly used in practice (e.g., the FIM™) or provide a unique approach to assessment. For example, the Independent Living Scale measures task initiation (Ashley et al., 2001). Information for learning to use each assessment is also provided. The IADL instruments that were selected include a range of activities. More ADL and IADL assessments can be found in the resources listed in Box 48.1, and a more comprehensive list of assessments can be found in Unit XVI.

Step 7: Integrate the Information from Steps 1–6 to Select the Optimal ADL and IADL Assessment Tools

After establishing the purpose of the evaluation and the client's priorities and gathering some preliminary information about the client and relevant contextual features, assessment instruments can be selected that are client-centered, yield appropriate data, are reliable and valid, and are feasible to administer. Occupational therapists should engage in best practice by considering the evidence regarding the selection and use of assessments, for example, the reliability of instruments and the validity for a given clinical situation. Additional considerations for evidence-based evaluation are discussed in the Commentary on the Evidence box. Perhaps the best data-gathering strategy is to use a combination of methods and sources, relying on the convergence of data for the best profile of clients' activity abilities and limitations.

It is often most effective to begin the evaluation with a questioning approach to provide an overall profile of the client's abilities and limitations, to understand clients' priorities, and to target activities that require in-depth evaluation. Questioning is then followed by observational

TABLE 48.2 SUMMARY OF SELECTED ADL AND IADL INSTRUMENTS

Title	Areas Addressed	Population	Method/Rating	Learning to Use the Assessment
Assessment of Living Skills and Resources (ALSAR)	11 IADL skills	Adults	Interview with guiding questions; uses a three-point ordinal scale	Self-study using published references, including Williams et al. (1991) and Hilton, Fricke, & Unsworth (2001).
Assessment of Motor and Process Skills (AMPS)	85 calibrated ADL and IADL activities; client and therapist select 2 or 3 for assessment	Children and adults	Interview to identify 2 or 3 tasks for performance testing; activities rated on 16 motor skills (e.g., reaches, lifts) and 20 process skills (e.g., initiates, searches); uses a four-point ordinal scale	Training required. Software for scoring and required rater calibration available only through course. Course information and extensive reference list are available from AMPS Project International: http://www.ampsintl.com
Canadian Occupational Performance Measure (COPM)	Activities classified into three areas: self-care (ADLs and some IADLs), productive (some IADLs and work), and leisure	Children and adults	Self-report using a semi-structured interview; problems identified by client are rated for importance (scale of 1–10); the five most important problems are rated for both performance and satisfaction (also scales of 1–10).	Self-guided training available through the manual (Law et al., 2005) and on DVD or video from the Canadian Occupational Therapy Association: www.caot.org
Functional Independence Measure (FIM™)	18 activities: 13 ADL tasks and 5 tasks involving communication and social cognition (no IADL tasks)	Adolescents and adults	Observation by a trained observer; uses a seven-point ordinal scale, grading amount of assistance needed by clients to complete activity.	Training recommended for interrater reliability. Training often provided by employer. Also available from the Uniform Data System for Medical Rehabilitation: http://www.udsmr.org/fim2_services.php

TABLE 48.2   SUMMARY OF SELECTED ADL AND IADL INSTRUMENTS *Continued*

Title	Areas Addressed	Population	Method/Rating	Learning to Use the Assessment
Independent Living Scale	6 ADL tasks and 10 IADL tasks. Also rates behaviors in the context of tasks, including initiation and aberrant task behaviors.	Adolescents and adults with traumatic brain injury	Observation over the course of a week (needed for measuring initiation and aberrant task behaviors). Data may be supplemented by other team members.	Instructions for the test are available in Ashley et al. (2001). The ILS form and general information can be downloaded for free at http://www.neuroskills.com/cns/ilsmenu.shtml. The Ashley et al. article can be ordered for a nominal fee.
Kohlman Evaluation of Living Skills (KELS)	17 activities grouped into categories: ADLs, safety and health, selected IADLs, work, and leisure. Tends to emphasize knowledge component of activities.	Adults with cognitive impairments.	Combination of interview and performance; uses a three-point ordinal scale.	Manual included in test kit describes testing procedures. The KELS can be purchased from AOTA: www.aota.org
Melville-Nelson Self-Care Assessment	7 ADLs that are consistent with the Minimum Data Set	Adults in skilled nursing facilities	Performance-based. Tasks are rated on two scales: how much the client does and how much/ what type of assistance is given. Client performance ratings are made for subtasks and subsubtasks to help with planning intervention	Protocol describes standardized administration procedures. The form and protocol are available at http://hsc.utoledo.edu/allh/ot/melville/sca.html
Minimum Data Set— Section G. Physical Functioning and Structural Problems Scale (MDS)	10 ADL tasks activities	Residents in long-term care.	Performance, ascertained from multiple health care professionals, over all shifts during past 7 days; activities rated for self-performance and support provided	The Health Care Quality Improvement & Evaluation System (QIES) has manuals and self-help guides at https://www.qtso.com/mdsdownload.html#RAI Recorded training sessions are available at https://www.yourvirtualconference.com/qiesclasses.php

COMMENTARY ON THE EVIDENCE

Putting Evidence into Practice Through the Use of Standardized Assessments

Best practice in occupational therapy indicates that standardized ADL and IADL assessments should be used because they provide objective measures that are both reliable and valid (Dunn, 2005; Fasoli, 2008; Lorch & Herge, 2007). Reliable assessments enable practitioners to trust that differences in scores measured at different times represent true changes in ADL or IADL status and that reassessments done by another clinician can be reliably compared to a client's prior scores (Fasoli, 2008). Third-party payers also prefer documentation that describes clients' status and progress toward goals with standardized assessments. In spite of this, many clinicians continue to rely on nonstandardized assessments in clinical practice, often citing time constraints as a significant barrier to their use (Lorch & Herge, 2007). Many standardized ADL and IADL assessments, however, do not require much, if any, additional time or effort to conduct once practitioners are familiar with assessment protocols and scoring. For example, clinicians frequently begin their assessment with an interview to establish an occupational profile and clients' priorities (Radomski, 2008; Stewart, 2005). Practitioners can use the Canadian Occupational Performance Measure (COPM) to gather the same data in approximately the same amount of time. The COPM gathers descriptive data, as an informal interview does, but also includes reliable and valid quantitative measures of clients' self-reported performance ability and satisfaction on client-selected occupational performance tasks (Law et al., 2005). Clients' initial COPM scores serve as an objective baseline measure, and reassessment of clients' perceived progress can be quickly done by asking clients to rerate their performance and satisfaction on previously rated tasks. Standardized tests that do not require extensive additional time can also be selected when practitioners need to observe clients' actual performance. For example, the Performance of Self-Care Skills (PASS) uses a standardized approach to assessing a number of ADLs and IADLs, often by structuring observations of key elements of a task, such as sweeping up cereal placed on the floor by the therapist rather then having to observe the client sweep the entire kitchen (Holm & Rogers, 1999; Rogers & Holm, 1994). Practitioners must first become familiarized with the PASS scoring system, but once the practitioner is experienced, the assessment can be scored quickly and yields measures of three different parameters: independence, safety, and adequacy. Any or all of these performance parameters can be tracked and reported to document clients' progress toward goals.

Many standardized assessments are available for measuring ADL performance (Letts & Bosch, 2005). Why, then, do many practitioners continue to use informal ADL assessments in clinical practice? A search of the literature failed to reveal substantial research that answers this question. Research should be conducted to examine barriers that interfere with occupational therapy practitioners' use of standardized ADL assessments to enhance best practice during the evaluation process. Appropriate assessment tools for IADLs are more difficult to find. Standardized assessment of IADLs is more challenging because of the variability and complexity of IADL tasks.

One potential limitation to using standardized assessments for IADLs is that many IADL assessments that examine a range of IADL tasks (rather than a single skill, such as cooking) rely on self-report or proxy report; examples are the Extended Activities of Daily Living (Nouri & Lincoln, 1987), COPM (Law et al., 2005), Assessment of Living Skills and Resources (Williams et al., 1991), and some parts of the Kohlman Evaluation of Living Skills (Kohlman Thomson, 1992). The limitations of using reported performance were addressed earlier in this chapter. The development of reliable and valid IADL assessments that enable occupational therapy practitioners to objectively measure observed performance across many IADL tasks would increase their ability to engage in evidence-based evaluation.

assessments. If observational assessments raise additional questions about the client's activity performance abilities, the evaluation plan can be modified to gather more or different data.

Planning an effective ADL and IADL evaluation is best illustrated by a case example, following the steps described above.

Implementing the Evaluation: Gathering Data, Critical Observation, and Hypothesis Generation

Gathering Data and Critical Observation

Once occupational therapists develop an evaluation plan, they must carry it out. The thoughtful and deliberate

---

CASE STUDY: *Evaluation of a Client with Morbid Obesity and Respiratory Failure*

Mrs. Howard is a 59-year-old woman with a history of morbid obesity (she is 5′1″ tall and weighs 376 pounds). She was admitted to a hospital with difficulty breathing secondary to an allergic reaction to an over-the-counter medication. She subsequently went into respiratory arrest and required a tracheostomy and mechanical ventilation. She was weaned from the ventilator six weeks later and placed on supplemental oxygen. She developed a right foot drop, secondary to peroneal nerve compression that occurred during her prolonged bedrest. After two months in acute care, Mrs. Howard was transferred to a rehabilitation hospital, where she participated in occupational therapy (OT) for ADL and IADL training and physical therapy (PT) for mobility training. She was dependent in all areas of ADL and IADL on admission and made considerable gains in function before her discharge home, six months after her initial hospitalization. At discharge, she was ambulating short distances (up to 50 feet) independently with a rolling walker and a brace on the right foot (the brace was attached to her shoe). She had an extra-wide wheelchair for limited community outings (e.g., doctor's appointments), but the chair did not fit in her home. She continued to require supplemental oxygen and was independent in tracheostomy care and suctioning. Mrs. Howard was referred for home-based services, including skilled nursing, nutritional counseling, home health aide (three days a week, two hours each day), PT, and OT.

Occupational Profile

Mrs. Howard lived with her husband of 30+ years. He worked full time but was physically able and willing to assist his wife when he was home. Mr. and Mrs. Howard had two grown children and two school-aged grandchildren who lived in the area. Before hospitalization, Mrs. Howard was independent in ADLs and IADLs. She had primary responsibility for cooking, light housekeeping, and laundry. She worked 20 hours a week at the local public library. Mrs. Howard had several close friends she enjoyed meeting for lunch or shopping, especially bargain hunting at flea markets. She and her husband also frequently attended their grandchildren's sports events in a nearby town. The following considerations were used to select appropriate ADL and IADL assessments for Mrs. Howard:

1. **Identify the overall purpose(s) of the evaluation.** The primary purpose was to plan and monitor OT intervention, so baseline data needed to be effective for determining progress toward goals.
2. **Have clients identify their needs, interests, and perceived difficulties with ADLs and/or IADLs.** Mrs. Howard's primary goal was to regain her independence in ADLs and IADLs and leisure. She identified ADLs and IADLs, including driving, as priorities because she was concerned about being a burden on her husband. She reported that her biggest difficulties were with lower body ADLs (unable to reach) and with all IADLs (fatigue, shortness of breath, limited reach and mobility). She had frequent medical appointments and lived in a rural area, and she hated relying on others for getting to and from appointments.
3. **Further explore the client's relevant activities so that the activities are operationally defined.** The "problem activities" that Mrs. Howard had were briefly discussed for more detail. ADLs were completed in the typical fashion, except for the brace that she wore on the right foot. She reported that sexual activity was not currently a priority but that she would like to address it later, once she had sufficient energy for and independence in ADLs. IADL priorities for Mrs. Howard included the following:
   - Transporting laundry from the bedroom to the kitchen (top-loading washer) and out to the clothesline to dry (no dryer).
   - Cooking complete dinners, including accessing the refrigerator, oven, stovetop, cooking utensils, dishwasher, and sink. A sample dinner would include fish, baked potatoes, steamed green beans, and a salad.
   - Driving and riding in her minivan.
   - Accessing all areas of her one-story home except the basement, (home office for doing finances and using the computer, linen closets, etc.).

Additionally, Mrs. Howard reported adequacy parameters, including the ability to complete ADLs and IADLs in a timely manner and regain the ability

Continued

CASE STUDY: *Evaluation of a Client with Morbid Obesity and Respiratory Failure   Continued*

to sustain activity without fatigue or shortness of breath.

4. **Estimate the client factors that affect occupational performance and/or the assessment process.** Mrs. Howard's primary problems limiting function were caused by her obesity, which limited her reach and ability to move and caused fatigue and dyspnea. Cognition and perception did not appear to be factors that interfered with function on initial review of her rehabilitation records and the initial interview.

5. **Identify contextual features that affect assessment.** Contextual features that supported the evaluation process included the following:
   ◆ The assessment occurred in Mrs. Howard's home, providing the advantage of a natural environment.
   ◆ There was a ramp into the home, providing access to the yard and driveway.
   ◆ Mrs. Howard had years of experience with all of the tasks she wished to return to, which would support performance of tasks.

   Contextual features that were barriers to the evaluation process included the following:
   ◆ Clutter in the home that presented a potential safety issue.
   ◆ Mrs. Howard was on oxygen, with the unit in the bedroom and a very long tube that connected to her nasal cannula, so she had to manage the tubing as she moved around the house.
   ◆ The evaluation occurred during the week, and the therapist was alone with a client whose weight presented a potential safety problem to the therapist, who had no assistance for guarding Mrs. Howard when trying a new task.
   ◆ Mrs. Howard had private insurance, which required that the OT evaluation be completed in one visit.

6. **Consider features of assessment tools.** This step is included in the discussion of step 7.

7. **Integrate the information from steps 1–6 to select the optimal ADL and IADL assessment tools.** The time limit of one visit (approximately 60–75 minutes) had a significant impact on which assessments were selected. The occupational therapist decided to start with the COPM based on the following considerations:
   ◆ The COPM had well-established psychometric properties and assessed both ADLs and IADLs (Law et al., 2005).
   ◆ The COPM relied on self-report; however, Mrs. Howard was cognitively intact and had been learning to live with her disability for the past four

months. One advantage of the self-report format is that it did not pose any safety hazards. For example, the occupational therapist got a baseline performance and satisfaction rating on riding in a car (including getting in and out) without having to attempt the task alone with Mrs. Howard.

◆ Mrs. Howard indicated that she felt stress about burdening her husband. The COPM would help Mrs. Howard and the occupational therapist to prioritize the ADLs and IADLs that would reduce caregiver burden.

◆ The COPM included a satisfaction measure, which reflected some of the adequacy parameters that Mrs. Howard identified (e.g., if she could dress independently but it took her 45 minutes, she would give that a low satisfaction score).

◆ The COPM could be completed in about 20 minutes.

After the COPM, the occupational therapist selected the FIM™ subtests of transfers, lower body dressing, and grooming. Other subtests were not observed because they were activities that Mrs. Howard reported no difficulty with (including feeding, toileting, and upper body dressing) or because of time constraints (e.g., bathing). The FIM™ was identified as an appropriate measure for the following reasons:

◆ Mrs. Howard reported that she required physical assistance for lower body dressing and getting out of bed (on the FIM™, transfers start from supine and end in standing for people who do not use a wheelchair), and the scale was believed to have adequate sensitivity in levels of physical assistance to document progress.

◆ The FIM™ included client appliances in the lower body dressing measure, and Mrs. Howard reported that her brace was one thing she was not able to master while in the rehabilitation center.

◆ The occupational therapist had discharge FIM™ scores from the rehabilitation center, so performance in the clinic could be compared to performance in the home with the same tool to examine the impact of the home context on performance and aid in problem-solving for intervention.

◆ These tasks could be completed in 25 minutes.

Two additional parameter measures were used to supplement the FIM™. Lower body dressing and grooming were timed, which required no additional assessment time. Dyspnea was measured after each of the three subtasks, using a 100-mm visual analogue scale, where 0 = "no shortness of breath," 50 mm = "moderate shortness of breath,"

CASE STUDY: *Evaluation of a Client with Morbid Obesity and Respiratory Failure*   *Continued*

and 100 mm = "severe shortness of breath" (Lansing, Moosavi, & Banzett, 2003). Mrs. Howard was asked to place a mark on the line that best represented her dyspnea. Completion of the dyspnea scales required little additional time, fitting into the 25 minutes allowed for the FIM™.

At this point, Mrs. Howard needed a rest, although the occupational therapist wanted to include some observation of IADLs in the evaluation. While Mrs. Howard took a rest, the therapist used the walker to do an informal accessibility assessment for several key areas in the home, including Mrs. Howard's dresser, closet, personal computer, kitchen appliances, and cabinets. Although standardized assessments are available, the occupational therapist used a nonstandardized approach because Mrs. Howard's walker required additional room for accessibility and the therapist needed to focus on a few key areas, since time was limited. The occupa-

tional therapist could also begin some immediate treatment by making a list of suggestions that would make Mrs. Howard's environment more accessible. The therapist could review the recommendations with Mrs. Howard so that she could enlist a friend or family member in modifying the context, making treatment sessions more effective. The informal assessment of context and review with Mrs. Howard could be completed in 15 minutes.

Finally, the evaluation was concluded with a nonstandardized assessment of a kitchen task. Mrs. Howard made a cup of tea. The kettle was placed in a low cabinet to assess her ability to retrieve it. The tea was in an over-counter cabinet. The therapist gathered descriptive data and also timed the task and used the visual analogue scale to measure dyspnea on completion. The task took less than 10 minutes. After the assessment, Mrs. Howard settled into her favorite chair to enjoy her cup of tea.

---

selection of appropriate assessments, described above, is key in making the actual data gathering run smoothly. A few additional considerations about the actual implementation of the evaluation warrant discussion. The occupational therapy practitioner who is doing an assessment should do the following:

◆ Collect all equipment and supplies needed for carrying out the evaluation plans, making sure test kits are complete and organized and that necessary equipment and supplies are available, including clients' personal items (e.g., clothing from home). Novice practitioners might find it helpful to create a list of needed items to make sure that everything is available and in working order.

◆ Schedule assessment sessions in the best environment available. For example, a client in an inpatient rehabilitation center would find it more comfortable to dress in his or her room than in a curtained-off area in a busy clinic.

◆ Be sensitive to individual needs for modesty, which can vary greatly among clients. Many ADLs are personal tasks that are typically done alone, including dressing, bathing, and toileting. Assessment for potential impairment in sexual activity should be included in ADL assessments but must be handled with sensitivity.

◆ Structure the optimal social context. For example, the practitioner might wish to have family members present during an interview to gain their perspectives about a client's abilities or needs, whereas having several family members observing a performance-based assessment of

cooking might be distracting to the client and interfere with the evaluation process.

◆ Bring appropriate tools to record data. A well-planned evaluation session will reveal a lot of information about a client. Standardized tests often come with forms for recording data. Facilities may also have forms for recording data using assessments typically performed in that setting. The practitioner might also want to jot down relevant observations, for example, noting that a client complained of shoulder pain when putting a shirt on overhead or that a client's grocery list included primarily nonnutritious foods. If possible, practitioners should record directly on facility-based documentation forms to reduce the time needed for completing the evaluation report later on.

During the evaluation, the practitioner should engage in critical observation, which can be framed by questions the practitioners ask themselves throughout the process, such as the following:

◆ What are some of the possible underlying causes of the occupational performance deficits that are being observed or reported? For example, a client who is unable to reach the clothes in his or her closet might may be limited by a variety different factors, including upper extremity weakness, impaired range of motion, poor coordination, diminished standing balance, or a clothes rod that is out of reach for the client's height. Observations that are made as the client tries to get clothes from the closet can provide clues to the underlying causes that
FIGURE 48.1 Observations made during reach: Lateral flexion of the trunk suggests that the client is compensating for an inability to raise the arm, which could be from limited passive range of motion or decreased strength. The height of the closet rod relative to the client's size should require only about 50% of typical shoulder flexion. Balance does not appear to be an issue, as the client appears stable even while shifting his center of gravity toward the left as he reaches.

will aid the occupational therapist in making sound treatment decisions, as shown in Figure 48.1.

◆ What changes might need to be made in the initial evaluation plan on the basis of data from the first assessments? For example, a cooking assessment might reveal mild cognitive deficits that were not apparent during initial interactions with a client, so the occupational therapist would add a cognitive assessment to the evaluation plan.

◆ Are there discrepancies in the evaluation data that were collected? Discrepancies need to be clarified and reconciled and can provide valuable insight into the nature of the client's ADL and IADL limitations. For example, a practitioner might ascertain through performance testing that a client can execute bed-to-wheelchair transfers, yet the client might insist that he cannot. The inconsistency might arise because, although the client

performs the transfer independently with the practitioner present, he feels insecure about his abilities and will not transfer on his own. In this example, the use of different data sources identified a performance discrepancy between skill and habit that would not have been apparent from the use of one source alone.

Hypothesis Generation

The evaluation data that are obtained through questioning, observing, and testing methods must be analyzed, synthesized, and integrated into a cohesive problem statement. This integration of data is accomplished through diagnostic reasoning, which is a component of clinical reasoning (Rogers, 1983; Rogers & Holm, 1991). The clinical reasoning of practitioners occurs as a kind of internal dialogue about the interpretation of the data. Evidence supporting one interpretation is weighed against evidence rejecting that interpretation, and the interpretation that has the most supporting or compelling evidence is selected. If the evidence fails to sufficiently support one interpretation over another, more evaluative data are collected to supplement the reasoning process. This process is best illustrated through an example, based on the cases presented in Table 48.1. Melinda and David had the same dressing scores on the FIM™, a quantitative ADL assessment, but the occupational therapist's clinical interpretation of the descriptive data will lead to very different assumptions about the problems that are causing dressing impairments for the two children. Before reading on, take a minute to reflect on the different observations reported in Table 48.1, and consider the following:

◆ What are the underlying factors that interfere with Melinda's ability to dress independently? What are Melinda's strengths, that is, what skills support her dressing performance? What observed behaviors led to your conclusions about Melinda's strengths and limitations?

◆ What are the underlying factors that interfere with David's ability to dress independently? What are David's strengths, that is, what skills support his dressing performance? What observed behaviors led to your conclusions about David's strengths and limitations?

For Melinda, limited attention, impaired awareness of occupational performance deficits, and inconsistent response to feedback seemed to be underlying problems that limited her ability to dress independently. This is a hypothesis or clinical judgment rather than an objective observation, because constructs such as attention and awareness of deficits cannot be directly observed and must be inferred from specific behaviors. At the same time, Melinda's physical capabilities seemed to be an asset and supported performance in many ways. Compare the observations and clinical judgments made by the occupational therapist about Melinda to those made about David. In both cases, the children required verbal cueing and occasional

physical assistance; however, descriptive data led the occupational therapist to a very different hypothesis about David's dressing limitations. The underlying problems for David were physical impairments, for example, diminished sitting balance, incoordination of the right upper extremity, and decreased endurance. Behaviors that supported performance included attention to task, follow-through with feedback, the ability to recall adaptive strategies, and engagement in active problem solving. Generating hypotheses about the nature of the occupational performance deficit is crucial for selecting effective intervention, which must address the underlying problem. For example, adaptive equipment could be provided to help David reach his feet independently or to compensate for poor right hand coordination during buttoning; however, this equipment would be of no help to Melinda and would likely impede performance by distracting her from the task.

Through this process, the practitioner arrives at a cohesive understanding of the ADL and IADL performance of the client, factors that are interfering with performance, and appropriate therapeutic actions given the nature of the client's deficits. This understanding is presented to clients or their proxies for verification and collaborative decision making concerning the therapeutic action to be implemented.

ESTABLISHING CLIENTS' GOALS: THE BRIDGE BETWEEN EVALUATION AND INTERVENTION

The OTPF includes the establishment of clients' goals as the final step in the evaluation process and as the first component of the intervention plan (AOTA, 2002), so this important step really serves as a transition from evaluation to intervention. Synthesizing evaluation results into a meaningful, individualized intervention plan is a complex cognitive task and can be overwhelming for the student or new occupational therapy practitioner. The process of planning and implementing interventions is much easier for practitioners who have reasonable, attainable, and measurable goals. The following section is focused on the multiple factors that influence outcomes to help guide novice practitioners in the clinical reasoning for establishing effective client goals and to structure the problem-solving process for more experienced practitioners, especially when they are managing particularly complex or challenging clients.

Establishing goals requires analysis of the evaluation results in conjunction with additional factors that influence outcome, namely, the client's ability to learn, the client's prognosis, the time allocated for intervention, the client's discharge disposition, and the client's ability to follow through with new routines or techniques. The next section focuses on using performance parameters to

establish meaningful goals for clients that have a clearly identified behavior and an appropriate degree of performance, that is, a characteristic of the behavior that is measurable (e.g., "independently" or "without pain") (Sames, 2005). Goal behaviors may be aimed at underlying skills, for example, increasing strength or range of motion to support participation in ADLs. However, examples in this chapter will focus on establishing goals with occupational performance behaviors, such as bathing or doing laundry.

Identifying Appropriate Goal Behaviors

A comprehensive evaluation examines ADL and IADL performance across relevant performance parameters, described earlier in this chapter and in Chapter 46. Three of these performance parameters—value, level of difficulty, and fatigue and dyspnea—can be used to establish goals for intervention that target appropriate client behaviors.

Value

Occupational therapists should select goal behaviors, that is, ADL and IADL tasks, that reflect the values that the client defined during the evaluation. The value that clients place on given activities influences their motivation for participation in any intervention aimed at improving performance for that activity. Because many occupational therapy interventions require the acquisition of new skills through practice, motivation can greatly influence the ultimate functional outcome. Clients who put little value on the activity that is being addressed during an intervention might appear to be uncooperative in treatment and are unlikely to follow through with programs outside of direct treatment that are necessary for improving skill in that activities.

ADLs and IADLs are often highly valued by both children and adults because of the dependency on others that accompanies role dysfunction (Robinson-Smith, Johnston, & Allen, 2000). However, occupational therapy practitioners should be careful not to assume that ADLs and IADLs are immediate priorities. Some people, especially those with severe activity limitations, might need or want to accept assistance from others in ADLs so that they can conserve energy to perform other activities. This was the case with Mr. Fritz, a 32-year-old with a recently sustained spinal cord injury that resulted in C6 quadriplegia. He was married, had three small children, and was self-employed as a tax accountant. His wife worked part-time as a nurse and took care of their children before and after school. The family depended on Mr. Fritz's income, and he had no disability insurance coverage. Although outcomes in ADLs were initially established for Mr. Fritz, it soon became apparent that attempts at self-care retraining were being met with resistance and frustration. Further discussion of the targeted intervention outcomes revealed that Mr. Fritz was anxious to return to work and that he could do this if

he could use the computer in his home office. Although he expressed an interest in becoming independent in self-care, he felt that the best option for him was to return to work as quickly as possible to minimize the financial burden on his family from his current inability to work. His wife was able and willing to help him with self-care tasks at home. The couple felt that self-care retraining could be delayed until the family business was again operational. With intervention outcomes refocused on activities most valued by Mr. Fritz—namely, computer access and home mobility— he became highly motivated to participate in therapy.

Clients' values should drive long-term goals, but occupational therapy practitioners may help clients focus on ADLs initially when they establish priorities in more complex occupational performance areas (e.g., IADLs, work, or leisure) that make the intervention process inefficient and potentially ineffective (Cipriani et al., 2000). Self-care training often helps clients to develop capacities and problem-solving skills that can later be applied to activities that are more complex than self-care, particularly when dealing with severe disorders of sudden onset (e.g., stroke, traumatic injury). For example, suppose Mr. Fritz could not work from a home office and wanted to focus on driving in order to get to work, which is a realistic ultimate goal for someone with C6 quadriplegia. Initiating intervention with driver training, however, would be impractical because Mr. Fritz lacked the prerequisite functional mobility skills early in his rehabilitation. ADL training—involving bathing, dressing, transferring, and wheelchair mobility—can facilitate the development of functional mobility skills. Such training, therefore, would logically precede driver training. In this situation, Mr. Fritz's needs could be met by referring him to social services for assistance with financial planning to help the family manage until he could return to work. The occupational therapy practitioner should also educate Mr. Fritz about the commonalities among skills needed for both self-care and driving. This plan recognizes Mr. Fritz's valued roles and progresses him to the desired outcome in the most efficient way possible.

When the most valued activities and roles are beyond the client's potential skill level, the occupational therapy practitioner helps the client to refocus priorities so that goals are realistic and achievable. If Mr. Fritz were the owner and cook of a small restaurant, for example, it is unlikely that he would meet the essential job requirements of a short-order cook even if the kitchen were adapted for wheelchair accessibility, because the activities require bilateral hand function and must be done quickly. It is possible, however, that he could perform the activities of restaurant owner. For example, he could manage personnel, handle the finances, operate the cash register, and seat customers. In this and similar situations, occupational therapy practitioners assist clients in establishing goals that reflect realistic behaviors by using their expertise in activity analysis and functional adaptation (Liddle & McKenna, 2000).

Difficulty

The perceived ease with which a client completes an activity and the projected difficulty that will remain after intervention are important considerations in selecting goal behaviors (Thornsson & Grimby, 2001). The occupational therapy practitioner, who is skilled in activity analysis and has knowledge of pathology and impairment, must determine the prognosis for functional difficulty. This prognosis must then be communicated to clients so that decisions about acceptable levels of difficulty can be made collaboratively. Clients set intervention priorities, in part, by weighing the projected level of difficulty within the context of value—that is, how much difficulty they are willing to tolerate to be independent in an activity. The frequency with which an activity is performed should also be considered in establishing goals for ADLs and IADLs that are likely to remain difficult for a client to perform. In general, a higher level of proficiency or ease of performance is needed for activities that need to be done routinely, whereas a lower level of proficiency or ease of performance may be acceptable for activities that are done only occasionally.

For example, James is a seven-year-old boy with spina bifida, which damaged his spinal cord at T4. He has a neurogenic bladder and requires routine intermittent catheterization. He identified self-catheterization as a critical task for fulfilling his roles as self-carer and student, because he would prefer not to have help with this personal task from family or school personnel. James will need to be able to self-catheterize independently and efficiently for this task to fit into his school day. The occupational therapist believes that James will be capable of achieving independence with little difficulty after a period of practice. The goal is agreed upon, and treatment begins. Another client, Amy, also has spina bifida, which resulted in incomplete spinal cord damage at C7. She can typically get adequate emptying of her bladder without self-catheterization. On rare occasions, however, she has episodes of urinary retention, requiring catheterization within about one hour of experiencing symptoms. Amy would also like to be independent so that when she must be catheterized at school, she does not need help. The occupational therapist thinks that independent self-catheterization using safe and clean technique is a reasonable goal for Amy, but it will always be difficult because she has impaired hand function and positioning herself so that she can see and reach to insert the catheter is challenging. Amy will need to go to the nurse's office to transfer to a bed. Despite the difficulty, Amy opts to work on this goal. Because she has to catheterize herself so infrequently, she believes that her skill level will be adequate for meeting her needs.

Fatigue and Dyspnea

Fatigue, the sensation of tiredness that is experienced during or following an activity, and dyspnea, difficult or

labored breathing, can interfere with activity performance (Fuchs-Climent et al., 2001; Liao & Ferrell, 2000; Vanage, Gilbertson, & Mathiowetz, 2003). Both fatigue and dyspnea are likely to be exacerbated by activity performance. The occupational therapist uses activity analysis to take into account the effort that is required to perform a task and its typical duration. In addition, the client's entire daily routine must be examined so that the energy demands of one activity can be weighed in relation to the client's other activities (Mathiowetz, Matuska, & Murphy, 2001). Assisting clients to examine the physical demands of their preferred activities can help them to prioritize activities so that appropriate goals can be established. Similar to budgeting money, clients must be encouraged to look at their "energy dollars" and decide how they wish to spend them. The occupational therapy practitioner contributes to this decision-making process by bringing valuable information about options for activity adaptation that can reduce the energy demands of activities, thereby saving clients' energy for other tasks.

For example, Mrs. Hernandez lived alone in an apartment in a retirement community. Her sister and brother-in-law also resided in the community, and she had many close friends there. She has had multiple sclerosis for many years, with some weakness and spasticity, but she remained independent in her ADLs until a recent exacerbation, which required hospitalization. An increase in fatigue and decrease in strength resulted in the need for physical assistance with ADLs and the use of a wheelchair for mobility. The retirement community required residents to manage their own ADLs and prepare breakfast and a light evening snack. A hot meal was provided at midday. Mrs. Hernandez reported that she could not afford to hire an aide to help her daily with these tasks. The occupational therapy practitioner explained to Mrs. Hernandez that although independence in ADLs and simple meal preparation were reasonable goals, completing her ADL would likely be time-consuming and fatiguing, leaving her little energy for other activities. Mrs. Hernandez was enthusiastic about beginning therapy, indicating that she was willing to engage in fewer IADLs and leisure activities in order to be independent in ADLs and simple meal preparation because it would enable her to remain in the retirement community with family and friends.

A different scenario played out with Mrs. McKay, who also had multiple sclerosis. Like Mrs. Hernandez, she had a recent exacerbation that caused a functional decline, and achieving independence in ADLs was likely to expend much of her daily energy. Mrs. McKay had been working full-time as a programmer for a local radio station and was the mother of two young children. She perceived her role as a self-carer to be important, along with those of worker and mother. However, when it became apparent that independence in ADLs would leave her with little energy for performing work and parenting roles, she decided not to establish goals for independence in ADLs, opting instead to hire a personal care attendant for assistance so she could focus on work and parenting goals.

Identifying Appropriate Goal Levels

Treatment goals must include a measurable outcome that indicates how well or at what level the identified behavior will be done, sometimes referred to as the *degree of performance* (Kettenbach, 2004). Independence is the most common degree of performance; however, several performance parameters can also provide effective goals, especially when the client is independent but occupational performance deficits remain that warrant treatment. For example, this would be the case when a client can open jars independently, but it is painful and results in deforming forces to the hand joints.

Independence

The performance parameter that is most commonly focused on in occupational therapy interventions is independence in activity performance, which becomes the degree or measurable part of the goal (Sames, 2005). Across all ages and disabilities, the goal is generally to increase the level of independence (Croser, Garrett, Seeger, & Davies, 2001; Ford et al., 2000; Healy & Rigby, 1999; Nyland et al., 2000). Independence in activity performance may be divided into three phases: initiation of a task, continuation of a task, and completion of a task. The most common occupational therapy goals focus on the completion of the task, which implies that initiation and continuation of the task occurred; for example, a goal might be *"Client will be independent in feeding her cats by December 12, 2007"* or *"Client will require moderate assistance for bed to/from wheelchair transfers in one week."* Occupational therapy practitioners might also want to focus an independence goal on initiation of task performance when that is particularly difficult for a client.

Initiation is an aspect of activity performance that is frequently overlooked when goals are established, in part because it is difficult to evaluate and treat. The very presence of the occupational therapy practitioner may be a cue to initiate a task, and certainly a greeting, such as "Good morning, Mrs. Smith, today we will work on dressing," serves as a prompt for action. Adults are typically expected to initiate ADLs and IADLs independently. Expectations for children also exist, depending on the children's ages and skills and the division of task responsibilities among family members. Impairments in activity initiation may occur as a result of many diseases and disorders, such as attention deficit disorder, dementia, depression, schizophrenia, brain injury from trauma or stroke, multiple sclerosis, and Parkinson's disease. Family members generally find it frustrating to have to cue ("constantly nag") a client who has an initiation impairment for each aspect of a daily routine. The occupational therapist may

write an independence goal that includes initiation, such as *"Client will initiate and complete bathing independently three to seven times a week by November 30, 2007."* In this example, measuring progress toward the goal would require the client or a proxy to record the number of times in a week that the client initiated bathing without cueing or assistance from another person.

Safety

Safety is a quality of the person–task–environment transaction, so it cannot be observed or treated in isolation from independence (Letts, Scott, Burtney, Marshall, & McKean, 1998; Russell, Fitzgerald, Williamson, Manor, & Whybrow, 2002). Goals related to safety are typically linked to independence outcomes; that is, independent performance is assumed to be safe, since an occupational therapist could not ethically create a goal for independent performance that was not deemed to be safe. Although occupational therapy practitioners agree that safety is an intervention priority, there is less consensus about specific activity behaviors that are safe or unsafe. Many behaviors fall into a questionable zone, where some would rate them as safe while others perceive them as unsafe. In determining acceptable risk for setting independence goals, it is useful to consider clients' comfort level with risk, their ability to analyze the risks associated with a particular activity and devise a plan for managing them, and, most important, their ability to implement the plan expeditiously despite impairments. At times, the goal for level of independence in activity performance might need to be sacrificed for safety. A comparison of two clients with bilateral lower extremity fractures sustained in car accidents who are learning independent transfers illustrates this point.

Ted and Ryan were both recently injured, are non-weight-bearing on both lower extremities, and are learning sliding board transfers. Ted demonstrates good judgment and a realistic perception of his skills. The occupational therapist has determined that the following goal is realistic: *"Client will be independent in sliding board transfers from wheelchair to/from bed within three therapy sessions."* Through training, Ted learns to transfer safely with a sliding board by following specific guidelines (e.g., position wheelchair at a 45-degree angle to the bed; secure brakes on wheelchair; ascertain that bed height is level with the wheelchair). After a couple of sessions, he is able to follow these guidelines consistently; therefore, his goal of independence in transferring wheelchair to and from bed is met. Ryan's injuries are similar to Ted's, but he also incurred a mild brain injury. Although Ryan's motor skills are comparable to Ted's, Ryan has difficulty recalling the guidelines for transfers and is at risk for bearing weight on his lower extremities during transfers, which could interfere with fracture healing. Therefore, the occupational therapist believes that independent transfers could be unsafe because Ryan's memory deficits place him at risk for violat-

ing weight-bearing precautions. The occupational therapist incorporates safety considerations by setting a goal for Ryan that is aimed at a lower level of independence, for example, *"Client will require supervision and occasional verbal cues for sliding board transfers from wheelchair to/from bed while adhering to weight-bearing precautions within six therapy sessions."* The degree of independence in Ryan's goal was adjusted to realistically reflect his capacity for safe transfer performance.

In some situations, it may be better to establish client goals in which the goal behavior is directly related to safety rather than being assumed in the degree of independence indicated. Goals can be aimed at the occupational performance level, that is, the IADL "safety procedures and emergency responses" (AOTA, 2002); for example, the goal might be *"Client will verbally describe correct responses to a minimum of 10 potential home emergencies with 100% accuracy within three weeks."* Safety goals may also be aimed at developing safe habits, for example, *"Client will pause when entering a room and scan for obstacles on the floor 100% of the time to reduce fall risk during functional mobility by December 1, 2007."* or *"Client will report 100% compliance with condom use to reduce the risk of sexually transmitted diseases within three weeks."*

Adequacy

Several aspects of activity performance contribute to the adequacy or quality of the behavior stated in the goal, which can also be reflected in the goal as the degree to which the behavior is expected to be done. In addition to independence, these performance parameters may be crucial components of meaningful goals, especially for clients who are independent and safe with their performance but who feel dissatisfied with the process or some other aspect of the outcome. Goals with measurable adequacy parameters can be used to justify treatment even if clients are independent in tasks. Six adequacy parameters can be used as measurable outcomes: pain, fatigue and dyspnea, duration, societal standards, satisfaction, and aberrant task behaviors. Some of these parameters may be interdependent within a single client. For instance, pain might lead to changes in duration of activity performance (e.g., the activity takes longer) as well as the ability to meet normative standards and personal satisfaction. A goal should include only one measurable parameter so that it is clear what has changed in documenting progress toward goals.

PAIN.   Pain, either during or following an activity, can negatively influence engagement in ADLs or IADLs even if the activity is completed independently (Birkholtz & Blair, 2001a, 2001b; Dudgeon, Tyler, Rhodes, & Jensen, 2006; Mullersdorf, 2000). The source of pain and the prognosis for it must be carefully considered in establishing goals and selecting an intervention approach. Both the evaluation and the goals must include an index of pain so that inter-

vention remains focused on achieving the projected level of independence while simultaneously reducing the presence of pain. Often, the pain assessment can be incorporated into the goal as an indicator of the degree of pain; for example, the goal might be *"Client will prepare a simple meal (soup, sandwich, and beverage) independently with a maximum pain level of 2 cm on a 10-cm visual analogue scale within 2 weeks."*

FATIGUE AND DYSPNEA. Fatigue and dyspnea can influence the actual task behaviors that are selected for client goals, as was described earlier in this section, but when fatigue or dyspnea can be reduced through task adaptation or conditioning, goals can be established that use these performance parameters as performance outcomes. The initial evaluation should include baseline data for comparison. For example, a goal might be *"Client will complete morning care routine (shower, grooming, dressing) with a maximum score of 6 on the Borg Reported Perceived Exertion Scale* (Borg, 1998) *by November 28, 2007."* As long as the Borg Scale was used during the initial evaluation, a lower number (meaning less exertion) can be used in a goal to indicate progress toward becoming less fatigued during ADL or IADL tasks. Dyspnea can be monitored in a similar way, using a visual analogue scale or numerical rating scale (Gift & Narsavage, 1998). Diagnosis is important to consider when goals are formulated relative to fatigue and dyspnea. Overexertion can exacerbate symptoms or even the disease process itself for conditions such as cardiac disease and multiple sclerosis. Prognosis is another important diagnostic consideration in setting goals that measure fatigue or dyspnea. Clients with chronic obstructive pulmonary disease are likely to become worse; therefore, goals must be reasonable to achieve through activity adaptations and might need to accommodate a decline in function. A client with paraplegia secondary to spinal cord injury, by contrast, experiences fatigue from having to use the smaller muscles of the upper extremity for wheelchair mobility to compensate for the larger lower extremity muscles previously used for walking. Endurance is likely to improve significantly as upper extremity strength increases with use, and more ambitious goals for reducing fatigue could be appropriate.

DURATION. The length of time that is required to complete activities is typically thought of as a reflection of efficiency, which may be affected by many different impairments, including poor endurance, impaired coordination, and cognitive deficits such as difficulty sustaining attention for tasks, which is common in people with a variety of mental health disorders. Although measuring performance time may be relatively simple, interpreting time data in a meaningful way is often difficult. The duration of daily living activities depends highly on the nature of the activity and the task objects that people choose to use in performing the activity. It takes longer to prepare dinner than it does to fix a light snack. Most of us spend more time dressing when we are going out to dine in an elegant restaurant than we do we when are going to a fast-food establishment. Therefore, it is difficult to establish meaningful norms for ADLs and IADLs, but duration is often a parameter that clients wish to incorporate into their occupational therapy goals when they are frustrated by slow performance.

Establishing acceptable time frames for ADL goals must be done collaboratively with clients and their significant others. Occupational therapists should consider safety and independence parameters simultaneously. Clients may be at increased risk when they rush through activities or even when they attempt them at a typical pace. For example, clients with swallowing deficits might need to eat more slowly than people without such deficits to avoid choking. People with poor fine motor coordination or sensory deficits might need to slow down when using sharp knives to improve control of the knives and prevent injury. In these examples, setting goals to decrease the duration of performance would be inappropriate because it could result in unsafe performance.

Societal and cultural standards also need to be taken into consideration in establishing outcomes for activity duration. In the United States, timeliness is highly valued, and efficient performance in community skills is expected. Shoppers might become irritated when they are standing in a checkout line behind a customer who takes five minutes to identify and count currency, though in other cultures, this delay might go unnoticed. An American with cognitive or visual impairments that interfere with the ability to count currency might wish to decrease the time required for this activity to reduce embarrassment when shopping. The goal, then, needs to include an efficiency measure to reflect this performance parameter, for example, *"Client will independently complete a simple cash transaction (select appropriate currency and count change) in less than one minute within three weeks to support participation in shopping."*

SOCIETAL STANDARDS. Performance standards, determined by the society and culture in which the client lives, are likely to exist in terms of both the end result and the process through which it is achieved. As is discussed in Chapter 46, the line between acceptable and unacceptable performance is likely to be thick rather than narrow and may vary considerably, depending on characteristics such as age, gender, and cohort (generation) membership.

Societal standards exist, for example, for neatness. A client might dress safely and independently, but if the colors of clothing clash or the client's appearance is disheveled (the end product), this client's dressing might not meet societal standards. If the client is a teenager, such an appearance might be considered acceptable. However, if the client is a public relations manager going to work, it is likely to be labeled unacceptable and could well put the client's job in jeopardy. Occupational therapists and clients

may identify relevant societal standards for inclusion in goals. Identifying societal standards might seem subjective and difficult, but the use of measurable indicators of societal standards is critical for effective goals and can justify intervention. A goal for a client who eats rapidly, putting food in his mouth when it is still full, might include a measure of societal standard, such as *"When eating during a social event, the client will demonstrate appropriate pacing as evidenced by completing a meal in no less than 15 minutes, swallowing each bite before putting additional food in his mouth, and conversing between bites of food by December 10, 2007."*

SATISFACTION.   In addition to societal standards, clients have their own standards of acceptable performance, which also need to be incorporated into goals (Natterlund & Ahlstrom, 1999). Setting goals with satisfaction measures requires collaboration with clients, as personal standards will vary greatly from person to person. Mr. Balouris, for example, is always losing things. He never seems to know where his wallet and keys are, and he is always searching for something. Nonetheless, items seem to turn up, and he sees no reason to go to the trouble of organizing his apartment better to help him keep track of his belongings. Mr. Johns, however, has always been meticulously neat and could put his hands on items the minute he wanted them. Recently, he sought medical attention for memory problems. He complained that he needed to search for items because he failed to put them in their usual places. He was particularly concerned about his memory problem because of a family history of Alzheimer's disease. He was referred to occupational therapy to learn strategies to help him remember where items are placed. Objectively, Mr. Johns is not performing any worse than Mr. Balouris; however, Mr. Johns interprets his performance as impaired; furthermore, he is dissatisfied with his performance.

Clients must rate their own level of satisfaction with a task, since it is a subjective experience. Client satisfaction can be measured quickly and easily with a visual analogue scale or numerical scale, such as the ten-point scale that is used in the COPM (Law et al., 2005). Satisfaction measures are easily incorporated into goals to reflect the degree of performance, for example, *"Client will be independent in locating items needed for ADLs and IADLs in the home with a satisfaction rating of at least 8/10 within 3 weeks to support participation in ADLs and IADLs."*

ABERRANT TASK BEHAVIORS.   Goals and interventions may also address any aberrant task behaviors that interfere with activity performance (Ashley et al., 2001; Rogers et al., 2000). Aberrant task behaviors vary widely and include unwanted motor behavior, such as athetoid or ballistic movements, and behavioral problems, such as self-stimulation or hitting caregivers. Exploration of the underlying cause of the aberrant task behavior facilitates the establishment of realistic goals and the selection of

effective intervention strategies. Goals are aimed at eliminating or diminishing aberrant task behavior in the context of ADL and IADL tasks, for example, *"Client will decrease tongue-thrusting behaviors during feeding to a maximum of 3 episodes a meal within two months to support oral feeding that meets the client's nutritional needs."*

Additional Considerations for Setting Realistic Client Goals

The occupational therapist uses performance parameters to identify goal behaviors and degrees of performance, but a number of additional factors that can affect goal achievement must also be considered. Most of these are contextual, such as physical and social environment, financial resources, time available for intervention, and the client's past experience and learning ability. The prognosis for impairments, given the client's disability, can also affect goal achievement.

Prognosis for Impairments

The client's potential for improvement of performance skills and patterns and client factors must be examined within the context of any existing disease or disorder and resulting impairments (Hansen & Atchison, 1999; Ostchega, Harris, Hirsch, Parsons, & Kington, 2000). First, the practitioner must consider any precautions or contraindications pursuant to the diagnosis that could preclude the use of certain intervention strategies. Compare, for example, two clients whose endurance significantly limits their performance. Mrs. Tanaka has chronic fatigue syndrome, a disorder that may worsen if she becomes overfatigued. An aggressive program to increase endurance is contraindicated for her, so alternative intervention strategies should be explored, and goals for increasing endurance for ADLs must be reasonable, given Mrs. Tanaka's potential for exacerbation of her disease. Conversely, Mr. Krull is very deconditioned from inactivity resulting from major depressive illness and would like to increase his endurance to support participation in heavy home maintenance tasks, such as mowing the lawn and finishing an addition on his house. An activity program to increase endurance is not contraindicated and would help to increase Mr. Krull's participation in IADLs.

Second, the prognosis for improvement of impairments, given the client's diagnosis (i.e., disease, disorder, or condition), must be considered. Increasing impairment is expected in progressive disorders, such as muscular dystrophy, Alzheimer's disease, and rheumatoid arthritis (both adult and juvenile). Goals must be established with these potential declines in mind so that the goals are realistic. Occupational therapy practitioners must evaluate impairments separately, however, because progressive diseases might not affect all bodily structures and functions directly. Jorge, a teenager who has muscular dystrophy, illustrates

this point. He has significant muscle weakness in the trunk and all four extremities and has developed some limitations in pelvic and ankle range of motion (ROM) that preclude maintaining an optimal position for functioning from his wheelchair. His muscle strength is expected to decline, even with intervention. His ROM restrictions, however, are secondary to the muscle weakness, not a direct result of the muscular dystrophy. Intervention gains can be expected in ROM with treatment, despite the overall prognosis. In turn, increased ROM can enhance function by increasing the options available for positioning Jorge in his wheelchair.

Stable or diminishing impairments may be anticipated in many disorders and after injury. Pharmacological intervention, for example, may improve the impairments associated with depression so that occupational therapy intervention can be focused on transferring gains made in mental and psychological capacities into ADL and IADL performance. Typically, clients of all ages who have had brain injuries from trauma or strokes can expect some spontaneous return of motor function in the early stages of recovery. Projected intervention goals should take into account the typical improvements for this diagnosis. Accuracy in predicting "typical improvements" takes time and experience to develop, and the novice practitioner might find it helpful to consult with more experienced clinicians to facilitate the ability to set realistic goals.

Experience

Information gathered in the evaluation about a client's past and recent experience with an activity is important to consider so that relevant and attainable goals can be established. Recent experience may facilitate progress in reestablishing independence in an activity because the client is learning a new way to do the activity rather than developing a new skill. For example, Mrs. McCarthy needs to relearn cooking skills following a stroke. She uses a wheelchair for mobility and has minimal use of her right (dominant) hand. Her cognitive skills are intact, and she can easily follow a recipe. Furthermore, she demonstrates good problem-solving skills in adapting cooking activities to improve her performance. Miranda, a 19-year-old with spastic hemiplegia secondary to cerebral palsy, has limited use of one hand and uses a wheelchair for mobility, like Mrs. McCarthy. She wants to cook simple meals and bake cookies. Her intervention is likely to require more time and guidance than Mrs. McCarthy's intervention, because Miranda has to learn basic cooking skills along with the activity adaptations that are required to compensate for her impairments.

At times, adults are also confronted with needing to learn new activities. Some of these activities relate to skills that are needed to manage new impairments, such as performing self-catheterization, donning pressure garments, or learning to operate an environmental control unit. New learning may also be needed when new roles are assumed,

for example, when a spouse becomes disabled or dies and the partner has to take on new responsibilities. Whenever a skill is unfamiliar to a client, additional intervention time and education from the occupational therapy practitioner might be needed for basic skill acquisition and should be incorporated into the goal and the intervention plan.

Client's Capacity for Learning and Openness to Alternative Methods

The client's capacity for learning and openness to using alternative methods for task completion must be evaluated, because intervention often requires learning new methods of completing activities (Flinn & Radomski, 2008; Fuhrer & Keith, 1998). Fewer intervention options exist for clients with limited learning capacity, and the duration of the intervention might need to be longer. Some clients who do not want to use a special device to do a task that most people do without a device might resist treatment that incorporates adaptive equipment (Lund & Nygård, 2003). Clients with a good capacity for learning and openness to alternative methods often are able to address more task deficits because of increased intervention options and the reduced time required for learning. It is important to view capacity for learning on a continuum; clients can fall between the extremes, and capacity might be better for some tasks than for others. A client might be capable of learning the relatively simple task adaptation of using a joystick to drive a wheelchair but be unable to master a more complex electronic aid to daily living, even one that relies on the same movements that are used to control the joystick.

Projected Follow-Through with Program Outside of Treatment

Efforts to contain health care costs have led to increasingly shorter lengths of stay in hospitals and rehabilitation centers and a reduction in outpatient and home-health visits. Clients are expected to take a more active role in their therapy programs and to supplement formal interventions with self-directed intervention (e.g., home programs). Goals therefore need to be established with some estimate of the client's capacity to follow through with a self-directed program, as this will greatly influence the success of any intervention (Cope & Sundance, 1995).

Several of the performance parameters that were previously delineated can give the occupational therapy practitioner guidance in this area. Clients have more motivation for programs that are aimed at activities that they highly value than at those that they do not value, making a client-centered approach critical for success. In addition, performance parameters such as difficulty, fatigue, pain, and satisfaction must be graded so that self-directed programs are manageable within the context of the client's daily routines. The meaning of *manageable* must be established by clients in consultation with the occupational therapy practitioner and should take into consideration clients' daily

activities and responsibilities, tolerance for frustration, and perseverance.

Many clients require some assistance to practice activities, and the occupational therapy practitioner must be sure that these resources are available. This assistance may include setting up an activity, providing assistance for specific activity steps, and allowing ample time (as prescribed) for effective practice. It is important to remember that impairments can affect the client's ability to initiate or persevere with everyday activities. For these clients, assistance is needed for initiation and follow-through in the home program. This responsibility often falls on family members, and occupational therapy practitioners need to interact with and educate family members about their critical role.

Time for Intervention

The projected timeline for occupational therapy may be influenced by multiple factors, including the functional prognosis, the client's motivation for improvement, and the client's finances. In managed health care, it is becoming common for health insurance carriers to set the number of visits or length of stay (Kramer et al., 2000). The occupational therapy goals must be tailored to meet the client's needs as much as possible within the time allotted. Nonetheless, it must also be recognized that best practice takes into account *all* the client's needs. Often, with clear and complete documentation of adequate progress toward established goals, third-party payers will approve additional occupational therapy visits. Occupational therapy practitioners need to be aware of their professional responsibility to clients to request intervention extensions and to support these requests through detailed documentation.

Resources and the Expected Discharge Context

Established functional goals must be achievable within the client's available resources, including social and financial resources (Seigley, 1998). Clients' expected discharge environments must be considered in establishing goals and selecting interventions that will be relevant to the environment in which clients will ultimately perform tasks (Cox, 1996; Dunn, 1993; Dunn, Brown, & McGuigan, 1994; Law et al., 1996). The social context is critical for clients who require assistance from others after discharge; that is, it is important to determine whether there are people who are willing and able to provide needed assistance. Clients' needs vary broadly in terms of the type and dura-

ETHICAL DILEMMA

Can Client-Centered Care Conflict with the Needs of an Organization?

Jessica is an occupational therapist working in a subacute rehabilitation unit in a skilled nursing facility. She completed an evaluation on Mrs. Cabrini, an 82-year-old woman with multiple medical problems, including a recent total hip replacement secondary to a fracture, cardiovascular disease, and rheumatoid arthritis. Mrs. Cabrini would like to be independent in transfers, indoor mobility, and toileting, which would enable her to return to her home in an assisted living facility. She reported that she could get daily help with dressing and bathing and would prefer to do that because she fatigues quickly and wants to save her energy for the daily morning craft group. During the evaluation, Mrs. Cabrini tolerated about 30 minutes of therapy in the morning and 30 minutes in the afternoon, divided between occupational therapy and physical therapy. Jessica established client-centered goals collaboratively with Mrs. Cabrini. The physical therapist agreed that the client could work productively for only two 30-minute treatments a day, and they opted to split the time, so Jessica documented that the intensity of occupational therapy would be 30 minutes daily, seven days a week.

Jessica's supervisor approached Jessica and asked her to increase Mrs. Cabrini to 45 minutes a day so that Mrs. Cabrini would qualify for a higher Resource Utilization Group (RUG) under the Medicare prospective payment system. The supervisor told Jessica that if the facility cannot increase reimbursement rates by having more clients in higher RUGs, they might need to lay off staff, which would have a negative impact on client care. Jessica's supervisor also suggested that it would be easy to justify the increased treatment if Jessica added more ADL goals, such as independence in dressing and bathing, to Mrs. Cabrini's care plan.

1. What should Jessica do in this situation?
2. How might client-centered care influence Jessica's actions?
3. How can Jessica balance the needs and wishes of her client with the needs of the facility?

tion of assistance required. Some clients need only supportive services, such as help with shopping or housecleaning. Those with significant activity limitations and intact cognition might require considerable physical assistance but can be left alone once ADLs have been completed, they have eaten, and they are mobile in their wheelchairs. Clients with cognitive impairments do not always need physical assistance but might need verbal cueing to maintain activity performance, and this assistance might need to be constant. Inadequate support in the client's expected environment can necessitate a change in the discharge plan. Some families or friends might be able to provide the level and type of assistance needed, whereas other families might be unable or unwilling to do this.

The physical environment must also be considered in setting realistic goals (Gitlin, Corcoran, Winter, Boyce, & Hauck, 2001). For example, Mr. Feng has reached his goal of independence in bathing during his hospital-based rehabilitation. He requires a transfer tub seat, a hand-held shower hose, and a grab bar to bathe safely without help. The occupational therapy practitioner wants to order this equipment for him. However, Mr. Feng reports that he must shower in a 4 by 4 foot shower stall because the only bathtub is on the second floor and he cannot manage stairs. His shower will not accommodate the transfer tub bench that he requires for safe transfers and balance during showering. An alternative bathing goal should have been established at the beginning of intervention so that Mr. Feng's program focused on developing skills he could use at home, such as sponge bathing at the sink.

The adaptability of the discharge environment must also be explored before setting goals. A house that is high above the street on a small lot with 21 steps to the front door makes the installation of a properly graded ramp impossible. Wall grab bars cannot be installed on fiberglass tub surrounds, making a safety rail placed on the side of the bathtub the only feasible option, regardless of where the client really needs the most support. Clients living in rental units might be unable to make structural alterations as desired because they do not own the unit.

Last, the client's expected discharge environments must be explored if activities are likely to be performed in more than one place. Clients in a hospital-based setting may be focused primarily on returning home, but most people do not confine themselves to a single environment. Adaptations for toilets, such as raised toilet seats and toilet armrests, are commonly used for people with limited mobility. Home adaptations are easily made, but clients are often in environments that have not been adapted, such as public buildings, friends' homes, airplanes, hotels, and portable toilets at the local fair. If clients are likely to be in these environments, their goals should address their ability to perform tasks in varied settings.

? PRACTICE DILEMMA

HOW DOES ONE PROVIDE OPTIMAL CARE WITH LIMITED RESOURCES?

Jon is an occupational therapist in a large rehabilitation hospital in major city. The occupational therapy department recently installed the latest **electronic aids to independent living (EADLs)** in an on-site apartment that they use for treatment. Henry is a 16-year-old who has muscular dystrophy. He has a reclining power wheelchair that he can drive independently with a head switch. He has very limited use of his upper extremities. Henry lives alone with his mother, who works in a low-wage job. He receives Medicaid.

Henry's disease has progressed such that he is no longer able to get into and out of his home without assistance or operate common electronic devices, including the television, telephone, and lights. Because his mother works during the day, Henry must attend an after-school program, which is primarily for small children. Henry has told his occupational therapist that his most important goal is to be able to go home from school and access his home. The occupational therapist is sure that this could be an achievable goal for Henry with an EADL system that would enable him to be independent in unlocking and opening the door, turning lights and electronic devices on and off, and using the telephone and computer. The therapist is also aware, however, that Medicaid will not pay for an EADL in his state.

1. How should Jon proceed? Should he train Henry in the use of the EADL, even if it will not be possible for him to purchase it?
2. What team members might the occupational therapist consult with to help him progress Henry toward his goal?
3. Does the diagnosis of muscular dystrophy, a progressive disorder, affect the approach that Jon would take to solve this problem?
4. How can Jon help Henry to achieve his goal?

INTERVENTIONS FOR ADL AND IADL DEFICITS

Interventions for ADL and IADL deficits are based on clients' goals and involve selecting treatment approaches and activities, carrying out the treatment, and reviewing the intervention to ensure that it is effective in progressing clients toward their goals.

Planning and Implementing Intervention

Five intervention approaches are described in the OTPF: create/promote, prevent, maintain, modify/adapt, and establish/restore (AOTA, 2002). While any of these approaches can be used to support ADL and IADL performance, modify/adapt and establish/restore are the most commonly used in practice and will be the focus of intervention discussed in this chapter. Both the adaptive and restorative approaches need to be combined with client and/or caregiver education to ensure carryover of the program to function in everyday life (Flinn & Radomski, 2008). The selection of specific treatment activities is guided in large part by the frame(s) of reference selected by the occupational therapy practitioner for each client. Specific frames of reference are beyond the scope of this chapter but can be found in Unit VIII. The following subsection focuses on broader intervention approaches and their related strategies. It includes a discussion of client and caregiver education, grading activities to progress clients to the established goals.

Selecting an Intervention Approach

The occupational therapy practitioner considers a number of variables when deciding whether it is more appropriate to focus on compensating for a client's deficits through adaptation or restoring underlying skills needed to reach goals. These considerations are addressed in the sections that follow.

Modify.   Activity performance can be enhanced through compensation for activity limitations rather than restoration of previous capacities. This is often necessary when restoration is not an option. For example, at this time, a client with a complete C5 quadriplegia will not regain previous hand function, regardless of the restorative approach used. Compensation for impairments is needed for successful participation in ADLs and IADLs. Even for clients for whom restoration is possible, a compensatory approach might be more appropriate if time limitations or client motivation would lead to less than optimal outcomes. Compensatory strategies may also be warranted when some but not full restoration of function is achieved. Generally, compensatory strategies require less intervention time for achieving functional outcomes compared with restorative strategies.

Intervention for limitations in safe activity performance is often aimed at adapting the activity or the environment so that performance can be improved as soon as possible (Close et al., 1999; Cummings et al., 1999). In contrast, improvement in independence can occur over time, as long as adequate assistance is available. Intervention for safety should include an educational component for clients and their caregivers when clients are relearning familiar activities with reduced capacities or within new and unfamiliar performance environments.

Three general intervention strategies may be employed under the compensatory approach. The activity or task method may be altered, the task objects may be adapted, or the environment may be modified. Combinations of these methods may be used to maximize client performance. Examples of these three intervention strategies for selected ADLs and IADLs are included in Table 48.3.

ALTER THE TASK METHOD.   When the task method is altered, the task objects and contexts are unchanged, but the method of performing the task is altered to make the task feasible given the client's impairments. Many one-handed techniques for tasks that are normally done with two hands use this strategy, including one-handed dressing, one-handed shoe-tying (Figure 48.2), and one-handed typing techniques. To master an altered task method successfully, clients require the capacity to learn. The necessary level of learning capacity depends on the complexity of the method that is to be learned. People often rely on automatic processing for well-learned ADLs and IADLs so that they require little direct attention. Automatic processing of routine tasks frees the individual for other things, such as planning one's workday while getting ready in the morning or chatting with a child while grocery shopping. Practice is a necessary component of all learning and is especially crucial for clients who wish to develop or return to automatic performance of ADLs (Flinn & Radomski, 2008). Clients benefit from good follow-through with a training program to meet adequacy parameters, such as reducing difficulty and duration of performance and increasing satisfaction.

ADAPT THE TASK OBJECTS OR PRESCRIBE ASSISTIVE DEVICES. The objects that are used for the task may be altered to facilitate performance. For example, handles can be built up on utensils for clients with decreased finger ROM or training in the use of memory aids (e.g., memory notebooks, checklists, cue cards, and electronic cueing devices) may help clients who have difficulty initiating tasks (Knoke, Taylor, & Saint-Cyr, 1998; Schwartz, 1995). For some task adaptations, the task objects do not significantly alter the task method, so the need for learning is less than it is when the method is altered. When this is the case, the need for practice is also reduced, and performance can improve quickly. Examples of simple adaptations include utensils with enlarged or extended handles, a cutting

TABLE 48.3	EXAMPLES OF THE THREE APPROACHES TO MODIFYING TASKS TO COMPENSATE FOR IMPAIRMENTS		
Task	**Alter the Method**	**Alter the Task Objects**	**Modify the Task Environment**
Bathing	Substitute washing at the sink for someone who is unable to get into and out of the tub safely even with adaptive equipment.	Use a bath mitt and soap on a rope so that objects are not dropped by someone who cannot bend down to retrieve them.	Install grab bars and a transfer tub seat to enable the client to remain seated during bathing.
Grooming	Client learns to stabilize small containers with the ulnar digits while unscrewing lids with the radial digits to compensate for loss of the use of one hand.	An extended handle is added to a razor so that a woman can shave her legs without bending forward.	An extendable, wall-mounted mirror is mounted at an appropriate height for a wheelchair user.
Toileting	Use an alarm watch to encourage regular emptying of the bladder.	Use a toilet aid to extend the range of reach for toilet hygiene.	Install a bidet on the toilet to eliminate the need for manipulating toilet paper for hygiene.
Dressing	Learn to dress the affected side first to compensate for loss of use of one side of the body.	Use a sock aid to put socks on without having to reach the feet.	Lower clothing racks or replace a high dresser with a low one to increase access to clothes.
Feeding	Serve different food items (e.g., meat, starch, vegetable) in consistent places on the plate for someone who is blind.	Use a built-up handled utensil to compensate for diminished prehension in the hand.	Have an elementary school child eat with a few friends in a small room rather than the cafeteria, which is too busy and distracting.
Transfers	Sit first in the car seat before swinging the legs in rather than entering the car by leading with the leg.	Use a sliding board to eliminate the need for the lower extremities to support body weight.	Rearrange furniture to allow the wheelchair to be positioned near to the bed or a favorite chair.
Cooking	Sit at the kitchen table to chop vegetables to conserve energy.	Use a cutting board with aluminum nails to hold vegetables for cutting or peeling.	Install a mirror above the stove to enable a wheelchair user to see items cooking.
Paying bills	Round check entries to the nearest dollar to simplify the math for a client with cognitive impairment.	Use large checks, a dark pen, and a writing guide to compensate for low vision.	Install four plastic wall pockets to sort bills due each week of the month for a client with poor attention or memory.
Shopping	Shift to online and catalogue shopping to reduce the need for community mobility.	Purchase a walker basket for carrying items.	Request assistance from a grocery store employee to help reach items.

board with nails to stabilize food while cutting, and elastic shoelaces.

The prescription of assistive devices must take into account the client's capabilities and willingness to use the device, as well as the features of the device, a process that is frequently oversimplified. For example, a sock aid can help a client with poor sitting balance to reach her feet without leaning forward, which could throw her off balance. However, if the client's balance deficit is secondary to hemiple-gia and she also has poor use of one hand, it will be very difficult or impossible for her to get the sock onto the sock aid, which typically requires both hands (Figure 48.3). Figure 48.4 depicts the number of decisions that an occupational therapy practitioner makes when selecting an adapted spoon, a very simple type of adaptive equipment. Although many assistive devices that occupational therapy practitioners prescribe are quite simple mechanically, some are sophisticated and include complex electronics, circuits, and

1. Lace laces in usual way.
2. Put both lace ends back through the holes they exited until the loops formed are small.
3. Put the lace ends through the opposite loops and pull to tighten loops, allowing just enough room to put the lace end back through the loop.
4. Put lace ends back through the loops, forming another loop.
5. Pull on these loops alternately to tighten.
FIGURE 48.2   One-handed shoe-tying method.

microprocessors, such as electronic aids to daily living that interact with smart houses.

One disadvantage of adapting task objects is that the adaptive equipment must be available to clients whenever and wherever they engage in the task. This might or might not pose a problem, depending on the task and the adaptation. Clients who use memory books at work to compensate for cognitive impairments can incorporate the structure and cues needed into a daily planner or a hand-held personal data assistant, a tool that was used habitually before the impairment. If a client requires built-up utensils for eating, however, and wishes to eat at a restaurant, the utensils must be taken along. This is cumbersome, and some clients find it embarrassing.

Finally, some clients find that the use of adaptive equipment reduces satisfaction with task performance. To enhance personal satisfaction with task performance, they might be willing to cope with the increased

FIGURE 48.3   A sock-aid is useful for people with limited reach, for example, from limited balance or range of motion. However, the client needs to have the use of both hands to get the sock onto the device, which could make it impractical for some clients.

Type of Spoon
• Tea

difficulty of doing a task without adapted tools. For example, Ms. Lindstrom, a woman with multiple sclerosis, found that her mobility was safer and easier in a wheelchair, but she preferred to walk when out in the community. Her dissatisfaction with the wheelchair overrode other considerations.

MODIFY THE TASK ENVIRONMENT.   Modification of the environment itself may be used to facilitate task performance (Dunn et al., 1994). Typically, when the environment is modified, the demand for learning and practice is less than that required for learning an alternative method or using adapted task objects. Environmental modifica-

tions are often fixed in place so that clients do not need to remember to bring along the necessary adaptations and the adaptations cannot be easily displaced (e.g., they cannot be dropped out of reach). Usually, the task method is unchanged, or only minimally changed, so that clients can rely on previous experience. Examples include installing a wheelchair ramp, installing a floor-to-ceiling pole in the bathroom (Figure 48.5), recessing plumbing under the sink to accommodate a wheelchair user, increasing available light, labeling cupboard doors to compensate for cognitive deficits, and installing a toilet seat frame.

The biggest drawback of environmental modifications is that clients might become limited in terms of performance

FIGURE 48.5 A floor-to-ceiling pole that can be used to facilitate stability during transfers.

context. They must do the task in the modified environment or in one that has been similarly modified, because the modifications are not easily transportable and might be custom designed for a specific setting.

ESTABLISH/RESTORE. A restorative approach typically focuses intervention at the impairment level with the aim of restoring or establishing the capacities that are needed for functional tasks (AOTA, 2002). Intervention may be used to restore capacities such as strength, endurance, ROM, short-term memory, visual scanning, and interests. More information about specific techniques can be found in the chapters in Unit XI. Regardless of the specific frame of reference or techniques used, however, one must always establish the link between the impairment and the resulting activity limitations. Careful documentation of the evaluation assists other health professionals and third-party payers to understand the connection between the intervention and the established functional outcomes. Clients must also be educated about the relationship between their inherent capacities and the everyday tasks that they pursue so that they understand how the intervention will ultimately lead to improved task performance.

All intervention programs that are designed to restore or establish inherent capacities must provide clients with a structured opportunity to transfer the gains made in these capacities to relevant functional tasks (Latham, 2008a). This ensures that the intervention outcome is functional and helps to maintain gains made through increasing capacity and reducing impairment by providing an oppor-

tunity for practice within the daily routine. For example, stretching exercises that result in increased right shoulder flexion active motion should be accompanied by functional tasks that require movement into the newly acquired range, such as using the right upper extremity to reach up to pin pictures on a bulletin board or dusting bookshelves. Other examples can be found in Table 48.4.

Intervention that is aimed at restoration is often most efficient for clients for whom a few impairments affect many tasks and for whom diminished capacities can be expected to improve. For example, Mr. Stapinski had circumferential second-degree burns to both upper extremities. The resulting bilateral restrictions in elbow flexion prevented him from completing most ADLs owing to an inability to reach his face, head, or trunk. Tasks could be easily adapted by using long-handled devices, but extended tools would have been needed for many ADL tasks (e.g., eating utensils, toothbrush, comb, brush, bath sponge). Because clients with burns can be expected to increase ROM with passive stretching, scar management, and exercise, intervention was most efficient when it was aimed at increasing Mr. Stapinski's elbow flexion. Adapting selected task objects improved his ADL performance in the short-term; however, the long-term goal of restoring Mr. Stapinski's capacity to flex his elbows enhanced function across many different tasks.

A restorative approach may be appropriate for some clients with progressive disorders even though their capacities are expected to deteriorate, given the typical course of the condition. The focus, however, becomes slowing the decline of specific capacities and skills. For example, clients with Parkinson's disease may reduce bradykinesia with the use of a movement exercise program (Curtis, Bassile, Cote, & Gentile, 2001).

For clients with some types of impairments, carefully structured everyday activities can restore or establish capacities while simultaneously permitting the practice of the activities. Clients who are severely deconditioned might find their activity level limited by poor endurance. Intervention could rely on aerobic exercise to increase cardiopulmonary endurance, with the goal of participating in functional activities when an adequate increase in cardiopulmonary capacity was achieved. Instead, an intervention that graded the intensity and duration of daily activities could be as effective in increasing cardiovascular fitness while enabling the client to participate in desired tasks. In addition, gains that are made in endurance are immediately transferred into functional activities. Children and adults may engage more effectively in play activities that incorporate the necessary repetitive movements compared to a rote exercise (Melchert-McKearnan, Deitz, Engel, & White, 2000). Practice and participation in ADL and IADL programs also give clients with a new disability an opportunity to become familiar with their new bodies (Guidetti, Asaba, & Tham, 2007)

TABLE 48.4	INTEGRATING TREATMENT GAINS FROM AN ESTABLISH OR RESTORE APPROACH INTO FUNCTIONAL TASKS		
Impairment	**Task to Reduce Impairment**	**Task to Integrate Gains Made into ADL/IADL**	**Functional Outcomes**
Impaired grip strength	Theraputty exercises	Cooking task that begins with light resistance (e.g. stirring Jello) and progress (e.g., stirring brownie mix)	Increased ability to grasp task objects firmly (e.g. opening containers, doors, pulling up pants)
Decreased upper extremity muscle endurance	Using an arm ergometer	Wheelchair mobility, increasing time and difficulty (e.g., progress from flat surfaces to ramps)	Increased ability to engage in sustained upper extremity work (e.g., propelling a wheelchair, shampooing hair, washing windows)
Hyperresponsiveness to tactile stimuli	Brushing skin	Progress from bathing in a tub to a shower, which provides a stronger stimulus	Ability to tolerate tactile stimuli in everyday tasks, including dressing, brushing teeth, and interacting with others
Poor visual scanning	Paper-and-pencil cancellation tasks (e.g., cross out all the M's on a sheet of letters)	Find items in a kitchen cupboard or grocery store shelf	Ability to use a more organized scanning process for locating objects (e.g., finding a blouse in the closet, a brush on a cluttered dresser, the milk in the refrigerator)

Depending on the nature of the performance discrepancy and the degree of impairment, the intervention time that is needed in establishing or restoring underlying skills can be longer than that required for compensatory approaches. This increased time must be taken into consideration, particularly in managed care settings. In addition, clients must recognize that the rehabilitation period might be longer and that follow-through with a home program is vital if gains are to be made.

INTEGRATING INTERVENTION FOR IMPAIRMENTS AND ACTIVITY LIMITATIONS. At first glance, it might seem that the modify/adapt and establish/restore approaches are mutually exclusive—that is, that the outcome is either to establish/restore the impaired capacity or to compensate for it. Using both approaches simultaneously might seem a bit like using a belt and suspenders. However, a carefully crafted program enables clients to be more functional through the use of compensatory strategies while at the same time working to restore functional capacities. It is critical that the occupational therapy practitioner reduce the use of compensatory strategies as clients make gains in skill performance when using the two approaches.

For example, Mr. Stapinski, whose burns resulted in bilateral limitations in elbow flexion, might benefit from using utensils with extended handles. With the extended handles on the utensils, he can feed himself independently during the two to three weeks that it takes to increase his elbow flexion sufficiently for him to feed himself without these utensils. The extended handles should be fabricated to require him to flex fully within his available range and should be shortened as gains in ROM are made, so that the new range is incorporated into the feeding task.

Whenever task or environmental adaptations are anticipated to be temporary, it is necessary to consider cost in relationship to the anticipated time the equipment will be needed, and the potential benefit to clients. Thermoplastic or wood extensions can be added temporarily to the handles of regular utensils rather than prescribing the more costly commercially available utensils with elongated handles. For some tasks, safety concerns supersede cost considerations. Using a collapsible lawn chair in the shower would be an inexpensive alternative to a shower chair, but it would not provide adequate stability.

Education of the Client or Caregiver

Caregiver training may be implemented to maximize a client's functional outcome while minimizing the efforts of the caregiver (Bogardus et al., 2001; Dooley & Hinojosa,

2004; Hepburn, Tornatore, Center, & Ostwald, 2001; Miller & Butin, 2000). For example, Mr. Ford sustained a left cerebrovascular accident and required minimal physical assistance with verbal cueing from the occupational therapy practitioner for wheelchair transfers. Mrs. Ford was physically able to help her husband but had no prior experience in transferring a person with hemiparesis. One day, she decided to help her husband move from his hospital bed to the chair. Because she did not block his right knee or tell him to wait for her cue before standing, they both fell onto the bed while attempting to execute the transfer. Fortunately, no one was hurt. As a consequence of this experience, Mrs. Ford was convinced that she could not care for her husband at home. At the same time, she was distressed by the thought of having to admit him to a long-term care facility. She was receptive to receiving transfer training from the occupational therapy practitioner and was delighted to find that by using the proper physical and verbal techniques, she could easily and safely assist her husband. In this example, caregiver training increased the client's level of independence and the probability that he could go home at discharge.

INSTRUCTIONAL METHODS. A variety of instructional methods are available for client and caregiver education (Fuhrer & Keith, 1998), and methods should be selected that best meet the person's needs. When a facility has a homogeneous client population, group instruction can be an efficient and effective method for providing basic education. Many arthritis centers provide group instruction in joint-protection techniques. Teaching a group is cost-effective and, when well structured, can facilitate learning through peer interaction. For caregiver groups, the contact with others who are experiencing similar problems in their caregiving roles can provide valuable emotional support and an opportunity for constructive group problem solving.

Some type of individualized instruction is typically needed to complement group instruction so that information can be tailored to meet the specific and unique needs of each person. If group instruction has preceded the individualized instruction, the client-specific sessions can be relatively short and focused on application of the information learned in the group to the client's particular circumstances. For example, clients would be taught how to apply proper lifting techniques to the weights and dimensions of objects in their own homes.

Individualized instruction is more appropriate for many clients and caregivers because the personal nature of the tasks that need to be learned does not lend itself to group instruction (e.g., bathing). Furthermore, in intervention settings that serve a diverse case mix, the opportunity for group instruction rarely occurs. One-to-one client or caregiver education and training enables the occupational therapy practitioner to obtain immediate feedback from the person as the session progresses and to alter the amount and focus of learning accordingly.

A vast array of media are available to occupational therapy practitioners to facilitate the client's or caregiver's learning process. Written materials may be developed specifically for a client or caregiver, or published materials can be used if appropriate ones are available. Videocassette or digital recorders are widely available, even in clients' homes, and custom or commercially made videotapes or DVDs can be effective teaching tools. Audiotapes can also be effective, particularly when visual input would be distracting. For example, an audiotape may be used to facilitate visual imagery for relaxation or stress reduction. The Internet is accessible to the general population, and many occupational therapy clinics have Internet access. A wealth of information about a variety of disorders is available that is specifically geared toward clients and caregivers. Clients can also find peer support groups through chat rooms, Web forums, or e-mail lists.

CAREGIVER TRAINING. In addition to evaluating clients' learning capacity, the learning capacity of their caregivers needs to be appraised. Like clients, caregivers have varied learning styles, capacities, and experience. In many situations, the caregiver is a family member who is still coping with the emotional impact of having a family member with a disability, whether it is a new parent with a child with cerebral palsy or the spouse of a someone who has had a stroke. People who are under emotional stress often need more time and repetition to process information accurately (Blake & Lincoln, 2000). In other cases, caregivers have been providing care for years and bring a wealth of caring expertise to the treatment session. The occupational therapy practitioner should work collaboratively with all caregivers but may move into a more consultative role with experienced caregivers who can articulate problems and engage actively in problem solving based on prior learning (Toth-Cohen, 2000). When caregivers are expected to assist clients physically, their physical capacity for providing this assistance also warrants evaluation.

Caregivers have varied learning styles, and instruction that caters to their preferred style is likely to be the most efficient and effective (Banford et al., 2001). Some people, for example, are kinesthetic learners. They learn most quickly through doing. Visual learners might prefer to watch a demonstration of the activity several times before attempting it themselves. Others might prefer written instructions. All learners benefit from the opportunity to ask questions to clarify instructions. Media that support teaching by a practitioner can be a great asset. Videotapes or DVDs, for example, provide caregivers with an excellent visual image of how an exercise or activity is to be done. Often, home- or clinic-made videotapes can be made of a client's activity performance. These productions add little time to the intervention session, because they are recorded as activities are practiced during regular therapy. They have the advantage of providing richer and more detailed information than is feasible in oral or written instructions.

When caregivers are helping to carry out an intervention program, the goals and general intervention strategies should be made clear to them. For restoration programs, clients might need assistance with implementing specific

exercises or grading of activities in a way that will help to restore skills. Caregivers need to learn specific cueing strategies so that home programs are carried out accurately, whether in clients' homes, group homes, or long-term care settings. Caregivers are often pivotal in motivating clients. Motivating clients who have disorders that impair motivation, such as depression, can be particularly challenging. Helping caregivers to understand that disinterest and lack of motivation are a part of the disorder and providing concrete strategies for managing the "getting going" phase of the home program will foster its success (Resnick, 1998). For clients with behavior problems, such as the reactions that may accompany autism or Alzheimer's disease, teaching caregivers behavior management strategies that defuse potentially volatile situations can be invaluable to their success as caregivers.

Caregiver training for assisting clients with functional activities should focus first on safety for clients and caregivers. The occupational therapy practitioner should emphasize components of the activity that promote safety, such as locking the wheelchair brakes or blocking the client's knee to prevent buckling when transferring to and from the wheelchair. As intervention progresses, the occupational therapy practitioner should inform caregivers of the activities that are safe and unsafe to perform outside of the therapy situation. For example, although a client might be working on bathtub transfers during therapy, skilled facilitation to get into and out of the tub safely might be required, making it premature for the client to practice these transfers at home.

When caregivers need to provide physical assistance, they should be trained in using proper body mechanics, especially during transfers or bed mobility and also for wheelchair positioning. Assisting a client in a wheelchair with ADLs, such as brushing teeth or feeding, while the caregiver is standing can fatigue the caregiver's lower back muscles. Taking care of the caregiver is frequently overlooked in occupational therapy interventions, but it is an essential component of the person–task–environment transaction, particularly when it is anticipated that the client will require assistance over a long period of time.

COMMENTARY ON THE EVIDENCE

Finding the Best Educational Strategies for Client Learning

As individual treatment time has been reduced by third-party reimbursement plans, client and caregiver education has played a more important role in treatment. Many studies have demonstrated the effectiveness of different and varied educational programs. For example, patient education programs have been effective in improving self-management and reducing pain and disability for people with rheumatoid arthritis (Hammond, 2004), reducing the impact of fatigue on occupational performance in people with multiple sclerosis (Vanage et al., 2003), and increasing confidence and activity participation in older adults who have a fear of falling (Cheal & Clemson, 2001). Eklund, Sonn, and Dahlin-Ivanoff (2004) compared a health education program for people who have visual impairment with traditional individualized intervention and reported that participants in the health education program had higher perceived security for a number of ADLs and IADLs, supporting the need for structured client education programs. Researchers typically describe the educational programs that were used in their studies, and the educational methods reported vary significantly. Although there is ample research to support the efficacy of patient education programs on client outcomes, no studies were found that compared varied educational approaches for clients to identify best practice in this area. Learning is a complex process, and factors such as motivation and self-efficacy should be addressed in planning learning experiences (Edelstein, 2005). Clients must be ready to learn, so the timing of education can also affect its effectiveness (Hammond, 2004) and should be further explored. Many educational programs are aimed at changing clients' habits, such as engaging in home exercise programs or incorporating energy conservation techniques into daily activities, which may require behavioral approaches for supporting the development of new habits (Hammond, 2004). Future research should also examine the impact of varied impairments on the effectiveness of education, for example, problems with initiation, attention, or executive function. Gathering additional evidence will enable practitioners to become even more effective in helping clients to reach their goals.

Grading the Intervention Program

Intervention programs should never be static. It is important to progress the client continually toward the established intervention goals. The specific means of grading intervention when a restoration approach is being implemented depends on the impairments and the intervention strategies that are being used (Latham, 2008b). (The chapters on restoration of impairments in this text provide more specific guidance.) If the intervention plan uses both restoration and compensation, the program can be graded by reducing the amount of task and environmental adaptations as clients' capacities are restored. Intervention for activity limitations can be graded by modifying many of the performance parameters that were described earlier in the chapter. Clients may increase their level of independence in task performance, take more responsibility for safety, feel more personal satisfaction from a task, reduce the level of difficulty or required exertion, or decrease the duration or the occurrence of aberrant task behaviors.

GRADING TASK PROGRESSION FROM EASIER TO HARDER. One means of grading an intervention program is to begin with easier tasks and progress to more difficult ones. Task difficulty will be relative to a client's activity limitations and underlying impairments. For example, paying bills might be relatively easy for a client with quadriplegia to perform once the use of a writing tool is mastered, whereas lower extremity dressing is much more difficult. Conversely, a client with a head injury that resulted in significant cognitive impairment with relatively preserved motor skills is likely to find lower extremity dressing to be relatively easy but money management extremely difficult.

INCREASING COMPLEXITY WITHIN THE TASK.   Rather than progressing only from easier to harder activities, intervention may also be graded by increasing the complexity within an activity or by progressing from simple to more complex ways of doing it. Cooking skills might extend from simple preparations such as cold sandwiches to more complex, multiple-course dinners. Even seemingly simple tasks can often be graded. A sock-donning intervention, for example, might be scaled from using looser ankle socks to tighter knee socks and finally to tight antiembolus hose.

SAME TASK IN VARIED PERFORMANCE ENVIRONMENTS. A critical part of a graded intervention program involves progression from the intervention environment to the real-life environment in which the activity will actually be performed. This can involve transfer from a clinic to a home setting or the more subtle dynamics associated with the transfer of help from the occupational therapy practitioner to the natural caregiver. The client who is independent in donning a jacket while sitting on a mat table in the clinic might be unable to do so when sitting on a chair with a back or when standing (the way a jacket is typically donned by people who are able to walk). Providing practice in increasingly demanding performance environments can facilitate the generalization of skills, thereby enhancing the client's functional flexibility.

Intervention Review

ADLs and IADLs are evaluated on entry to occupational therapy to provide a measure of the client's baseline performance status. Regardless of the extent and length of the intervention, reevaluation of ADL and IADL performance is needed to ascertain whether the intervention is resulting in improvement, whether the intervention should be continued or changed, or whether maximal benefit from occupational therapy has been achieved and activity performance has reached a plateau. Occupational therapy practitioners routinely engage in informal review of interventions by observing clients' performance during treatment and considering the actual or potential impact of their performance on established goals.

Periodically, a more formal intervention review or reevaluation is needed to objectively measure clients' progress toward goals and for documenting their progress in clinical records. The best strategy for reevaluation is to readminister the evaluations that were done at entry. Using the same ADL and IADL content, the same measurement parameters, and the same data-gathering methods enhances the possibility of detecting change in the client's performance that is attributable to intervention. If the reevaluation varies from a prior evaluation, the potential for detecting change is reduced. For example, if ADL performance is evaluated in the occupational therapy clinic by using observation immediately before discharge and by using a telephone survey sometime after discharge, it is not possible to determine whether increased performance is reflecting the client's actual improvement or is the result of the change in data-gathering method (observation versus questioning).

CONCLUSION

This chapter described the complex practice of evaluating and treating clients with ADL and IADL deficits. Performance parameters of value, independence, safety, and adequacy were reviewed, and their relevance to the selection of specific assessment tools was described. Occupational therapists should establish objective baseline measures through the use of standardized ADL and IADL assessments whenever possible; however, the realities of the treatment setting may also require the use of nonstandardized assessments. Developing objective goals that address all relevant performance parameters is a crucial first step in implementing treatment by providing a "road map" for guiding client care. General treatment approaches that occupational therapists use to increase participation in ADLs and IADLs include

modifying the task or environment, establishing or restoring underlying impairments, and client and caregiver education. Grading activities effectively will maximize clients' progress toward goals. Specific treatment activities vary significantly according to the clients' ages and disabilities and are beyond the scope of this chapter. Readers should use this chapter to guide them in the overall process of ADL and IADL intervention and refer to sources that focus on specific client populations and service delivery models when selecting specific treatment activities.

ACKNOWLEDGMENTS

I would like to thank Dr. Margo B. Holm and Dr. Joan Rogers for inviting me to coauthor two prior editions of the ADL/IADL treatment chapters for *Willard & Spackman's Occupational Therapy,* which ultimately led to the opportunity to author this evaluation and treatment chapter. Dr. Holm and Dr. Rogers have an ability to conceptualize and articulate occupational therapy practice that is both scholarly and practical. Their contributions from prior editions continue to shine brightly through in this chapter.

PROVOCATIVE QUESTIONS

1. The only occupational therapist at a small community hospital happens to be male. He receives a referral on a female client who sustained a lumbar fracture and must wear a back brace at all times. The client cannot reach her perianal area for hygiene and bathing and needs to be able to manage these tasks, as well as dressing, when she returns home. The client comes from a culture in which it is unacceptable for women to be seen unclothed by men. She has requested a female occupational therapist, but the hospital does not employ any. How should the occupational therapist handle this situation?

2. How would intervention differ for clients who wish to be autonomous (i.e., able to direct their own care) but plan to have assistance with ADLs and/or IADLs on a long-term basis?

3. What do you do when clients and their caregivers have different opinions about treatment priorities? For example, the mother of a 12-year-old boy with cerebral palsy would like her son to become independent in getting ready for school in the morning, but he thinks that it would take too long and would require him to get up too early. Or a 73-year-old woman who has had a stroke with resulting left hemiparesis and a moderate left neglect would like to cook again, but her husband thinks that she would be unsafe and would rather do the cooking himself. He says that it would be much more efficient, and it is very frustrating for him to have to cue her all the time.

Caregiving and Childrearing

49

ELLEN S. COHN AND
ALEXIS D. HENRY

" One person caring about another represents life's greatest value "

—JIM ROHN

Learning Objectives

After reading this chapter, you will be able to:

1. Describe an ecological, developmental, and occupation-centered perspective of caregiving and childrearing.
2. Discuss the process for evaluating caregiving and childrearing needs.
3. Choose interventions based on clients values and occupational performance relative to caregiving and childrearing.

Caregiving and childrearing, which are essential to the continuity of life, are common yet highly complex occupations. Both public and private, these occupations are deeply significant, intensely personal, openly shared, and socially constructed. In this chapter, the terms caregiving and childrearing are used interchangeably to describe the occupation of nurturing the well-being of others. Understanding the meaning, ideals, and values of caregiving and childrearing from societal and individual perspectives is essential to occupational therapy practice. Historically, intervention focused primarily on parents whose child had a disability. Interventions were typically designed to help parents support the development of their child with disabilities, and limited attention was given to helping parents create sustainable routines to enhance family priorities and lifestyles. Also overlooked by occupational therapy are caregivers who have a disability themselves. Accordingly, this chapter presents an overview of childrearing and caregiving occupations, followed by evaluation and intervention approaches for those who are caring for individuals with disabilities across the life course and those who are caregivers with a disability.

Historically, childrearing and caregiving were most often provided by women, with men having limited participation in caretaking of others. Today, males are more often active participants in childrearing and caregiving (Lamb, 2000). Therefore, in this chapter, childrearing and caregiving are viewed as gender-neutral occupations.

CHILDREARING AND CAREGIVING OCCUPATIONS

Childrearing and caregiving take place in multiple environments and can be conceptualized by using ecological (Bronfenbrenner, 1979), developmental (Olson et al., 1983), and occupation-centered (Jackson, 1998) perspectives. Ecological perspectives support the view that childrearing and caregiving are influenced by the interaction between the person, the occupation, and the environment. These interactions are reciprocal and dynamic. People generally interpret experiences through their own customized world view. The ecological perspective reminds practitioners to consider the numerous factors that influence caregivers' ideals, decisions, and actions. The **family**, defined, as "a group of people living together or in close contact to take care of each other and provide guidance for their dependent members," is the center of the ecological system, supporting the growth of family members (Wood, 1995). Personal factors such as family member characteristics (e.g., age, education, socioeconomic status) and characteristics of the care recipient (e.g., age, type of disability) influence how a family conceptualizes parenting, disability, and the role of services (Luster & Okagaki, 1993).

On the basis of an ecological perspective, Harkness and Super (1994) proposed a theoretical framework, the "developmental niche," for understanding how cultural settings influence children's lives, including their daily activities. In this framework, the cultural constructed environment of the child is conceptualized as including three interrelated operational subsystems: (1) the physical and social setting where the child lives, (2) culturally regulated customs of child care and childrearing, and (3) the psychology of the caretakers. The physical and social setting shapes a person's activity through the kinds of activities available and through the defining activities of the people who are present. Customs, as defined by Harkness and Super (1994), refer to techniques of protecting, teaching, and socializing that are so commonly used by members of the community and are so thoroughly integrated into the larger culture that caretakers do not need to give them conscious consideration. That is, customs are often viewed as the natural way to do things. The caretakers' psychology, including their beliefs and values, organize their behavior toward others and many larger decisions, such as the appropriateness of certain behaviors. These subsystems operate in a coordinated manner, interact differentially with other features of the larger environment, and are mutually adapted. The concept of a developmental niche provides a useful framework for identifying and collecting relevant information related to factors that affect caregiving and childrearing occupations.

For example, cultural and societal factors influence caregiving actions. In Asian cultures, elderly people are cared for within the family; therefore, alternative living situations outside the family home might not be acceptable options for older adults in Asian cultures (Spector, 1996). In the Hmong culture, epilepsy is seen as a gift that is possessed only by the respected shaman. This cultural belief is contradictory to the medical model in Western societies, which considers epilepsy a disease to be treated with medication. Such clashing worldviews can have major implications for practitioners who are striving to support people in their childrearing and caregiving occupations (Fadiman, 1997). Only when the influence of cultural beliefs is examined is it possible to understand caregivers' actions and goals for intervention.

Extended family, neighborhoods, coworkers, and other parents may be integral components of a caregiver's personal social network, therefore influencing the attitudes and beliefs of caregivers (Dyck, 1990). This social network can provide childrearing assistance and support for caregivers. Although social networks are typically a source of support for caregivers, extended family members can in some cases undermine the confidence of a struggling parent or caregiver.

Another factor that influences caregivers and families is the developmental concept of the family life cycle. Olson and colleagues (1983) proposed a model to conceptualize and describe the family life cycle that includes specific phases or life events and challenges to be confronted during each phase in the family life cycle. For example, families make a transition when a child is old enough to be launched from the immediate family system and live on his or her own or in a new setting. Developmental trajectories intersect with other family dynamics, and over time, changes occur in both the structure and function of the family. Practitioners need to understand and consider the impact of the major events that families might be experiencing at a given time.

Along with ecological and developmental perspectives, scholars in occupational science advocate for an occupation-centered perspective (see Chapter 1). Rather than focusing on specific tasks or activities in isolation, separate from an understanding of the meaning of tasks, an occupation-centered analysis focuses on the overarching occupation itself. Ruddick's (1995) analysis of mothering helps us to understand the meaning associated with childrearing across cultures and countries. Although Ruddick focuses on mothering, her analysis is applicable to fathers as well. According to Ruddick, the "work" of parenting includes protection, nurturance, and training. Protection requires scrutiny of the child and the environment, coupled with an acceptance that a child will inevitably be subjected to minor or major mishaps that parents cannot control. Parents must accept their own limits as protector and still continue with the intent of keeping their child safe. Protection falls on a continuum from a lack of protection to overbearing. Nurturance or fostering of growth refers to developing a child's body and spirit. Fostering growth requires the ability to change as the child grows. A caregiver provides the conditions for growth; these conditions vary among cul-

tures, socioeconomic levels, and other environmental factors. Training involves teaching the child behaviors and values that are necessary to achieve acceptance by family and society. Along with protection, nurturance, and training, parents of children with disabilities identify advocacy and obtaining appropriate resources as a critical aspect of parenting (Landsman, 1998).

Jackson (1998) addresses the "enfolded nature of occupations," a term that acknowledges the multiple factors that influence occupations (pg. 58). Jackson cites DeVault's (1991) research, which suggests that parents are often not delineating their childrearing and caregiving tasks; rather, they are folding them into one another. De Vault's example of "feeding the family" illustrates that parents provide sustenance to the child while simultaneously fostering social communication skills for acceptance into society. Dyck's (1990) analysis of working parents offers another example of enfolded occupations. Dyck proposed that women develop strategies to remain a "good mother" while participating in the labor force. Strategies might involve hiring an after-school babysitter to drive a child to activities so that the parent can work while the child engages in developmentally stimulating programs. An occupation-centered analysis directs practitioners to consider the social, symbolic, and interpersonal meaning associated with childrearing and caregiving (Jackson, 1998).

Caring for individuals with disability, whose needs may extend indefinitely into the future, poses potential benefits and burdens. The demands of long-term caregiving have been associated with depression, grief, physical health problems such as fatigue, and occupational imbalance, which can lead to social isolation for the caregiver (Pearlin, Mullan, Semple, & Skaff, 1990). Donovan VanLeit, Crowe, and Keefe (2005) interviewed mothers of children with disabilities and found that the mothers were most concerned about taking care of their own health and well-being; expanding their social life; improving their child's quality of life; managing their household (including time and resources); balancing work, home, and community responsibilities; and sharing the work load. Similar concerns have been expressed by caregivers of individuals with other diagnostic conditions and ages (Hasselkus & Murray, 2007).

Caregiving does not always result in long-term negative effects on family members. Rather, the lives of many parents, across socioeconomic classes and in families with children with various disabilities, are positively changed as a result of the birth of a child with a disability (Scorgie & Sobsey, 2000). Some parents reexamine their expectations, with a transformation of values, resulting in a new sense of "what really matters." Chen and Greenberg (2004) noted that family members of relatives with schizophrenia report greater sensitivity to others and awareness of themselves and view the family member with schizophrenia as an active and valued member of their family. Parents of younger children with disabilities report acquiring new life-enriching roles such as being a parent-group leader, writer, or speaker at conferences. Some parents learned better communication skills and used these skills to foster open, supportive family relationships (Scorgie & Sobsey, 2000).

EVALUATING CAREGIVING

The first step in developing interventions for parents and family caregivers is to gain an understanding of the daily experiences and responsibilities of the individuals who are engaged in these occupations. The evaluation process should be family-centered and collaborative, with a goal of identifying family strengths, priorities, and values as well as challenges associated with caregiving. It is best to begin with an open-ended conversation or interview, initially focusing on the daily routines associated with caregiving and family life, which can help the practitioner to gain an understanding of the daily challenges a parent or caregiver might face. This process can also help to develop trust and rapport between the practitioner and the caregiver (Orsmond, 2005). The practitioner might begin by asking a parent to describe a typical day, from morning to night. Who in the family is responsible for the daily tasks of caregiving, and how and when are these tasks accomplished? How do weekdays differ from weekend days? What makes a typical day go well or not so well? What are the typical stressors, and how or when do they occur? In addition to the parent or primary caregiver, other family members can be asked about their daily routines.

In the context of a conversation about a typical day, the practitioner can explore how the family's customs, beliefs, and attitudes affect the daily routines of caregiving. It is also important for the practitioner to gain an understanding of the person's sense of competence as a parent or caregiver, as well as in other important occupations. What does the individual feel that she or he does well, and what does the family do well? What things are difficult? What are the strengths or assets of the children or other family members? What aspects of caregiving are most important to the individual and other family members? In what areas are changes needed?

In addition to exploring the daily routines and challenges of parenting and caregiving, the practitioner can use an interview to understand whether and how the individual is able to meet his or her own needs while caring for other family members. For those with the responsibility of caring for other family members, participation in other occupations is largely dependent on their ability to adequately meet the demands of their caregiving occupation. It is important for the practitioner to explore how caregivers balance the demands of caring for others with the demands of school, work, homemaking, and self-care.

The supports and resources that are available to the family and caregiver should also be explored. During the

interview, the practitioner can determine the extent to which other people, such as friends, neighbors, and extended family members, are a source of support for the caregiver and family. Beyond social supports, what other resources are available to the caregiver and family? Does the family have adequate financial and other material resources to meet their needs in terms of housing, food, transportation, health care, and recreation?

No occupational therapy interviews have been developed that specifically focus on the occupations of childrearing or caregiving. However, questions about these occupations can easily be incorporated into existing broad occupational performance interviews, such as the Occupational Performance History Interview II (OPHI-II) (Kielhofner et al., 2004) or the Canadian Occupational Performance Measure (COPM) (Law et al., 1998). The Importance, Satisfaction, and Performance scales of the COPM could be used to rate the tasks associated with the caregiving occupations. These two interviews are discussed in greater detail in Chapter 34. Whether a practitioner uses one of these formal interviews or a more informal approach, the practitioner should be mindful that he or she might be interviewing vulnerable families, with either children or adults at risk. Interviews should be conducted in an honest, sensitive, and respectful manner that avoids judgment but seeks to identify the strengths and needs of the caregiver and other family members (Orsmond, 2005). An important goal of an occupational therapy interview is to develop a positive partnership with the parent or caretaker so that occupational therapy interventions can empower caregivers and enhance their ability to meet their caregiving obligations. Guidelines for effective interviewing are discussed in Chapter 34.

Following an interview, the practitioner might elect to conduct further evaluations of specific occupational performance skills and patterns, such as hands-on childcare or homemaking activities. For example, because these activities often involve both physical and cognitive tasks, a practitioner might elect to evaluate biomechanical capacities related to lifting, transferring, carrying, bending, and squatting while caring for others (Sanders & Morse, 2005) or might evaluate cognitive capacities related to money and household management or meal planning (see Chapters 54 and 57).

Numerous rating scales have been developed to assess various aspects of parenting and caregiving. Although such rating scales should never substitute for a face-to-face conversation with a client about his or her parenting or caregiving occupations, practitioners might find one or more of these measures to be useful adjuncts to an interview and/or performance skills assessments in planning interventions. Additionally, these types of scales can be appropriate to use as outcome measures to assess the impact of supports and services for families. Basic information on a sampling of existing parenting and caregiver assessments is presented in Table 49.1.

A family-centered, collaborative evaluation process leads to goal setting and intervention planning that is directed by the parent or caregiver's values, beliefs, goals, experiences, and needs. Approaches to goal setting and intervention are discussed below.

Parenting a Child with a Disability

When parents learn that their child has a disability, there may be feelings of anger and a process of mourning the loss of the "perfect child." Initially, parents may have feelings of shock and denial, followed by anger and depression. Parents may repeat the process of mourning as they encounter unexpected discrepancies between reality and their hopes and expectations. Among and within families, there may be great variability in reactions to and perceptions of the family member with a disability. Mothers of children with disabilities report more stress than fathers do, while fathers report more trouble forming bonds with their children (Beckman, et al., 1998). Services need to be tailored to meet the different needs of each family member. Scorgie and Sobsey recommend that practitioners avoid catastrophizing the effects disability can have on a family. Rather, parents should be made aware that initial feelings of grief are common but that many families adapt to disability in the family. Connecting parents in the initial stages of coping with parents who have adapted positively to life with a child with a disability can aid families in forming a positive outlook for the future (Scorgie & Sobsey, 2000).

Within the last decade, research on parenting children with disabilities has focused on adaptation and adjustment with an emphasis on what families do to sustain daily routines that consider families realities, interests, and values (Fiese et al., 2002; Gallimore, Bernheimer, & Weisner, 1999; Segal, 2004; Summers et al., 2006). Bedell, Cohn, and Dumas (2005) note that families typically have intimate and firsthand expertise and knowledge related to their family members, family life, and the illness or disability of their family member and know best which intervention recommendations can most likely be implemented in the home and community. In their exploration of the strategies that parents use to promote social participation for their children with acquired brain injury, Bedell, Cohn, and Dumas observed that parents need time to allow the recovery process to unfold for themselves and their children. To develop effective interventions based on collaborative partnership with families that honor families' knowledge and expertise, Bedell and colleagues advocate asking parents about the strategies that parents already use and whether they perceive the strategies to be effective rather than reinventing the wheel.

Caring for an Adult with a Disability

Parents of a child with disabilities often continue parenting throughout the child's life into adulthood (Hodapp,

TABLE 49.1 PARENTING AND CAREGIVING ASSESSMENTS

Title	Authors (Date)	Major Domains Assessed	Method of Administration
		Parenting and Family Life Scales	
Parenting Stress Index	Abidin (1995)	Parent characteristics such as competence, isolation, attachment, health, role restriction; child characteristics such as distractibility/hyperactivity, adaptability, demandingness; overall family stress	Self-report
Parenting Sense of Competence Scale	Johnston & Marsh (1989)	Parenting self-esteem, parenting efficacy, and parenting satisfaction	Self-report
Family Environment Scale	Moos & Moos (1983)	Dimensions of family environment, including quality of relationships within the family, opportunities for personal growth, and degree of organization/control within family	Self-report
Family Support Scale	Dunst, Trivette, & Deal (1988)	Perceived helpfulness of partner/spouse support, informal kinship support, formal kinship support, social organizations and professional services, total number of sources of support, and overall social support	Self-report
Home Observation for Measurement of the Environment Inventory	Caldwell & Bradley (1984, 2001)	Quality and quantity of psychological stimulation and cognitive support available in the home; four versions for children from ages 0–3, 3–6, 6–10, and 10–15 years are available	Observations and rating of parent/child interaction; parent interview
Beach Center Family Quality of Life Scale	Park, Hoffman, Marquis, Turnbull, Poston, Mannan, Wang, & Nelson (2003) Hoffman, Marquis, Poston, Summers, & Turnbull (2006)	Perceived importance of and satisfaction with family interaction, parenting, emotional well-being, physical/material well-being, and disability-related supports	Self-report

TABLE 49.1 PARENTING AND CAREGIVING ASSESSMENTS *Continued*

Title	Authors (Date)	Major Domains Assessed	Method of Administration
		Adult Caregiving Scales	
Caregiver Strain Index	Robinson (1983)	Perceived strain related to caregiving and impact on caregiver's employment, finances, physical and social well-being, and time use	Self-report
Caregiver Well-Being Scale	Berg-Weger, Rubio, & Tebb (2000)	Caregiver well-being from a strengths-based perspective, assesses caregivers' basic human needs and satisfaction with activities of daily living	Self-report
Zarit Burden Interview	Zarit, Reever, & Bach-Peterson (1980) Zarit, Todd, & Zarit (1986)	Perceived burden among family caregivers of older adults with dementia	Interview or self-report
Perceived Change Index	Gitlin, Winter, Dennis, & Hauck (2006)	Brief, 13 items, perceived change in well-being in affect, somatic, and ability to manage	Self-report
Caregiver Well-Being Scale	Tebb (1995) Berg-Weger, Rubio, & Tebb (2000)	Extent to which caregiver's basic human and activity of daily living needs are met	Self-report
Bakas Caregiver Outcome Scale	Bakas & Champion (1999)	Changes in caregiver's social functioning, subjective well-being, and physical health as a result of caregiving	Interview or self-report
Task Management Strategy Index	Gitlin, Winter, Dennis, Corcoran, Schinfeld, & Hauck (2002)	Caregiver's use of strategies to simplify everyday self-care tasks for people with Alzheimer's disease and related disorders	Self-report

Dykens, Evans, & Merighi, 1992). Adolescence is often a time when caregivers realize the permanence of the child's disabilities and begin to worry about the future. The features of the disability may change as the child ages and the child's size increases (Seltzer, Krauss, Orsmond, & Vestal, 1997). As the caregiver ages, his or her health needs may change. Aging can have an effect on community involvement, leading to increased social isolation and stress for both the person with a disability and the caregiver. Practitioners can address the caregiver's physical and psychological well-being by providing additional supports in the home and community, making referrals for respite services, and, if appropriate, providing strategies to minimize behavioral difficulties (Biegel, Sales, & Schultz, 1991).

Middle-aged adults, often described as the "sandwich generation," may face the simultaneous demands of parenting adolescents or young adults and caring for their elderly parents (Sorensen & Zarit, 1996). Family caregivers are the primary source of support for frail older people, and 80% of all family caregivers for the elderly provide unpaid help seven days a week (Hasselkus, 1989). Hasselkus's (1989) research on family caregivers for frail older people living in the community suggests that caregivers are focused on getting things done to sustain the family system, achieving a sense of well-being for the care receiver, and achieving a sense of well-being for themselves. The caregiver's quality of life is linked to the quality of life for care recipients; therefore, both the caregiver and recipients will benefit from supportive intervention. Caregivers of older adults, either their spouse or parent, often require support to address the emotional stress of experiencing a loved one decline in function. Hasselkus and Murray (2007) recommend collaborative intervention in which the practitioner strives to understand the meaning caregivers attach to their role and supports the caregiver to balance daily occupations.

BEING A CAREGIVER WITH A DISABILITY

Adults with disabilities experience the same desires to form intimate relationships and to have and raise children as do adults without disabilities. Estimates of the prevalence of disability suggest that there are millions of families in the United States in which one or both parents have a disability (LaPlante, Carlson, Kaye, & Bradsher, 1996; Nicholson, Biebel, Williams, & Katz-Leavy, 2004). Moreover, families in which an adult has a disability have an increased likelihood of having at least one child with a disability (LaPlante et al., 1996). Caregivers with disabilities and/or persistent illness have not historically received services from occupational therapy practitioners or other rehabilitation providers. Despite a functional approach, few rehabilitation providers have been responsive to an individual's

needs as a parent. One cancer survivor stated, "Nobody ever asked me if I had children" (Tannen, 2000).

Caregivers with disabilities face the same daily responsibilities and stresses associated with childrearing as do those without disabilities. Having a disability adds additional challenges, and limitations associated with a disability can affect a caregiver's ability to perform daily occupations. Caregivers may have physical, cognitive, or psychiatric challenges. Other factors that can put an individual at risk for difficulty in caregiving include being a teen parent, having a history of substance abuse, having been abused in childhood, domestic violence, and divorce (Huxley & Warner, 1993; Kowal et al., 1989; Panzarine, 1988). Moreover, to the extent to which disability and other risk factors are associated with poverty, a lack of knowledge of and access to supports and resources, lack of education, lack of skills, and limited life experience, parents with disabilities may face even more daunting challenges (Whitman & Accardo, 1993).

Current research on the effects of disability and persistent illness on parenting is limited. Disability or illness is often viewed as the predominant characteristic of the individual. Emerging from this perception of disability are numerous stereotypes concerning parents with disabilities and illness. These stereotypes include the ideas that parents with disabilities are too immersed in their own self-care to adequately care for their children, that children are used to satisfy the personal needs of parents with disabilities, that parental tasks cannot be performed effectively by parents with disabilities, and that parents with disabilities pass on a negative self-image to their children. These stereotypes can be challenged with interventions to support parents (Tannen, 2000).

Parents with Physical Disabilities

Parents with physical disabilities may have compromised mobility, movement, and/or stamina, which present challenges to the physical demands of parenting. A national survey of parents with disabilities that was conducted in the late 1990s indicates that parents with physical disabilities encounter multiple barriers to parenting and have service needs across multiple areas (Toms Barker & Maralani, 1997). Many parents reported needing adapted baby- and child-care equipment; barriers to obtaining equipment included lack of availability and cost. A majority of parents reported using personal assistance services for help with caregiving, yet many felt that these services interfered with their role as parents. Parents also reported having difficulty in obtaining affordable accessible housing, needing assistance in recreation with their children, and encountering problems with transportation that interfered with or prevented routine child-care activities (Kirshbaum & Olkin, 2002; Toms Barker & Maralani, 1997).

Thus, parents with physical disabilities can be helped by environmental modifications that allow them to participate

fully in their role as parents (Farber, 2000). Occupational therapists at Through the Looking Glass, a community-based nonprofit organization in Berkeley, California, that provides services to parents with disabilities, have developed resources and training materials on adaptive baby-care equipment for parents with physical disabilities (Vensand, Rogers, Tuleja, & DeMoss, 2000). Parents with conditions that are characterized by periods of symptom exacerbation and diminution, such as multiple sclerosis or rheumatoid arthritis, might need assistance in planning for these periods and in accessing community support services that will be useful during exacerbations (Crist, 1993). Women with physical disabilities who are planning pregnancy might need to consider the possible medical complications that can occur with disability. Prospective mothers need practitioners who have positive attitudes and expertise in managing pregnancy in women with physical disabilities (Toms Barker & Maralani, 1997).

Parents with Cognitive Disabilities

Parents with cognitive disabilities might lack knowledge and skill in specific areas of parenting, such as providing for a child's safety, nutrition, or daily routine care. These parents can have difficulty with problem solving, social skills and advocacy for family needs. For example, a woman with a traumatic brain injury, which can cause cognitive and social skill deficits, might have a difficult time assisting her 12-year-old daughter in solving social problems between friends at school (Uysal, Hibbard, Robillard, Pappadopulos, & Jaffe, 1998).

Parents with cognitive disabilities might have difficulty following directions or learning new skills. They might tend to overgeneralize skills and problem-solving strategies to contexts that require different or more complex skills. Individuals with cognitive disabilities have greater success in learning when strategies are broken down into steps; are demonstrated, modeled, and practiced; and are paired with rewards. Because of difficulties with generalization, skills-training services to parents with cognitive disabilities should be provided in naturally occurring environments, such as the home and community (Bakken, Miltenberger, & Schauss, 1993).

Parents with Psychiatric Disabilities

The stigma associated with mental illness is probably the most pervasive factor affecting access to and participation in services among parents with psychiatric disabilities. Because of the presumption that people with psychiatric disabilities are compromised in their ability to parent, many parents do not seek support services because they fear the loss of custody of their children. Parents with psychiatric disabilities (and those with developmental dis-

abilities) are at an increased risk of custody loss, yet many parents with psychiatric disabilities are raising or helping to raise their children (Hemmens, Miller, Burton, & Milner, 2002; Nicholson, Biebel, Hinden, Henry, & Stier, 2001; Wong, 1995).

The needs of a family in which a parent has a psychiatric disability are often not addressed until the child is in need of services. When services are provided, they are often child-centered and provided by clinicians who are not trained to work with adults. Moreover, services have tended to be problem-focused and deficit-based rather than preventive or strengths-based (Nicholson, Geller, Fisher, & Dion, 1993). Across the country, strengths-based, family-centered services that are specifically targeted to the needs of parents with psychiatric disabilities and their children are rare, but their numbers appear to be growing. Recent efforts by Nicholson and colleagues have focused on articulating the needs of parents with psychiatric disabilities and their families and on identifying emerging practices to build an evidence base for services for these families (Hinden, Biebel, Nicholson, Henry, & Katz-Leavy, 2006; Nicholson & Henry, 2003a; Nicholson, Hinden, Biebel, Henry, & Katz-Leavy, in press).

Parents with psychiatric disabilities may benefit from parenting skills training and from training in strategies to cope with exacerbations in symptoms. For example, parents might need help in planning for care for their children during times when the parent need to be hospitalized. Parents can also benefit from training in ways to advocate for services for themselves and their children (Henry & Nicholson, 2005). Peer support groups can provide opportunities to build social networks and decrease isolation. A strong social support network can act as a mediator of stress, increasing the parent's functioning during stressful times. Extended family members can be an important source of support for parents with psychiatric disabilities. However, in instances when parents with psychiatric disabilities have strained or disrupted relationships with their families of origin, extended family members might not offer support or might even undermine the individual's role as parent. Many parents worry about their children's understanding of mental illness; practitioners can help parents to develop ways of talking with children about mental illness that are age-appropriate (Nicholson, Henry, Clayfield, & Phillips, 2001).

Nicholson and Henry (2003b) developed a collaborative goal-setting checklist, the *ParentingWell® Strengths and Goals* form (Box 49.1), which practitioners can use together with parents to help parents identify things that they do well, to determine the things that parents would like to do better, and to set priorities for change. Although developed for use with parents with psychiatric disabilities, the form lists typical parenting responsibilities and concerns and so can be appropriate to use

BOX 49.1	PARENTINGWELL® STRENGTHS & GOALS

Here is a list of things you may need to do as a parent. For each one that applies to you, *circle* the answer that describes you best.	This is a strength of mine.	I do this okay.	I'd like to do this better.	Does not apply.	Check items to work on.
1. Manage everyday household tasks	Strength	Okay	Better	DNA	
2. Plan and make healthy meals	Strength	Okay	Better	DNA	
3. Understand the relationship between my feelings and my actions	Strength	Okay	Better	DNA	
4. Manage my family's money	Strength	Okay	Better	DNA	
5. Set limits with my child	Strength	Okay	Better	DNA	
6. Have positive interactions/visits with my child	Strength	Okay	Better	DNA	
7. Have a pleasant routine with my child	Strength	Okay	Better	DNA	
8. Find fun things to do with my child	Strength	Okay	Better	DNA	
9. Get adequate child care for my child	Strength	Okay	Better	DNA	
10. Balance work or school, and parenting	Strength	Okay	Better	DNA	
11. Know what to do when my child has problems	Strength	Okay	Better	DNA	
12. Identify my child's strengths	Strength	Okay	Better	DNA	
13. Have positive "family time"	Strength	Okay	Better	DNA	
14. Know my legal options as a parent	Strength	Okay	Better	DNA	
15. Get help for myself, if I need it	Strength	Okay	Better	DNA	
16. Talk with my child about my situation or worries	Strength	Okay	Better	DNA	
17. Keep in touch with my child who is not living with me	Strength	Okay	Better	DNA	
18. Live a substance free lifestyle	Strength	Okay	Better	DNA	
19. Communicate well with my child	Strength	Okay	Better	DNA	
20. Have good relationships with my child's caregivers/helpers	Strength	Okay	Better	DNA	
21. Express anger without hurting anyone	Strength	Okay	Better	DNA	
22. Keep my child and myself safe	Strength	Okay	Better	DNA	
23. Make time to take care of myself	Strength	Okay	Better	DNA	
24. Manage stress and worries in healthy ways	Strength	Okay	Better	DNA	
25. Cope with bad things that have happened to me in my life	Strength	Okay	Better	DNA	
26. Get special services and supports for my child	Strength	Okay	Better	DNA	
27. Other:	Strength	Okay	Better	DNA

with a variety of parents served by occupational therapy practitioners.

INTERVENTIONS FOR CAREGIVERS

Occupational therapy can involve the provision of direct or indirect services. In partnership with parents and caregivers, practitioners can provide direct services in skills training, environmental adaptations, or support services.

Areas of skills training may include the following:

- Helping the caregiver to organize daily and weekly schedules to support the well-being of the caregiver and recipient, including engagement in meaningful occupations and physical well-being
- Teaching the caregiver biomechanical principles to promote proper alignment of the body and safety for both caregiver and recipient

CASE STUDY: *A Mother with Depression*

Missy, a mother of two who has coped with depression for many years, talks about the importance of connecting with others:

I can't possibly overstate the importance of my support network in getting me through rough times. My family, my friends, my doctor, my minister—they have all been my scaffolding during bad times and good. There is nothing like experiencing a mental illness (or any other, for that matter) to teach you the strength of those bonds. Something my minister said to me once had a huge impact on me. I was in the midst of a terrible depression, and, as happens with a depressed mind, I kept thinking that eventually everybody would get tired of my dark mood and not want to be around me anymore. I felt like I was sucking all the good energy out of these people I love so much and giving nothing back but darkness and despair. On a particularly bad day, my minis-

ter said to me, "You need to know that you are still a blessing to other people, even during your darkest moments." It was a lesson in what it means to love and be loved—that good relationships can endure the ups and downs. I can't think of a lesson more relevant to the job of parenting, which is all about unconditional love. Parenting is the world's hardest job, with or without a chronic illness. As much as I would prefer not to have this illness, it has taught my children early on in their lives about the need for compassion and that nobody, not even Mom, is without challenges in life. And they have benefited from the care of so many people who have been there to help. If it truly "takes a village to raise a child," and I think it does, it means you have to push back against the tendency to isolate yourself in your own home, to be willing to ask for help and then be willing to accept it when it is offered.

- Teaching parenting skills such as home maintenance, time and money management, child behavior management, and advocacy for services
- Teaching parents to support their child's development and to nurture their relationship with their child
- Helping caregivers to communicate with recipient about disability

Environmental adaptations may include the following:

- Creating living spaces in the home that are accessible for family members with disabilities

- Helping caregivers to access human and other resources
- Designing or choosing adapted caregiving equipment with design features that promote safety and proper body alignment
- Designing environments to minimize fatigue

Support services may include the following:

- Providing support groups for family caregivers or parents with disabilities
- Accessing naturally occurring resources such as friends, neighbors, and community services

---

COMMENTARY ON THE EVIDENCE

Intervention for Caregivers

A meta-analysis of the research on caregiver intervention has shown that such intervention can result in positive outcomes for families (Sorensen, Pinquart, & Duberstein, 2002). One impressive example is an occupational therapy intervention designed by Laura Gitlin and her colleagues. They conducted a randomized controlled study of the effectiveness of their Home Environmental Skill-Building Program, a skills training intervention to help families manage dementia care problems at home. The program, consisting of home visits and telephone sessions, focused on education, problem solving, communication, environ-

mental and task simplification techniques, and home modifications (Gitlin & Corcoran, 2005). The recipients of intervention reported less upset with memory-related behaviors, less need for assistance from others, and better affect. Their spouses reported less upset with disruptive behaviors. Men reported spending less time in daily oversight, and women reported less need for help from others, better affect, and enhanced management ability, overall well-being, and mastery relative to control group counterparts (Gitlin et al., 2003). These findings provide valuable support for the benefits of occupational therapy interventions for caregivers.

In addition to direct services, practitioners can provide indirect services, such as advocacy for the needs of families in which a member has a disability or referral to a range of community-based services that may be available for parents and caregivers. These can include formal services such as mental health and substance abuse services, Early Intervention and Head Start programs, school-based services, and respite services. In addition, there are a variety of informal services that may benefit parents and caregivers. These can include national self-help and support groups such as Children and Adults with Attention Deficient/Hyperactivity Disorder (CHADD), the National Depressive and Manic Depressive Association, and the Alzheimer's Association. Many of these national groups have local chapters. Finally, there are many community supports, such as faith-based institutions, community centers, and libraries, that provide assistance to parents and caregivers.

SUMMARY

Childrearing and caregiving are complex lifelong occupations. Across the life course, individuals are likely to engage in parenting and or caring for other family members. People who are engaged in these occupations might benefit from direct or indirect interventions to support their nurturing role. Engaging caregivers in meaningful occupations has the potential to contribute to the well-being of both caregivers and care receivers.

Occupational Therapy Evaluation and Intervention Related to Education

YVONNE L. SWINTH

Learning Objectives

After reading this chapter, you will be able to:

1. Identify different educational settings in which an occupational therapist may provide services.
2. Describe the OT process within an educational setting.
3. Recognize key requirements of occupational therapy services under the Individuals with Disabilities Education Improvement Act.
4. Describe how a disability may affect the occupation of student.

OCCUPATIONAL THERAPY IN EDUCATIONAL SETTINGS

Occupational therapy practitioners work in a variety of educational settings. These may include public schools, charter schools, private schools, alternative schools, vocational schools, and university settings (Case-Smith, Rogers, & Johnson, 2001). Across these settings, practitioners work with students in a variety of age groups across the age span. For example, an occupational therapy practitioner might work with young children in a preschool or elementary-age children in public schools or adolescents in an alternative high school. Occupational therapists might also work with an older adult client who is returning to school to learn a new skill after an injury (e.g., work

hardening, job retraining) or for personal enhancement (i.e., leisure activity). Public schools are the most common work setting for occupational therapy practitioners; more than 30% of all practitioners who are members of the American Occupational Therapy Association (AOTA) identify public school as their primary work setting (AOTA, 2003). According to the Bureau of Labor Statistics (2006), "employment growth [for occupational therapy practitioners] in schools will result from the expansion of the school-age population, the extension of services for disabled students, and an increasing prevalence of sensory disorders in children. Therapists will be needed to help children with disabilities prepare to enter **special education** programs." It also is anticipated that the niche for occupational therapists working in other educational settings (e.g., colleges, universities, community colleges, and continuing education venues) will grow as these children become young adults and desire to continue their education.

The primary focus of this chapter is on the evaluation and intervention of occupational performance within early intervention and public schools, since this is the most common educational setting that employs occupational therapy practitioners. However, the reader is encouraged to consider the wide variety of educational settings that may benefit from the skills and expertise of an occupational therapist. These types of occupational therapy services may be innovative and preventive and may increase the occupational performance of individuals in ways that historically have not been explored or considered. For example, occupational therapy practitioners might develop a health promotion program for an entire school system to increase students' engagement in physical activity. Colleges or universities may benefit from an occupational therapist's expertise in addressing universal design, access to curricular materials for students with disabilities, or ergonomic needs of staff and students. Many of the principles that are discussed in this chapter can be generalized to any educational setting.

A variety of legislative and funding sources support occupational therapy services in different educational settings. While the Individuals with Disabilities Education Improvement Act (IDEA, 2004) specifically addresses services in early intervention and schools, every educational setting must meet the requirements of Section 504 of the Rehabilitation Act (1973) as well as the Americans with Disabilities Act of 1990 (ADA) (P.L. 101-336). Thus, occupational therapy services in settings such as universities and continuing education venues can be provided under Section 504 and the ADA. Section 504 supports reasonable accommodations for individuals with a disability, a history of a disability, or a perceived disability if accommodations are needed to allow the individual to participate in educational settings. The ADA is a civil rights act and provides protection to individuals with disabilities similar to those provided to individuals on the basis of race, color, sex, national origin, age, and religion. The ADA supports the right of individuals with disabilities to have equal opportunities to live, work, and play within society (including educational settings).

Additionally, an occupational therapy practitioner may work in a hospital or private clinic as the primary work setting and contract services to an educational setting. In some instances, a public school district may hire occupational therapy practitioners to provide services to any student that needs their support (special education or general education). Table 50.1 provides an overview of legislation and funding that support occupational therapy services in educational settings.

Practice within the public schools is guided by federal legislation, with a focus on the occupation of education and the role of the student. Occupational therapists began working in the schools after 1935, when federal grants to the states created Crippled Children's Services under a special section of the Social Securities Act. Initially, these services were provided in segregated settings or special schools and primarily to children with orthopedic and neurological impairments (Hanft & Place, 1996). In 1975, the Education for All Handicapped Children Act (EHA) (P.L. 94-142) was enacted. This act required states to provide special education and **related services**, including occupational therapy, to all eligible children ages 6 through 21. Amendments to the EHA in 1986 (P.L. 99-457), added services for preschoolers (ages 3 to 5 years), and provided incentives for states to develop statewide systems for providing early intervention services to infants, toddlers, and their families. In 1990, the EHA was renamed the Individuals with Disabilities Education Act, or IDEA (P.L. 101-476), and additional services were added. These included assistive technology devices and services, transition services, and increased focus, funds, and programs for children with emotional disturbances. Further amendments were made to the IDEA in 1997 (P.L. 105-117), which mostly fine-tuned the original intent of the law (AOTA, 1999) and included increased emphasis on access to the general education curriculum for students with disabilities (see Box 50.1).

The latest amendments were completed in December 2004, and the name was changed to the Individuals with Disabilities in Education Improvement Act—IDEA 2004 (P.L. 108-446) or "the new IDEA." These amendments continued the trend toward increased access to the general education curriculum and increased the emphasis on pre-referral intervention or **early intervening services** (commonly referred to as *response to intervention* or RtI) by bringing more of the IDEA 2004 in line with the No Child Left Behind Act of 2001. The amendments also place an emphasis on the use of scientifically based (research-based, evidence-based) practices, high-quality preservice training and professional education, dispute resolution without going to court, increased representation of minorities in fields such as teaching and occupational therapy, and the use and development of appropriate technology (including

TABLE 50.1 OCCUPATIONAL THERAPY SERVICES IN EDUCATIONAL SETTINGS

Legislation/Sources of Funding	Population Served	Role of Occupational Therapist
Individuals with Disabilities Education Improvement Act of 2004 (IDEA, 2004)	Students who are eligible for special education and require the related service of occupational therapy in order to receive FAPE in the LRE (IDEA 2004 is applicable only for students (age 0 to 21) who receive special education services through their public school setting.)	To collaborate with the IEP team to determine the student's needs and then to provide services as outlined in the IEP in order to support student performance relevant to the educational environment.
Section 504 of the Rehabilitation Act	Students who have a disability, a history of a disability, or a perceived disability that affects their performance in school. (In the public schools, these are generally students who are not eligible for special education.) Students who meet the definition of "individual with a disability" are defined as those individuals who have a physical or mental impairment that substantially limits one or more major life activities.	To collaborate with the 504 team to provide the accommodations and adaptations that the student needs to access the school environment and services.
Americans with Disabilities Act (ADA)	The ADA ensures equal opportunity for individuals with disabilities in employment, state and local government services, public accommodations, commercial facilities, and transportation. Thus, it is a civil rights legislation that supports participation in the educational setting by students who have a disability.	To provide support through consultation and monitoring to ensure that students with disabilities have access to and can participate in the educational setting. Often involves working with environmental adaptations, accommodations, and the use of assistive devices.
Other funding sources ◆ General education funds (for public schools) ◆ Private insurance ◆ Private agencies (e.g., United Cerebral Palsy) ◆ State agencies (e.g., Division of Vocational Rehabilitation)	Any student who needs the support of an occupational therapy practitioner.	To support student performance in occupations relevant to the educational environment.

Adapted from Swinth, Y., Chandler, B., Hanft, B., Jackson, L., & Shepherd, J. (2003, April). *Personnel issues in school-based occupational therapy: Supply and demand, preparation, and certification and licensure.* Gainesville, FL: Center on Personnel Studies in Special Education. Retrieved July 15, 2003, from http://www.coe.ufl.edu/copsse

assistive technology). It should be noted that this emphasis on the use of research to inform practice is applicable across all educational settings, not just the public schools, owing to both policy priorities and the priorities of the AOTA.

Since 1975, the key goals of the IDEA 2004 (originally the EHA) have remained the same (see Box 50.2), with an increasing shift from the old paradigm of "if we cannot fix them, we exclude them" to a new paradigm of "disability as a natural and normal part of the human experience" (Silverstein, 2000, p. 1761). Thus, the role of occupational therapy under the IDEA 2004 has shifted to include a focus on contextual factors such as access to the environment so

that individuals with disabilities can participate in their environments rather than on "fixing" the disability.

The IDEA 2004 has four parts, A through D; however, this chapter will primarily address parts B and C. (Part A addresses the general provisions of the IDEA, and Part D addresses research and training.) A positive addition to the 2004 amendments is the inclusion of related service providers, including occupational therapists, as a priority for monies and support, under Part D, related to research and training. Under Part C of the IDEA 2004, occupational therapy can be a primary service for infants and toddlers from birth through 2 years of age who are eligible for early intervention services (AOTA, 1999). Part B of the IDEA 2004 identifies occupational therapy, as a related service, for children ages 3 through 21 years for whom the team determines the service is necessary in order for students to benefit from their special education program. Two key concepts of Part B of the IDEA 2004 are a **free appropriate public education** (**FAPE**) in the **least restrictive environment** (**LRE**). (See Box 50.3 for definition of key terms found within the IDEA 2004.) The IDEA 2004 allows each state and local education agency some latitude in how the federal legislation will be imple-

BOX 50.3

COMMON TERMS IN THE IDEA 2004

Early intervening services: Academic and behavior support to succeed in general education but is not part of special education.

Free Appropriate Public Education (FAPE): Special education and related services provided at public expense that meets the standards of the state education agency (SEA).

General education: The environment, curriculum, and activities that are available to all students.

General education curriculum: The same curriculum as for nondisabled children.

Individualized Education Program (IEP): A commitment of services that ensures that an appropriate program is developed that meets the unique educational needs of children ages 3–21.

Individualized Family Services Plan (IFSP): A commitment of services that ensures that an appropriate program is developed that meets the unique developmental and preeducational needs of children 0–3 and their families.

Least Restrictive Environment (LRE): The environment that provides maximum interaction with nondisabled peers and is consistent with the needs of the child/student.

No Child Left Behind: P.L. 107-110, aimed at improving the educational performance of all students by increasing accountability for student achievement. Emphasizes standards-based education reform with the belief that high expectations will result in success for all students.

Related services: Transportation and such developmental, corrective and other supportive services (including speech-language, audiology, psychological, and physical and occupational therapy services) needed to help the child benefit from special education.

Response To Intervention (REI): An integrated approach to service delivery that includes both general and special education and includes high-quality instruction, interventions matched to student need, frequent progress monitoring and data-based decision making.

Special education: Specially designed instruction at no cost to parents to meet the unique needs of a child with a disability.

Source: Adapted from National Council on Disabilities. (2000). *Back to school on civil rights: Advancing the federal commitment to leave no child behind.* Washington DC: National Council on Disabilities

mented as long as the FAPE and LRE provisions are not compromised. Thus, there are differences across states and local programs regarding the specifics of how services are provided under the IDEA 2004.

The purpose of the IDEA 2004 is "to ensure that all children with disabilities have available to them a free appropriate public education that emphasizes special education and related services designed to meet their unique needs and prepare them for further education, employment and independent living" (Section 300.1). Occupational therapy practitioners in the public school setting provide services within this structure and are generally a related (supportive) service to the educational program (specially designed instruction). Students come to school to get an education, and in the schools, occupational therapy serves this priority. Thus, occupational therapy services in an educational setting are different from services in a clinical setting.

FACTORS THAT INFLUENCE THE OCCUPATIONAL THERAPY PROCESS IN EDUCATIONAL SETTINGS

A variety of factors affect the occupational therapy process in educational environments. Two key factors are the composition of the educational team and how decisions are made. Regardless of the educational setting in which an occupational therapist works, typically, a team of professionals typically influence the occupational therapy process.

Educational Teams

The concept of teaming, or collaborating as a team, to make decisions about the program and services to be provided has been a guiding principle of occupational therapy services in public schools since the inception of federal law. With the reauthorization in 1997, the IDEA became more explicit regarding the emphasis on teaming and collaboration among professionals and families to make effective decisions about student need(s). The IDEA 1997 clearly specified that whenever decisions are made about a student, the parents or caregivers must be involved. Two types of teams are involved in a student's program: the evaluation team and the Individualized Education Program (IEP) team. Both teams must include qualified professionals who are knowledgeable about the student and his or her need(s). If a decision is being made about occupational therapy involvement in a student's program, then an occupational therapist must be involved in the teaming process. The IDEA 2004 has maintained these tenets regarding decision-making and teams, although according to IDEA 2004, a team member may not attend a meeting, if there is written permission from the parent and the absent team member sends relevant data to the meeting.

In the public schools, the specific composition of each team is driven by the student's needs and may include general and special education teachers, therapists (physical, occupational, and speech), psychologists, counselors, parents, the student, and different community members. The focus of the team decision-making process must be on student outcomes and performance with an emphasis on participation in the general education environment whenever possible.

Team Decision Making

Effective and efficient delivery of services in the school environment requires a systematic process for team decision making and problem solving. There is a tendency by professionals to identify a need and immediately start proposing and implementing solutions without first identifying the necessary outcomes needed for the student to participate in the educational environment. Educational teams employ a variety of tools that support a systematic process of decision making and team problem solving (e.g., McGill Action Planning System, Choosing Outcomes and Accommodations for Children). For example, the McGill Action Planning System (MAPS) consists of seven specific questions that support the planning process and identification of team generated outcomes for students with disabilities (O'Brien, Forest, Snow, Pearpoint, & Hasbury, 1989). The questions include the following:

1. What is the student's history?
2. What are your dreams for the student?
3. What are your fears for the student?
4. Who is the student? (one-word statements that describe the student)
5. What are the student's strengths, gifts, and abilities?
6. What are the student's needs?
7. What would the student's ideal day at school look like and what must be done to make it happen?

A typical MAPS planning session can take up to two hours. The entire team (parents, students, therapists, and teachers) as well as other invited members (siblings, other family members, or community members) provide input in answer to each question. The questions are not quick or easy to answer, but the result of a good planning session is a strong foundation from which to develop the student's program, including any occupational therapy services. The process focuses on the value of integrating the student in neighborhood schools and in general education classes in order to develop friendships and to ensure a high-quality education for the child (Vandercook & York, 1988). By the time the team members are addressing question 6 ("What are the student's needs?"), they have the background to be able to establish both short-term and long-term outcomes. These outcome goals are then used to guide a discussion regarding the student's ideal day and how to get there.

One primary role of the occupational therapy practitioner in the school setting is to contribute to the evaluation process. Ideally, this is done in a collaborative manner with other team members. The practitioner's contribution might be to help the educational team determine eligibility for special education and/or related services and/or collaborate to determine the need for occupational therapy. Several key assumptions underlie the evaluation process in schools under the IDEA 2004 that occupational therapy practitioners do not have to address in other settings. These assumptions are briefly discussed below.

ASSUMPTIONS ABOUT THE EVALUATION PROCESS IN THE SCHOOLS

As with other occupational therapy practice areas, the **evaluation** process in the schools is dynamic and ongoing and often continues during intervention (Stewart, 2005). According to the IDEA 2004, the evaluation determines whether a child has a disability and the nature and extent of the special education and related services that the child needs (Section 300.15). The IDEA 2004 does not require use of a specific type of **assessment** method or tool. Rather, it requires that a variety of tools and strategies be used to gather relevant "functional and developmental information" related to enabling the child to "be involved in and progress in the general education curriculum" (Section 300.304(1)). In addition, the evaluation should help to determine the child's educational needs and how the disability affects the child's participation in school activities. A child does not "qualify" for occupational therapy on the basis of testing under the IDEA 2004. Instead, occupational therapy services should be recommended and provided for a child if necessary for the child to "benefit from their special education program." Even though the evaluation process in the schools is guided by federal law, occupation remains the core of the occupational therapy practitioner's theoretical perspective. Within the educational setting, therapy practitioners draw on the appropriate frames of reference to guide the evaluation process.

In the public schools, a team of qualified individuals, which may include an occupational therapist, school psychologist, special education and general education teachers, physical therapist, speech-language pathologist, and others, is responsible for conducting the evaluation. The purpose of the evaluation process is not only to determine the student's needs in order to have access to the educational environment to the maximum extent possible, but also to determine the student's needs in order to perform within the school setting. Additionally, the IDEA 2004 requires that the evaluation help to determine services that will support a student's ability to demonstrate outcomes with a focus on the general education curriculum.

Therefore, the evaluation process is driven by contextual factors (the school environment) and student (client) needs (Dunn, Brown, & McGuigan, 1994). In other educational settings, although the IDEA 2004 requirement to have a "team of qualified professionals" is not mandated, it is consistent with best practice. In most other settings, the team will be smaller, but seldom does an occupational therapy practitioner make decisions in isolation. Regardless of the setting, the emphasis of the evaluation is on the occupational performance area of *education.* However, other areas of occupation such as social participation might need to be addressed if participation in these areas is affecting educational performance.

The evaluation process should be individualized (student-centered) and should use a top-down approach (Coster, 1998). This means that the occupational therapy evaluation should start by looking at student performance within context versus evaluating specific client factors out of context. As with any occupational therapy evaluation, a broad view of the student (client) must be considered. Thus, the emphasis is on the educational context, including physical, temporal, social, and cultural considerations. Within the educational setting, the focus of special education and related services is on student outcomes. If the educational staff and/or parents require services (e.g., specialized training) for the student to reach his or her outcomes, then the practitioner is responsible for addressing these needs (Primeau & Ferguson, 1999) as well as broader systems issues (e.g., curriculum, environmental adaptations) that might require occupational therapy input and support (Muhlenhaupt, 2003). Under the IDEA 2004, occupational therapy services are supportive in nature in order to help the child be successful in school as well as in after-school activities (Giangreco, 2001). Additionally, services can be provided "on behalf of" the child and "to the parents, teachers and other staff" so that these individuals can better support the child's learning (see Table 50.2).

THE EVALUATION PROCESS

The occupational therapist in the school setting focuses his or her evaluation on what is needed for the student to engage in meaningful and purposeful school occupations. The occupational therapy evaluation addresses the student's areas of strengths and concerns in areas of occupation, including activities of daily living, education/work, play/leisure, and social participation. In each of these areas, the occupational therapist addresses the performance skills and the student's physical, sensory, neurological, and cognitive/mental function. First, an occupational profile is developed in collaboration with the team, including the family and student, as appropriate. This profile is followed by an analysis of the student's occupational performance within the educational setting.

TABLE 50.2	CLIENTS TO CONSIDER DURING THE OCCUPATIONAL THERAPY EVALUATION PROCESS
Client	**Evaluation Consideration(s)**
Student	Gather data regarding the occupational profile and occupational performance
Parents/educational staff	On the basis of the student's occupational profile and occupational performance, determine whether there is any need for specific training, support, and/or dissemination of information.
System	On the basis of the student's occupational profile and occupational performance, determine whether any system supports (e.g., environmental modifications, curriculum development) are needed.

Following is a brief description of the occupational therapy evaluation process. The specific role of the occupational therapist during the evaluation process for any given student will depend on the expertise and skills of all the team members as well as the referral concerns. There may be overlap across professional disciplines regarding specific skills accessed (e.g., gross motor skills with physical therapy, feeding with speech therapy, or psychosocial issues with psychology), but the input of an occupational therapist is needed because of the unique emphasis of occupational therapy on occupation and context/environmental factors that affect occupational performance (see Fig. 50.1).

As in all other settings in which occupational therapy practitioners work, the occupational therapist is responsible for the administration of the evaluation methods and measures, the interpretation and documentation of results, and the communication of evaluation results with other team members. However, if an occupational therapy assistant is part of the team, he or she may contribute to any part of the process under the direct supervision of the occupational therapist.
Referral

Generally, the process of referral within the school setting is different from that in a clinical setting. As with any procedures within special education, specific steps can vary from state to state or from setting to setting. However, in most public school situations, if there is a concern about student performance, a team of professionals will discuss and implement different strategies within the general education classroom before referring the student for special education. If these strategies are not successful, then the student is referred for a special education evaluation to determine eligibility for services. Occupational therapy might or might not be involved in this step of the process. If the occupational therapist is not involved in the initial evaluation process, then the team may request an occupational therapy evaluation at any time after determining that the student is eligible for special education. If the occupational therapist is working in a state where the occupational therapy practice act requires a physician referral for services, then such a referral may be necessary before the implementation of services. If a physician refers a student for an occupational therapy evaluation, this referral does not guarantee services in a school setting. The occupational therapist in the public school must first ensure that the student is eligible for special education and then determine whether services are necessary for the student to benefit from his or her education program.

In other educational settings, the referral process may be less formal. For example, in some university settings, a referral might come through the center for disability access (e.g., a student access concern) or human resources (e.g., a staff ergonomic concern). Therapists who provide services in these types of settings might need to develop a referral system to ensure that the process meets the needs of the client(s). If a physician referral is required by a state

FIGURE 50.1   Occupational therapists evaluate a student's occupational performance within the educational context.

practice act, then the occupational therapist must comply with this requirement regardless of the setting.

Early Intervening Services

Over the years, educators and others have recognized the importance of providing appropriate support, when needed, as early as possible to students who are struggling. However, the current special education system requires that a student fail before being able to receive services. Over the past few years, some districts have explored providing services as early as possible. Because of the positive outcomes (e.g., many of these students never require special education services) of these services, the IDEA 2004 supports the option for a small amount of special education funds to be used for early intervening services or response to intervention (RtI). Within the IDEA 2004, RtI is defined as services that are provided for students, not in special education, who need "additional academic and behavioral support to succeed in a general education environment" (Section 300.226). Thus, in the public schools, when a classroom teacher is concerned about a student, initial interventions can be developed and implemented through a collaborative team process before the student is referred to special education. Increasingly, occupational therapy practitioners are involved with the planning and implementation of such prereferral or early intervening services. In some cases, effective prereferral interventions, such as the use of a move-and-sit cushion for a fidgety student or the development and implementation of a handwriting curriculum, may successfully support the student within the educational environment, and further intervention might not be needed.

Increasingly, research is suggesting that students need effective support when they first start having difficulty in school. Thus, IDEA 2004 has included early intervening services within the statutes. At this time, these services are not mandated, but part of special education funds (up to 15%) can be used by systems that wish to implement early intervening services. These services are for students "kindergarten through 12th grade (with particular emphasis on kindergarten through grade 3) who are not currently identified as needing special education or related services, but who need additional academic and behavioral support to succeed in a general education environment" (CFR, Section 300.226(a)). These supports are often referred to as *prereferral interventions* or *whole-school approaches.* Many districts are now implementing the RtI model to address this need (National Association of State Directors of Special Education, 2005).

RtI, which is based on research evidence and student outcome data, is an integrated approach to service delivery that includes both general and special education and includes high-quality instruction, interventions matched to student need, frequent progress monitoring, and data-

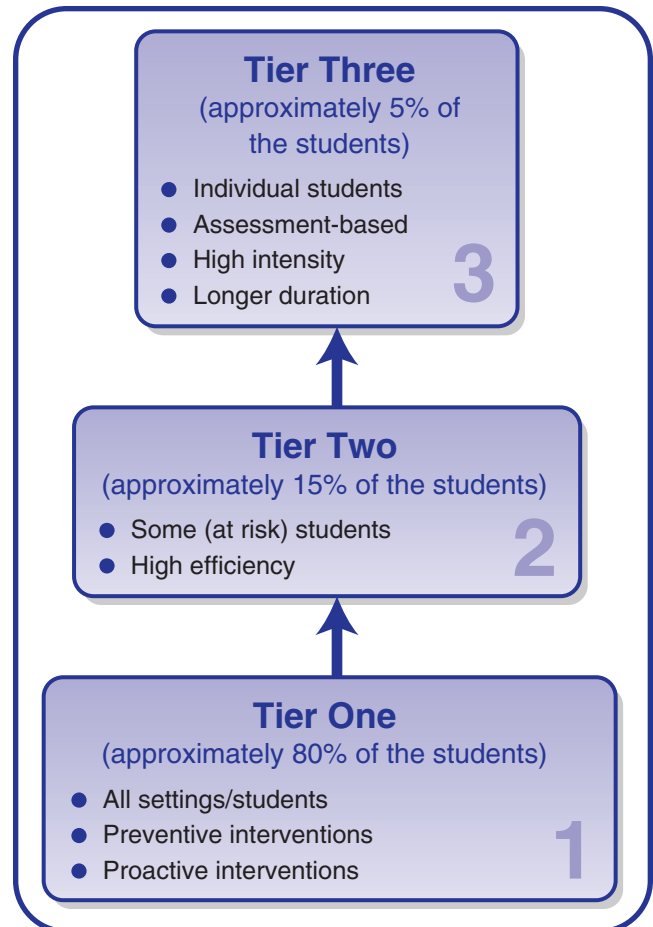
based decision making (NASDSE, 2005). It is a whole-school approach to services that are specifically directed at student need. RtI is based on a problem-solving model in which the team defines the problem, analyzes what is happening, develops a plan, and evaluates the effectiveness of the plan. This model generally uses a three-tiered approach to support (see Figure 50.2). The first tier involves screening and group intervention; this approach will generally address about 80% of the problems. The second tier is targeted, short-term interventions, addressing another 15% of the student needs. The final tier is intensive instruction, which is required by about 5% of the students. The role of occupational therapy at each tier varies across school districts. Some districts feel that the first tier should be addressed by the immediate team, whereas others include the occupational therapist early in the process. If the underlying concern is within the domain of occupational therapy, a therapist may be involved in the second or third tier of interventions. The following case study provides an illustration of how occupational therapy may be involved in early intervening services.


FIGURE 50.2 RtI three-tiered model. Adapted from NASDSE (2005).

CASE STUDY: *Early Intervening Services to Support Devon's Educational Program*

Background

Devon is 7 years old and in first grade. He has been having difficulty with literacy activities in the classroom since the beginning of the school year. His kindergarten teacher reports that Devon struggled the previous year as well but always "just made it." His first grade teacher is concerned that if Devon continues to struggle, he will eventually fall too far behind his peers to catch up. The elementary school that he attends has just started implementing prereferral interventions using a RtI model.

Tier One

Devon's student response team discusses his case with his first grade teacher. His teacher reports that he has difficulty copying and writing more than one or two words during any writing assignment. He often refuses to participate in reading activities as well. She reports that during literacy activities, Devon is fidgety and easily distracted and at times has behavioral outbursts. Using a problem-solving model, they determine that because it is November, they need to provide some proactive support to prevent future difficulties. The team decides to put Devon in a specialized literacy group that is explicitly designed to target first grade literacy outcomes. Occupational therapy was not involved during this first meeting because the team did not feel that there were concerns about Devon's performance

that required the skills and expertise of an occupational therapist.

Tier Two

For three months, Devon participated in the specialized literacy group, and data were systematically recorded to track the interventions that were used and Devon's progress. Devon's reading and writing skills improved, but he continued to be fidgety and easily distracted and to exhibit behavior problems during literacy activities. The team invites an occupational therapist to the second team meeting, wondering whether sensory processing might be affecting Devon's performance. The occupational therapist recommends strategies to the classroom teacher that can support Devon's sensory processing (e.g., use of a move-and-sit cushion, allowing Devon to hold small objects in his hand to fidget, use of a water bottle) during literacy activities. Devon's parents also agree to try these strategies at home. The teacher introduced the strategies to the entire group and allowed anyone to use them. Data were recorded to help Devon and the team determine the best strategies for him. The combination of the targeted instruction by the teacher and sensory strategies recommended by the occupational therapist resulted in improved performance, and Devon did not need to receive Tier Three intervention. One year later, he was still doing well.

In the public schools, if the early intervening services are not effective, the student is then referred to a special education evaluation team. The evaluation team determines whether the special education process, as outlined in the IDEA 2004, should be initiated or whether the student should be referred for some other type of support. Such support is provided under Section 504 of the Rehabilitation Act. For example, if a student requires additional accommodations or adaptations but does not require specially designed instruction to meet educational outcomes, then the evaluation team might not recommend a full special education evaluation. They would then refer the student to the school's 504 team. If the evaluation team feels that the student might need specially designed instruction (special education) in order to receive FAPE in the LRE, then the special education evaluation process would be initiated. Ideally, the occupational therapist should be involved throughout the decision-making process if the evaluation team feels that the student might require the services of an occupational therapy practitioner or that the student has needs that might require the expertise of an occupational therapist. Once the student is referred to special education and it is determined that the referral is appropriate, a team of qualified professionals design and initiate the evaluation.

The team should be knowledgeable about the student and the suspected areas of disability. The purpose of the evaluation is to determine whether the student has a disability, whether the disability adversely affects the student's educational performance in the general education curriculum, and the nature and extent of the student's need for specially designed instruction and any necessary related services.

THE OCCUPATIONAL THERAPY PROCESS

When occupational therapy is involved in the evaluation process, the occupational therapist can use the Occupational Therapy Practice Framework (AOTA, 2002a) as a guide to the process. As described below, the special education process closely parallels the occupational therapy process described in the Framework. A description of this process follows.

Occupational Profile

The occupational profile is developed by gathering data from the student, family, and educational staff (AOTA,

2002a). The occupational therapy assistant, community providers, and others who know the student also may contribute to this process. Often, the development of the occupational profile occurs over time. Several assessments and procedures that have been designed for use in the educational setting may be used to develop the occupational profile. Table 50.3 lists some of the assessments and procedures that are used in educational settings.

Most of these assessments are process oriented and must be completed with input from all team members, including the student and family. Many of the assessments have a problem-solving focus that addresses the student's strengths and concerns as well as contextual factors that may affect student performance and outcomes. The assessments also will help the occupational therapy practitioner to identify performance patterns and activity demands. By

OCCUPATIONAL PROFILE QUESTIONS FROM THE OCCUPATIONAL THERAPY PRACTICE FRAMEWORK (Adapted for the Educational Setting)

</td></tr>
</table>

1. Who is the student?
2. Why was the student referred to special education and/or for an occupational therapy evaluation in the schools?
3. In what areas of educational occupations (ADLs, education, work, play/leisure, and/or social participation) is the student successful, and what areas are causing problems or risks?

4. What contexts support engagement in desired educational occupations, and what contexts are inhibiting engagement?
5. What is the student's occupational history?
6. What are the student's, family's, and educational staff's priorities and desired target outcomes?

Adapted from AOTA (2002a).

completing one or more of these process-oriented assessments, the occupational therapy practitioner will have addressed most of the occupational profile questions that are outlined within the Occupational Therapy Practice Framework (see Box 50.4).

Analysis of Occupational Performance

Once the occupational profile has been developed, the occupational therapist works with the team to determine whether more specific assessments are needed to help further determine a student's needs. Within the educational setting, the occupational therapist addresses performance in all areas of occupation as it relates to the child's educational needs (see Table 50.4). Often the process-oriented tools not only help with the development of the occupational profile, but also help the occupational therapist better understand contextual factors, potential "whole-school approaches," and curricular and extracurricular issues. These tools help the occupational therapist to communicate observations of the person-activity-environment fit as it relates to the student's occupational performance in school.

TABLE 50.4   OCCUPATIONAL PERFORMANCE AREAS ADDRESSED FROM THE OCCUPATIONAL THERAPY PRACTICE FRAMEWORK (Adapted for the Educational Setting)

Occupational Performance Area	How Addressed in the Educational Setting
Activities of daily living (basic and instrumental)	Cares for basic self needs in school (e.g., eating, toileting, managing shoes and coats, dressing up and down for PE); uses transportation system and uses communication devices to interact with others
Education	Participates and performs in the educational environment including academic (e.g., math, reading, writing), nonacademic (e.g., lunch, recess, after-school activities), prevocational, and vocational activities
Work	Develops interests, aptitudes, and skills necessary for engaging in work or volunteer activities for transition to community life on graduation from school
Play/leisure	Identifies and engages in age-appropriate toys, games, and leisure experiences; participates in art, music, sports, and after-school activities
Social participation	Interactions with peers, teachers, and other educational personnel during academic and nonacademic educational activities including extracurricular and preparation for work activities

CASE STUDY: *Process for Developing an Occupational Profile for Kristi, A 13-Year-Old Student with Cerebral Palsy*

Background

Kristi is a 13-year-old student with tetraplegia cerebral palsy. She has received occupational therapy in the past in both clinical and school-based settings. Kristi and her family had recently moved, and the education team in her new school district decided to complete an evaluation to determine her educational needs.

Occupational Profile

The occupational therapist started gathering data for the occupational profile by talking to Kristi and her family and reviewing Kristi's past records. Through this process, the occupational therapist began to develop a summary of Kristi's occupational history and her strengths and concerns in the areas of occupation related to Kristi's educational program. The therapist then observed Kristi in her academic courses, physical education class, lunch, and transitional periods (e.g., on and off the bus, between classes). The team also met with Kristi and her parents to complete a MAPS.

Analysis of Occupational Performance

On the basis of the data that had been gathered, the occupational therapist summarized Kristi's occupational performance (strengths and concerns) related to most of Kristi's physical, sensory, neurological, and/or mental functions. Because Kristi had some difficulty with handwriting, the therapist also completed a Test of Visual Perceptual Skills and a Test of Visual Motor Skills to assess potential underlying client factors affecting Kristi's handwriting performance. The therapist also completed a manual muscle test to determine Kristi's strength and range of motion.

Summary

The occupational therapist summarized the following findings and recommendations to the educational team:

Occupational Performance Area	Strengths and Concerns
Activities of daily living (basic and instrumental)	Kristi is able to take care of her basic self-care needs within her school environment at this time. However, she has difficulty with some dressing activities that could affect her ability to participate in PE activities when she moves to the junior high and high school settings. Kristi and her mother also want Kristi to take a cooking class as soon as possible to determine Kristi's need for adaptive equipment for cooking. Kristi uses a school bus with a lift to get to and from school. She is able to communicate with her peers and teachers without any difficulty.
Education	Kristi is able to participate and complete assignments in her general education classes with accommodations and adaptations. She requires additional time to complete written assignments and utilizes a computer for longer papers. She needs to develop the self-determination skills necessary to independently problem-solve and implement accommodations/adaptations.
Work	Kristi states that she would like to be a lawyer or special education teacher. At age 14, the team will collaborate with Kristi and her parents to begin to develop her transition plan. This plan will support the assessment and address her needs for future environments.
Play/leisure	Kristi rides horses, swims at the YMCA, and enjoys playing computer games and watching TV.
Social participation	Kristi tends to keep to herself at school. Her mother states that Kristi is very social when at home with her family but that she has minimal interaction with other students her age. Kristi reports that she enjoys sports and that even though she cannot play, she would like to be involved by keeping scores or helping in some other way.

If it is determined that additional information about occupational performance related to physical, sensory, neurological, and/or mental functions of the student is needed, the occupational therapist may use standardized or nonstandardized assessments that focus on client factors (see Table 51.3). These assessments can help to determine specific information about occupational performance but should not be used without one or more of the process-oriented assessments. Additionally, the occupational therapist may use observation, parent or teacher interviews, and file review to support the analysis of a student's performance. The following case study describes the process of developing an occupational profile for Kristi, a junior high school student with cerebral palsy, as well as other steps of the occupational therapy process.

These findings and recommendations were included in the special education evaluation report, and the team used them to develop Kristi's special education program. Once her program was developed, the team discussed Kristi's need for occupational therapy support to meet her educational goals and objectives.

INTERVENTION

Occupational therapy service may address a student's performance in education, work, play/leisure, and social skills, with outcomes that are directed toward improving the student's participation in the curriculum, access to the school environment, and participation in extracurricular activities (see Fig 50.3 and 50.4). Within educational settings, occupational therapy practitioners need to be famil-

FIGURE 50.4 Occupational therapy facilitates student's use of a computer for written communication.

iar with and understand the educational environment in which they work as well the legislation and/or funding source(s) that support their involvement in the particular education setting.

Factors That Influence Occupational Therapy Interventions in Educational Environments

In addition to the setting and legislation, a variety of factors affect the planning and implementation of intervention by occupational therapy practitioners within educational environments. These include the unique characteristics of the system, the range of services provided, and the research evidence supporting intervention.

Unique Characteristics of the System

Each educational setting has unique characteristics that must be considered in planning and implementing intervention. Even within the same school district, different schools have unique strengths and barriers. Many occupational therapists who work in educational settings are itinerant and work among three or more schools. Variability can make it challenging for therapists to keep track of the uniqueness of different settings. Additionally, the different legislation (e.g., 504, ADA) and different emphasis (e.g., public schools, universities, continuing education, virtual classroom) also affect the uniqueness of the system. Therapists in educational settings need to attend to systemic issues, changes, and challenges in order to provide the most effective services. The reader is referred to Chapter 63 for an example of the reasoning of a school-based occupational therapist.

Range of Services

Occupational therapy practitioners provide a range of services in educational settings. Intervention may include

FIGURE 50.3 Occupational therapy in a group facilitates social and motor skills.

hands-on services (such as one-on-one or group activities) or team supports to identify and implement environmental adaptations and modifications to the physical layout of the school campus or the classroom. Finally, services may include system supports, which are activities such as working with the curriculum committee of a district to establish a handwriting curriculum or working with an elementary school principal to help design an accessible play area to be used during recess. Regardless of how services are provided, practitioners working in public schools must be aware of curricular issues such as education reform, standards-based assessment, and the requirements of general education. The IDEA 2004 requires that students with disabilities be considered for and have access to the general education curriculum whenever possible and be included in education reform and statewide assessments. Therefore, occupational therapy services may address the requirements of general education as well. For example, in some states, occupational therapists are being asked to address alternative assessments for students who have severe disabilities, or occupational therapists are involved in making decisions about reasonable testing accommodations for students with learning disabilities. To fully participate in these discussions and to support the implementation of the recommendations, the occupational therapist must have a basic understanding of the identified educational outcomes and testing requirements within the education system.

Additionally, occupational therapists need to understand the difference between accommodations and modifications and how these affect learning outcomes. Often these terms are used interchangeably, but in educational settings, the same strategies may be used in both categories, yet they have very different outcomes. *Accommodations* are adaptations or strategies that support student learning but require the same learning outcome as other students. *Modifications* are adaptations or strategies that change the learning outcome by requiring the student to learn something different or to learn less (Nolet & McLaughlin, 2000). Table 50.5 provides some examples of accommodations and modifications to illustrate these differences.

In educational systems such as universities or continuing education settings, a range of occupational therapy services may be provided as well. However, at this time, most occupational therapy services in these settings tend to be more collaborative/consultative or focus on accommodations rather than direct hands-on therapy services. For example, an occupational therapist might consult to a university computing center to recommend appropriate ergonomic arrangements or provide resources related to healthy computing.

Development of the Individualized Family Service Plan (IFSP) or Individualized Education Program (IEP)

Once the evaluation has been completed, the IFSP or IEP team collaborates to design the child or student's program (Giangreco, 2001). IFSPs are plans that include the child and family needs and are used in early intervention (0–3 services) programs. IEPs are programs that address the needs of students in preschool through high school. When developing the IFSP or IEP, the team, which includes the parents and student (if old enough), first reviews the evaluation results and writes a summary of the student's educational performance, called ***present levels of academic achievement and functional performance***. The present levels describe the student's strengths and areas of concern in relation to the expectations of the general education curriculum. The IEP team then develops the student's *goals and objectives* on the basis of the data summarized in the present levels and the agreed-upon outcomes that the team has identified.

TABLE 50.5 EXAMPLES OF ACCOMMODATIONS AND MODIFICATIONS	
Accommodations	**Modifications**
Alternative acquisition modes ◆ Sign-language interpreters ◆ Voice-output computers ◆ Tape-recorded books	Teaching less content ◆ Discriminating between animals and plants versus telling the distinguishing characteristics of animal and plant cells
Content enhancements ◆ Advance organizers ◆ Visual displays ◆ Study guides ◆ Peer-mediated instruction	Teaching different content ◆ Identifying different animals versus learning the human anatomy
Alternative response modes ◆ Scribe ◆ Untimed response situations	

COMMENTARY ON THE EVIDENCE

School-Based Practice

The IDEA 2004 requires that therapists utilize "scientifically based instructional practices, to the maximum extent possible" (Section 601(c)(5)(E)). This requirement is congruent with occupational therapy in any setting and is applicable to all professionals who provide services in public schools. Occupational therapy practitioners can use research evidence to examine the assumptions that guide their practice. For example, the value of consultation and education approaches and providing intervention within natural performance contexts is well documented in the research literature and serves as a guideline for best practice (Spencer, Turkett, Vaughan, & Koenig, 2006).

Although some research evidence is available, rigorous studies supporting effective practice in schools are still emerging. Swinth, Spencer, and Jackson (2007), in a paper developed for the Center on Personnel Studies in Special Education (COPSSE), summarized the current state of research supporting effective practices in the schools. (The reader is referred to the full report for specifics and in-depth information.) Since the mandate of IDEA is for services to be provided within the natural context as much as possible, Swinth and colleagues recommend that "occupational therapists working within the schools must consider outcomes within the context of the environment as well as the expectations in which their services are provided" (p. 8). Considering outcomes within the educational setting creates a challenge for therapy practitioners because some intervention strategies that have a strong research base in a clinical setting might not be as appropriate or as effective in educational settings. For example, rather than working on sensory processing in a one-on-one setting down the hall from the classroom in an environment that simulates a clinical setting, therapists in the schools might work with the teacher and student to implement sensory processing strategies in the classroom. The school-based therapist might work with the teacher to integrate tools such as move-and-sit cushions, a ball chair, and fidgets into the classroom routine (Schilling, Washington, Billingsley, & Deitz, 2003). Additionally, the therapist might work with the teacher to adjust the classroom environment, such as playing low music, decreasing the lights or using natural lighting, or developing a "quiet corner" where students can go to decrease the amount of sensory input they are receiving.

The COPSSE review of the evidence specific to school-based practice revealed a lack of high-level research-based evidence due to the few randomized controlled trails or meta-analyses of such trials related to school-based occupational therapy services. Despite this finding, a growing body of descriptive research does exist. "Thus, currently occupational therapists must rely more on effective or promising practices, clinical expertise and client values as well as systematically collected data when delivering effective practices" (Swinth et al., 2007, p. 34). To increase the breadth and depth of the evidence, a culture of inquiry needs to be established among school-based practitioners. Within this culture of inquiry, a strong research agenda should be established to help inform and shape school-based practice. This research agenda should study current practice strategies (e.g., the use of sensory principles in the classroom, the best use of the skills and expertise of an occupational therapist to address handwriting) as well as the current assumptions of school-based occupational therapy service delivery (e.g., therapy in a therapy room versus in the classroom, the effectiveness of collaborative service delivery). It should be noted that several studies support the idea that intervention in natural contexts is effective (Dunn, 1991; Palisano, 1989; Friend & Cook, 2003; Snell & Janney, 2005; Walther-Thomas, Korinek, McLaughlin & Williams, 2002; Thousand & Villa, 2000) However, many systems and school-based therapists continue to struggle with how and when to effectively move services out of a direct approach in a pull-out environment. Research is needed to help inform occupational therapy practitioners and others about how direct services can be provided effectively within natural contexts as well as how other approaches to service delivery (such as team supports or system supports) can be provided efficiently and effectively to improve student outcomes. Finally, high-level experimental and quasi-experimental studies that address the effectiveness of specific occupational therapy practices on students' educational access, participation, and performance (outcome measures) are needed.

Evidence reviews related to school-based practice are available from AOTA; one review addresses the psychosocial needs of children in the schools, and one review address school-based practice (Jackson & Arbesman, 2005;

COMMENTARY ON THE EVIDENCE *Continued*

AOTA, 2002b). Although these two reviews are not specific to occupational therapy services under the IDEA 2004, some of the summaries and data that are contained in the reviews can help to inform occupational therapy services in the schools.

School-based occupational therapy practitioners must balance the current state of the research with the need to make the best decisions possible to support student outcomes. Ilott (2004) has noted that occupational therapy is a "research emergent" profession. At times, the profession, including practitioners working in the schools, lacks a sufficient evidence base to fully determine which practices and interventions are most effective. "As a result, the competent school-based occupational therapist must think about 'effective practice' and engage in systematic data collection related to desired student outcomes. At all times, the therapist must utilize student/client evaluation and intervention activities to collect and document student performance (outcomes) which justify on-going decisions [related to] OT service continuation, modification, or discontinuation" (Swinth et al., 2007, p. 35). The following table provides an example of how school-based therapists can use research evidence to support their reasoning about intervention.

Intervention Question	Evidence Reviewed	Implications for Intervention Outcomes
Should school-based occupational therapists provide hands-on direct services in a one-on-one setting to address the handwriting needs of students?	◆ Case-Smith (2000) ◆ Case-Smith (2002) ◆ Denton, Cope, & Moser (2006) ◆ Cooley (2004)	Occupational therapy practitioners should consider the following when determining the type(s) of intervention provided to support a student's handwriting performance: ◆ While the research supports direct intervention to improve handwriting, it might not be the best use of the skills and expertise of an occupational therapist to address this need ◆ The implementation of a sensorimotor aspect to handwriting instruction may not be as effective as therapeutic practice ◆ Use of play with younger children may support improved fine motor skills ◆ Occupational therapy may help to improve letter legibility but might not affect speed or numerical legibility ◆ The dynamic tripod grasp is not the only functional pencil grip utilized in handwriting activities

Conclusion: On the basis of the evidence review, the occupational therapist determined that a greater emphasis on team and system support might better support the handwriting needs of the students in his district. The therapist felt that intervention for each student who is referred to occupational therapy could be best served through collaboration with teachers to develop handwriting clubs, implement adaptations in the classroom (e.g., pencil grasps, writing templates, assistive technology), promote fine motor practice and activities within the natural context of the classroom, and implement a comprehensive handwriting curriculum across the district. Direct occupational therapy services through one-on-one or group intervention would be provided only if it was determined through an occupational therapy evaluation that a student had underlying client factors (e.g., biomechanical, visual-motor, fine motor) affecting handwriting performance that could be improved through such direct intervention. The therapist hypothesized that by providing services through a team or system support approach, more children would benefit from occupational therapy, albeit indirectly, and that the number of referrals to occupational therapy would decrease so that the therapist would be evaluating only those children with handwriting concerns that had underlying client factors.

Different settings have different requirements for how goals and objectives are written. Under the IDEA 2004, the ideal is that goals and objectives are developed as a team. Thus, there might not be an "occupational therapy goal page." This is particularly common in some early intervention settings and is becoming increasingly common across all settings. Generally, it is expected that goals and objectives will identify a functional outcome (Fig 50.5), will state what the student will do and under what conditions the skill or behavior will be performed, and will include a timeline for completion (Borcherding, 2005).

As was discussed previously, collaborating with the team is an important aspect of occupational therapy service delivery in the schools. This collaboration sets the stage for focusing intervention strategies on specific student outcomes. Because parents (and older students) are involved in the team planning and decision-making process, their perspectives are well represented in the occupational profile that the occupational therapist develops. Throughout the collaborative process, the occupational therapist identifies where she or he may be able to support the student's occupational performance in the educational environment. The following case study provides an example of the goal-setting documentation for Shanna, a sixth grade middle school student with spina bifida.

After the goals and objectives have been developed, the team discusses which professional(s) should address particular goals (e.g., teacher and occupational therapist or maybe occupational therapist and speech-language pathologist), when they will be addressed (e.g., during physical education, during art, when walking in the hall), and where they will be addressed (e.g., in the general education classroom, in the cafeteria, on the playground). Each of these decisions is made on the basis of the student's need, not the personal preferences of professionals. Thus,

FIGURE 50.5 A functional outcome for a child in a preschool setting is participation with classmates during a field trip to pick pumpkins.

if needed, the occupational therapist designs the OT intervention plan on the basis of the outcomes that the entire educational team has identified.

The Occupational Therapy Intervention Plan

Once the team has developed the program and determines that a student would benefit from receiving occupational therapy as a related service, in order to reach anticipated outcomes, the occupational therapy practitioner develops a specific OT intervention plan. The intervention plan addresses the occupational performance areas as well as the performance skill or student factor that is affecting the student's ability to fully participate in the educational environment.

As in other settings, the occupational therapy practitioner considers student factors such as motor skills, process skills, and communication/interaction skills when determining student needs. Additionally, the practitioner considers performance patterns, such as habits and routines, the activity demands in the school setting, and the entire school context when determining student needs. With occupational performance as the core, a variety of conceptual frameworks for practice and frames of references guide occupational therapy interventions in educational settings. The primary perspectives may include occupational behavior, developmental, neurodevelopmental, learning, biomechanical, sensory integration, and coping perspectives (Kramer & Hinojosa, 1999). However, there are limited randomized controlled trials supporting or refuting specific occupational therapy interventions. Therefore, as much as possible, intervention needs to relate to the student's response to the intervention based on the occupational therapy and teacher data. Throughout occupational therapy intervention, the occupational therapy practitioner utilizes systematic data collection to inform intervention decisions, ensure the effectiveness of the intervention for the specific student, and help to support the best outcomes for the student.

SERVICE DELIVERY

Planning Intervention

When planning the intervention implementation, occupational therapists must consider the least restrictive environment requirement of the IDEA 2004: "to the maximum extent appropriate, children with disabilities are to be educated with children who are not disabled . . . removal of these children from the general educational environment occurs only when the nature or severity of the disability is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily (Least Restrictive Environment)" (Section 300.114(a)(2)(i)). Thus, occupational therapy is provided in the student's typical environment to the extent possible. Such environments may include the classroom, lunchroom, bathroom, or playground.

CASE STUDY: *Goal-Setting Documentation for Shanna*

Shanna is in the sixth grade at the Norwood Middle School. She has spina bifida and some cognitive delays. The school psychologist, Shanna's teacher, the occupational therapist, the physical therapist, and the speech therapist each completed an individualized evaluation. The occupational therapy evaluation included an occupational profile and an analysis of Shanna's occupational performance in her educational setting. As a result of the individual assessments, an evaluation report was written, and the following are some of the strengths and concerns identified:

Strengths

◆ Able to independently move about the school in her wheelchair
◆ Social skills with peers
◆ Verbal expressive language
◆ Creativity

Concerns

◆ Easily distracted in the classroom
◆ Cannot transfer in and out of her wheelchair independently
◆ Receptive language
◆ Written language
◆ Fine and gross motor skills
   (This is not an inclusive list of strengths and concerns.)

Excerpts from Shanna's Present Levels of Academic Achievement and Functional Performance

(Note: These excerpts and goal examples were developed and written as a team, not solely by the occupational therapist.)

Shanna currently participates in her general education classroom throughout her day. Her assignments are modified so that she can complete them in the same amount of time as her peers. Noise and visual stimuli can easily distract Shanna within her classroom environment. She goes to the resource room for assistance with math and written language when she cannot complete the assignment independently in her general education classroom.

Shanna can move about her school environment without assistance, using her manual wheelchair. In the classroom, she requires physical assistance to transfer from her wheelchair to desk chair and back. She has difficulty with fine motor skills. She is unable to control a writing utensil for a sustained period (more than five minutes). Her difficulty with writing affects her ability to complete written assignments and art projects with her peers. Her delays in gross motor skills affect her ability to participate in physical education and recess activities.

Shanna demonstrates good adaptive skills during social interactions with her peers. However, she is becoming increasingly aware of her disability and limitations. This awareness has caused some episodes of depression and has resulted in extended absences from school. Shanna demonstrates emerging self-determination skills in other areas as well. She can describe potential accommodations and adaptations that she would like to her parents and other familiar adults, but she does not advocate for herself during school.

Goal Examples

To address psychosocial skills: Shanna will demonstrate improved self-determination and self-advocacy by collaborating with her therapists and teachers to identify and implement any needed modifications and adaptations into her educational program from less than 50% of the time to 90% of the time as measured by therapist and teacher data by June.

To address written language: Shanna will use identified accommodations/adaptations and/or assistive technology (e.g., word processor, spell checker, adapted writing utensil) in order to complete her classroom assignments within the general education setting within the same amount of time as her peers from 75% of the time to 100% of the time as measured by therapist and teacher data by June.

Outline of OT Intervention Plan

Using the team-identified goals and objectives as a guide, Shanna's occupational therapist developed an intervention plan. This plan included some direct therapy to identify and to teach Shanna how to implement any needed accommodations or adaptations and how to use any assistive technology. The occupational therapist also worked with Shanna to teach other school district personnel about her accommodations and adaptations and assistive technology. Ongoing consultation and monitoring were included to ensure that Shanna was able to participate within her educational environment. Finally, because Shanna also received therapy from a community-based occupational therapist, the school therapist contacted the community therapist at least every six months to discuss Shanna's program. The therapist did not directly address written language or work on improving handwriting. This was part of the teacher's lesson plan. The occupational therapist collaborated with the teacher to address the underlying concerns affecting handwriting performance, including the implementation of accommodations and adaptations.

Service Delivery Models

Many different service delivery models are used within the educational setting. The IDEA 2004 defines four different categories for service delivery:

- Specially designed instruction
- Related services
- Supplemental aids and services
- Services on behalf of the child

In most educational settings, occupational therapists provide related services, supplemental aids and services, and services on behalf of the child. Depending on the rules and regulations in a particular state, an occupational therapist might provide the specially designed instruction. Generally, it would be rare that an occupational therapist would be the only professional providing special education services to a student with a disability. However, a student with normal cognition but significant motor delays (e.g., muscular dystrophy, spina bifida, cerebral palsy) might require more support than just accommodations or adaptations in order to participate within his or her educational setting.

Occupational therapists may choose to use a variety of service models specified in IDEA 2004. However, student need is the driving factor in deciding how services should be provided. The three most commonly described models in the occupational therapy literature are direct services, consultation, and monitoring (Case-Smith et al., 2001; Dunn, 1988; Hanft & Place, 1996). Direct service, often the most common model, occurs when the practitioner meets directly with the student or group of students on a regular basis. Monitoring occurs when the practitioner identifies the student's needs and designs appropriate interventions but another person implements the plan. The practitioner meets with the student regularly to monitor progress. Consultation uses the specialized expertise of the practitioner to improve the educational environment and train the teacher and parents to implement interventions for the student. The practitioner does not work directly with the student. The consultative therapy model is increasing in popularity as practitioners, parents, and teachers are becoming more educated and are recognizing the importance of communication among all team members in achieving desired outcomes (Sandler, 1997). However, the term *collaboration,* rather than *consultation,* reflects the interactive communication among team members (Friend & Cook, 2003; Snell & Janney, 2005; Thousand & Villa, 2000; Villa, Thousand, Nevin, & Malgeri, 1996; Walther-Thomas, Korinek, McLaughlin, & Williams, 2002). Terms such as *collaboration* might better describe the continuum of occupational therapy services and may be better understood by all team members. Finally, newer publications (Hanft & Shepherd, in press) are using terms such as *hands-on* (includes one-on-one, small group services, and the like in pull-out or natural contexts), *team supports,* and *system supports* to describe services in the schools. The terms to describe services in the schools continue to be refined and could be somewhat different depending on the setting, state, or system in which the therapist works.

Regardless of the terms that are used to describe services, it is not uncommon for service delivery models to be presented as a continuum and in a linear fashion. As a result, the assumption is made that services that are more collaborative are less restrictive than are direct services, and the goal is therefore to move toward a consultative or monitoring type of service delivery. However, for some students, the opposite might be true. Therefore, it could be more appropriate to view all the service delivery models as integrated features of an entire service delivery approach. Each service delivery model is important and valuable. To meet a student's identified need(s), therapy practitioners working in the schools may use a variety of service delivery models concurrently (e.g., some one-on-one, some small group, and some collaborative services) (Fig 50.6).

In addition to providing services on behalf of a specific student, some occupational therapy practitioners also provide services to the educational staff, parents, and/or the educational system. If the services are provided on behalf of a specific student, they are documented on that student's IEP. However, if occupational therapy practitioners are providing general services, then the recipient of services (or "client") may actually be the educational staff/parents or the system. Table 50.6 provides example of the range of interventions provided by an occupational therapy practitioner in the school setting.

Interagency Collaboration

Another important aspect of occupational therapy service delivery in educational settings includes collaboration between school personnel and staff from any clinic a child might be attending, as well as collaboration with other agencies. Interagency collaboration is particularly neces-

FIGURE 50.6   School-age children share materials in an occupational therapy group.

TABLE 50.6   OT INTERVENTIONS IN SCHOOL SETTINGS*

Performance Skill	Student Interventions	Educational Staff Interventions	Systems Intervention
Process skills ◆ Energy ◆ Knowledge ◆ Temporal orientation ◆ Organizing space and objects ◆ Adaptation	◆ Learning about self-regulation/levels of arousal and attention ◆ Use of sensory media during intervention ◆ Sensory integrative techniques ◆ Initiates activities and sustains attention to complete them ◆ Organization of desk and other work areas ◆ Accommodates/adapts to changes in the routine ◆ Work on visual perceptual skills ◆ Orientation to time and place ◆ Problem-solving ◆ Self-determination ◆ Behavior management	◆ Teach staff how to use sensory processing techniques in the classroom ◆ Provide in-services on programs such as the Alert Program (Williams & Shellen-berger, 1994) to help students learn to recognize how alert they are feeling and to identify sensorimotor experiences that can be used to change the level of alertness ◆ Training and collaborative program development	◆ Participate on curriculum committees ◆ Educate the system about specific environmental factors that support self-regulation and arousal in the school ◆ Environmental modifications
Motor skills ◆ Posture ◆ Mobility ◆ Coordination ◆ Strength and effort ◆ Energy	◆ Participation in physical education and recess activities ◆ Participation in classroom activities such as written work ◆ Posture/body alignment during school activities ◆ Mobility within the school environment ◆ Accessing assistive technology ◆ Teach energy conservation techniques	◆ Training on use of adaptive equipment and accommodations and modifications ◆ Training on positioning, lifting, and transferring	◆ Work with the school system to adopt a handwriting curriculum ◆ Application of universal design to physical environment and the curriculum ◆ Ordering appropriate adaptive equipment (e.g. lifts) for staff safety ◆ Campaign for proper use of backpacks ◆ Adapted equipment (e.g., weight training machines)
Communication/interaction skills ◆ Physicality ◆ Information exchange ◆ Relations	◆ Social skill development ◆ Psychosocial skill development ◆ Peer interactions ◆ Development of self-determination skills	◆ Training and collaborative program development	◆ Staff development activities ◆ Participation on curriculum committees

*This is not an inclusive list of interventions; rather, it is an outline of some possibilities. Specific needs of the student, staff, and system would help to define the specific interventions to be used.

sary if the occupational therapy practitioner is providing services for students who use assistive technology or during transition planning for older students. Interagency collaboration is important for any educational setting. For example, if a student with a disability who is attending a university needs specialized adaptive equipment in order to fully participate in the setting, the Department of Vocational Rehabilitation might help with the procurement of such device. Or if an occupational therapist is providing a continuing education course and one of the attendees is deaf, a sign-language interpreter might be needed.

Periodic Review

Inherent in service delivery in any setting is the documentation of services. Documentation serves as a communication tool to the students and families regarding the individualized program. Additionally, all decision making about occupational therapy intervention in the schools should be based on data, including research to the maximum extent possible. IDEA 2004 requires that the IFSP or IEP be reviewed at least annually, with regular updates to the family regarding the student's progress. (The IDEA 2004 requires that updates regarding student progress on IEPs be at least at the same intervals as general education report cards.) However, the occupational therapist should consistently (more often than quarterly) reevaluate the intervention plan to ensure that the student is moving toward achieving targeted outcomes. If necessary, the occupational therapy intervention plan or even the IFSP or IEP might need to be modified before the annual review.

OUTCOMES

Outcomes in any educational setting are determined by increased ability of the client (child, student, other professional(s), family, etc.) to participate (or support participation) in the occupation of student. With the emphasis in today's educational settings on evidence-based practices, it is important that occupational therapists working in these settings use strategies and techniques that are supported by research or effective or promising practices (Swinth et al., 2007). The challenge for most therapists in these settings is that there is limited research and the research that exists tends to be descriptive. However, in the public schools, the federal government has recognized this dearth in research and therefore supports promising practices. Occupational therapy practitioners working in educational settings can respond to this challenge by systematically collecting data when working with their clients and then using these data to support or change intervention. It is important that occupational therapists use research-based reasoning to inform their practice but that they not allow the lack of more experimental research to limit the scope of their practice in education settings.

SUMMARY

Occupational therapy intervention in the schools is guided by the IDEA 2004. Practitioners working in the schools collaborate with the IEP team to determine student needs and targeted outcomes. Once these needs and outcomes have been defined in the IEP and the team determines that occupational therapy services are needed, then the occupational therapist designs the specific OT intervention plan. Occupational therapy intervention in the schools focuses on the occupational performance of the student within the educational environment. Practitioners may also provide services that are directed to the needs of the educational staff, parents, or system. Specific intervention strategies and approaches should be based on research to the maximum extent possible. When research is not available but preliminary data indicate that a particular intervention or service delivery could be effective (promising), then the occupational therapy practitioner should utilize systematic data-based decision making to inform decisions about intervention for individual students.

PROVOCATIVE QUESTIONS

1. A school district administrator has asked you to design a specialized therapy room for the elementary schools. On the basis of current evidence, legislation, and what you know about school-based practice, what would you do?
2. The first grade teacher calls the occupational therapist "the handwriting teacher." What might you do to broaden the teacher's perspective on the role of occupational therapy in the schools?

Work

PHYLLIS M. KING AND DARCIE L. OLSON

Learning Objectives

After reading this chapter, you will be able to:

1. Explain the definitions and meanings of the terms *work* and *occupation* in occupational therapy practice.
2. Understand work practice in occupational therapy as it applies to populations described across the life course and by physical, mental, and social conditions.
3. Identify services offered by occupational therapy in work practice.
4. Understand the various types of practice settings in which occupational therapy provides work evaluation and interventions.

Occupational therapists and occupational therapy assistants strive to promote optimal levels of work performance for all individuals to promote a sense of well-being. The profession of occupational therapy supports the use of work as an evaluation and treatment medium, essential to providing a sense of meaning and productivity that is vital to health.

DEFINITION OF WORK

Work and work-related treatments have always been at the core of occupational therapy. *Webster's Universal College Dictionary* (1997) defines work as "exertion or effort directed to produce or accomplish something" (p. 906). In occupational therapy, the focus is directed more to the intrinsic value of work as "meaningful occupation." The profession defines *occupation* as a meaningful, purposeful activity (Primeau, 1996). In other words, occupational therapy considers work to be an occupation. Work is "any activity that contributes to the goods and services of society, whether paid or unpaid" (p. 57). It is one of the major human performance areas that encompasses life roles such as wage earner, homemaker, volunteer, and student.

ROLE OF WORK

Work plays an important role in an individual's life, contributing to the development of self-esteem, volition, a sense of belonging, and a sense of competence (Westmorland, Williams, Strong, & Arnold, 2002). "Work can offer a sense of mastery over the environment, as well as a sense of accomplishment and competence leading to an improved quality of life" (Siporin, 1999, p. 23). It provides structure for a person's life; fulfills the

Outline   *Continued*

work ethic; and improves an individual's morale, discipline, self-worth, and dignity (Harvey-Krefting, 1985). Engagement in meaningful occupations, including work, is known to promote good health and occupational balance (Wilcox, 1998). For many people, an interruption in work can disrupt that balance and have a significant impact on health.

ROLE OF OCCUPATIONAL THERAPY

Work performance can be influenced by physical, cognitive, perceptual, psychological, social, and/or developmental factors. Occupational therapists receive a comprehensive education in all of these areas as they relate to evaluation, treatment, and prevention programs. Work performance is just one of many areas to consider. The occupational therapist or the occupational therapy assistant (under the supervision of the occupational therapist) collaborates with the individual, other team members (e.g., employers, case managers), or agencies (e.g., educational, local/state mental health, vocational rehabilitation) to develop intervention strategies. These strategies are based on the individual's interests, abilities, and needs and are designed to explore and expand work options, to enhance or develop work-related capabilities, and to obtain or retain employment (Commission on Practice, 1999).

HISTORICAL CONTEXT

The precursors of occupational therapy and work programs date back to the 1800s, when "work programs" were formed to promote sanity and good morale in people with mental illness (Paterson, 1997). Soon afterward, work-related therapy was also used for people with physical disabilities to promote good health. Adolph Meyer (1977), one of the founders of occupational therapy, provided the first philosophy of the profession when he wrote that healthy living involved a "blending of work and pleasure" (p. 640). The use of occupation soon gained a reputation as being therapeutic. In the early 1900s, the "work cure" was incorporated into workshops where clients received profits from producing marketable goods. Therapeutic occupations, habit training, handiwork occupa-

tions, and preindustrial shops as curative work became more common (Jacobs & Baker, 2000).

Today, occupational therapy continues to be committed to work and work-related activities, with a greater focus and expansion on injury prevention services (e.g., ergonomics, preplacement screenings, joint protection education, and postural awareness) and engagement in partnerships to serve industry. Therapists increasingly practice outside of the medically based facilities and more in the workplace, engaging with employees and employers.

OCCUPATIONAL THERAPY THEORY AND FRAME OF REFERENCE

Occupational therapy theory, practice, and research have always approached performance from a holistic perspective. One model, the Person-Environment-Occupation Model emphasizes the complex, dynamic relationships among the person, the environment, and the occupation. It describes occupational performance as the outcome of a dynamic, interwoven relationship that exists among individuals, their roles and occupations, and the environments in which they live, work, and interact. According to this model, occupational therapy intervention seeks to enable optimal performance in occupations that the client defines as important (Kornblau, Lou, Weeder, & Werner, 2002). For example, Lori, an occupational therapist, assisting Jim, a 42-year-old husband and father of two children who seeks to return to his job as an office manager following a T12–L1 spinal cord injury, must consider Jim's personal strengths and limitations in the performance of self-cares, his psychological and social adjustment to his disability, and mobility skills in preparation for return to work. Variables in the home and office environment must be assessed and modified to optimize independence in functioning. Doorways might need to be widened, and a ramp might need to be installed for entry and exit to both environments. Transportation issues will need to be addressed with adaptation of Jim's motor vehicle to incorporate hand controls. An analysis of his office job will need to be conducted to identify work accommodations that will enable him to perform his job independently. Such accommodations might include a larger office space, a desk that accom-

modates a wheelchair, and relocating office equipment for ease in reach.

Occupational adaptation suggests competence in a person's occupational response. To obtain competence, the person must interact with the occupational challenges within the environmental context. A person's performance is largely dependent on the level of desire for mastery, the environment's demand for mastery, and the resulting press for mastery (Schkade & Schultz, 1992). How a person responds adaptively determines whether the person will experience relative mastery in his or her occupations. The strength of this desire influences the achievement of mastery. The occupational environment presents challenges to an individual's performance. Physical, social, and cultural aspects of the environment can either facilitate or impede performance based on the individuals' aptitudes and adaptive capacity. Occupational therapists can act as facilitators of the environment. They can address both the person-system deficits and the environmental demands to facilitate a person's mastery in his or her preferred work occupation (Kornblau et al., 2002).

According to the occupational adaptation frame of reference, Lori will need to consider Jim's level of motivation to return to work and the tasks that his job requires. He might need to return to his job to financially support his family. In this case, Jim's desire for mastery is probably high. The office setting might present physical challenges for him, with limitations in space in the office and bathroom to accommodate a wheelchair. Adaptation and relocation of office equipment such as a computer, telephone, desk, and file cabinets will need to be considered to optimize his ability to perform his job.

POPULATIONS

"Occupational therapists and occupational therapy assistants provide services to individuals or populations with deficits or problems in the area of work performance" (American Occupational Therapy Association, 2005, p. 676). Work-related services can be provided to individuals of all ages. Throughout the life course, participation in work provides social, developmental, and economic benefits. E. A. Larson (2004) suggested that children benefit from culturally acceptable work roles such as cleaning up after oneself or participating in household chores. Early exposure to self-care and chores can affect the child's relationships with family members and provide the foundation for other work skills in the future. Studies of adults with disabilities have shown that quality of life is improved through participation in competitive employment and meaningful occupations (Bond, 2004; Dickie, 2003). Working with older adults to promote participation in work is an emerging practice area for occupational therapists. As the proportion of older adults in the population grows, the role of the occupational therapist will be expanded to accom-

modate the needs of the older worker. Occupational therapy services are not limited to individuals with physical and developmental disabilities. Work participation is a part of occupational therapy programs for all individuals, including those with mental and behavioral disabilities.

School Programs

In 1997, the Individuals with Disabilities Education Act (IDEA, 1997, P.L. 105-17) mandated that along with the Individualized Education Plan, each adolescent who participates in special education would have an Individualized Transition Plan before reaching the age of 14. Transition is the process in which the members of the education and rehabilitation team prepare the student to leave the school setting and enter into employment and community living (Kardos & White, 2005). **Transition planning** includes four primary areas: postsecondary education, community participation, postsecondary employment needs, and residential outcomes (K. C. Spencer, 2000).

Occupational therapists offer a unique role in the transition process by promoting movement from school to postschool activities through occupation-based evaluation and interventions (J. E. Spencer, Emery, & Schneck, 2003). Career interest inventories and job exploration may be conducted. Interventions such as the use of adaptive equipment or assistive technologies might be considered to maximize function in chosen postschool activities. Occupational therapists incorporate daily living skills, work readiness, and community involvement into the students' therapy programs to prepare for eventual employment and community living.

Occupational therapists participate in achieving transition outcomes for each student by addressing their specific needs. Working with the student ensures that his or her preferences and interests provide the foundation for transition planning. Along with the students, their families, and the transition team, the occupational therapist may develop and provide prevocational programs, facilitate functional living skill development, modify environments, facilitate inclusion in community experiences, and provide education to parents and other staff. Occupational therapy in transition planning uses functional, real-life tasks and task analysis to help students develop functional living skills.

Work as a Focus with the Aging Population

Having a work identity is central to being an adult in the United States. "In contemporary American society, a sense of being something (at minimum, being a productive person) seems critical to perceptions of belonging and status as well as one's sense of personal worth" (Dickie, 2003, p. 251). According to the Bureau of Labor Statistics (1999), the median age of the American workforce is rising sharply and is expected to continue to rise through 2015 as the baby boomers (individuals born between 1946

and 1964) approach retirement age. The average American worker is projected to be over 40 years old in 2012, constituting more than 40 percent of the labor force. The increased age of the American worker is affected by both the aging of the baby boomers and the projected increased participation rates of workers over age 55 (BLS, 1999). As the workforce continues to age, significant challenges face employers and rehabilitation providers. Age-related neurological, cognitive, physical, and psychological changes need to be considered in working with older adults (Gupta & Stoffel, 2001). Older workers have been found to require more days off work to recover from injuries than their younger counterparts do (BLS, 2005). This is suggested to be due to slower recovery and comorbid conditions.

Kornblau (2000) viewed the changing workforce as a trend to be embraced by occupational therapists. "Occupational therapists can play a big role in designing and adapting the workplace for the changing workforce" (p. 1). Occupational therapists provide services to facilitate successful aging in the workplace. They help older workers and employers to understand occupational performance issues and strategies that are specific to older employees (Gupta & Stoffel, 2001). Occupational therapists help older workers and their employers to optimize the fit between a person's abilities and the demands imposed by the occupation and the environment (Sterns and Miklos 1995).

CONDITIONS

Problems in work performance can arise from aging, physical or mental illness or injury, and/or developmental or behavioral impairments. Occupational therapists provide services to individuals with a wide variety of conditions who have a particular goal of enhancing participation in work. The practice settings often, but not always, define the age and conditions of the population that is being served. School systems serve youths with learning and developmental disabilities as they transition to adult life and employment opportunities. Individuals with mental or behavioral illness are served in a variety of settings, including hospitals, community clinics, and homeless shelters. Work-focused interventions for individuals with these conditions include assessment, education and training in key areas to enhance successful integration into competitive employment. Occupational therapists working in hospitals, clinics, and on-site in industry provide services for adults with a wide array of medical conditions. Physical injuries and illnesses related to employment such as musculoskeletal disorders and traumatic workplace injuries benefit from integrated services that involve the worker, the employer, health care providers, and others involved in safe return-to work planning. Non-work-related medical conditions such as traumatic injuries or illnesses also require integrated planning to enhance the opportunities for participation in

work. Individuals with disabilities benefit from the education that occupational therapists provide regarding services and programs that promote safe employment. Legislation and federal and community agencies provide incentives to work, although many individuals lack awareness of the programs or are fearful that working will affect their benefits from Medicare, welfare, disability, insurance or workers' compensation (Fiedler, Indermuehle, Drobac, & Laud, 2002). Work-focused assessments, education, and interventions and the integration of services are apparent in all practice areas of occupational therapy for individuals of all ages and conditions.

SERVICES

Wellness, Health Promotion, and Injury Prevention

Wellness integrates fitness, nutrition, healthy relationships, a positive self-image, and the ability to take personal responsibility for self-care; it is the process of taking responsibility for realizing one's maximum health potential (Rothman, 1998). **Health promotion** is the movement toward optimal health and high-level wellness. These concepts are the basic tenets of occupational therapy. Rehabilitation programs commonly include strategies for empowering the client to gain or regain responsibility for optimal health and function. Community education programs, including topics such as energy conservation and work simplification, have long been part of occupational therapy's health promotion campaign. More recently, occupational therapists have conducted on-site educational programs in industries to encourage personal responsibility for wellness through prevention programs (Mungai, 1985). These prevention programs include stretching, fitness, safe work practices, and early recognition, reporting, and management of physical problems associated with work (Olson, 1999). Prevention, an important dimension of wellness, is defined as taking steps to avert the development of disease or illness (Rothman, 1998).

Wellness and prevention programs positively influence health and prevent injury (Massy-Westropp and Rose, 2004; Yassi, Gilbert, and Cvitkovich, 2005). Two major factors that motivate companies to initiate wellness programs are the resulting reduction of work-related injuries and the associated costs savings of a healthier workforce (Melnik, 2000; Naso, 2003; Rothman, 1998). Occupational therapists can incorporate wellness and health promotion into any practice setting. Siporin, (1999) emphasized the importance of training programs for individuals who have mental or behavioral disabilities in areas such as social skills, proper hygiene, and dressing for work. In this context, health promotion involves training in areas that prepare for more successful integration into community environments. Health promotion programs

can include the assessment of health risk factors, such as problem assessments, workforce symptom surveys or hazard checklists, education and training in lifestyle improvements, safety precautions, safe working techniques, and fitness programs (Olson, 1999; Rothman, 1998). In industry, on-site wellness programs result in decreased absenteeism, reduced health care costs, protection from lower back problems and musculoskeletal injuries, and improved productivity (Carrivick, Lee, Yau, & Stevenson, 2005; Melnik, 2000; Naso, 2003; Rothman, 1998).

Ergonomics

Ergonomics is a relatively new profession that focuses on the use of a **systems approach** for improving safety and productivity through the design of work systems and environments. The practice of ergonomics has been evident through documents dating back to the 1800s; however, the term *ergonomics* was not coined until 1949 (Dahl, 2000; Vitalis, Walker and Legg, 2001). The most recent definition of the term was established in 2000 by the International Ergonomics Association (IEA, 2005) as "the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data and methods to design in order to optimize human well-being and overall system performance" (Marshall, 2000, p. 1). In short, ergonomics has been defined as considering the whole system in the process of "fitting the job to the man" (Vitalis et al., p.1295).

A systems approach views the properties of the whole, or system, as arising from interactions and relationships among the parts. In this framework, the practitioner integrates the biological, psychological, and social factors of human performance within the environmental context (Dahl, 2000). Occupational therapists provide ergonomic services for individuals and populations in a variety of systems and settings. They use the principles of ergonomics to design safe and efficient living environments, workplaces, and products. The role of the occupational therapist in ergonomics is informed by knowledge of human performance and potential and the legislation that mandates safe accessible workplaces.

Workplace environments or systems include the organizational structure, environmental factors, tools and equipment, job tasks, and the workers (Dahl, 2000). All aspects of the system are considered in ergonomics. The occupational therapist assesses and analyzes the system to identify the presence of ergonomic risk factors. Workplace surveys, hazard assessments, and job task analyses are tools that are available to the practitioner. Collaboration with others within the system is necessary for an accurate and thorough assessment and intervention. The other members of the system include the workers, supervisors, engineers, and administration.

The occupational therapist benefits from good communication skills as well as comprehensive knowledge in the field of ergonomics.

Ergonomic interventions generally fit within three primary categories: administrative, engineering, and individual. **Administrative controls** or interventions include changes in the nature of work, such as scheduling, worker rotation, or the assignment of work tasks. **Engineering controls** include equipment and workplace designs or changes that reduce the human efforts that are needed. **Individual controls** include the physical, cognitive, and social skills and performance of the workers. Safe, efficient job design depends on coordination of all aspects of the system. Matoushek (2005) used the term ***work integration programs*** to refer to the incorporation of the clinical features of the injured worker into the organizational and ergonomic aspects of the system. Occupational therapists address both the accessibility of the workplace for all workers and the reasonable placement of individuals who have physical, psychological, or behavioral issues. Awareness of ergonomic principles provides a foundation for safely integrating workers into work.

Job Analysis

"Work performance supports participation and productivity, which are essential to the health and well-being of each individual" (AOTA, 2005, p. 676). The role of the occupational therapist in enhancing participation in occupation may include an analysis of work settings. A job analysis provides an objective basis for hiring, evaluating, training, accommodating, and supervising people with disabilities (U.S. Department of Labor, 1994). Regardless of the practice setting, the principles of job analysis are beneficial tools for the occupational therapist. Occupational therapists use these tools when planning the school-to-work transition for school-aged students and participation in supported employment or sheltered workshops by individuals with physical and/or mental disabilities. A job analysis also benefits clients who are preparing for their first experience with competitive employment or who are returning to employment after illness or injury. In addition, therapists who are employed in industrial programs may be called on to assist employers in describing jobs and/or determining the safety of the workplace. The occupational therapist may be engaged in assessing the job site with a thorough investigation of all aspects of the work environment or perhaps simply to explore discrete components of the job. "Approaches and techniques are intended to provide a foundation for analysis that can be applied to reducing the likelihood of injury, interrupting or minimizing the progression of an illness, or reducing the resultant disability of an injured worker" (Bohr, 1998, p. 229). Job analysis is a dynamic process that is appropriate to all practice settings that considers the worker, work environment, and work demands.

Job Description

A **job description** defines the essential functions of the job and how the job relates to other jobs and to the workplace (Bohr, 1998; Ellexson, 2000). An accurate and functional job description must define the essential work tasks, the physical and mental requirements of the worker, the necessary tools and equipment, and a description of the work space and environmental conditions of the job.

Essential tasks are the basic job duties that all employees must be able to perform with or without reasonable accommodation (Ellexson, 2000). The Americans with Disabilities Act (1990) mandated that job descriptions include the essential job functions. The essential duties are the reason that the position exists and the degree of expertise or skill that is necessary to perform the task. The job description also includes the **marginal functions** of a job. These are tasks that are not essential to the specific job or tasks that could, if necessary, be completed by another worker. Identification of marginal tasks assists the therapist in determining job placement and provides guidelines for training the worker for work.

Task Analysis

The terms *job analysis* and *job task analysis* refer to a thorough assessment of the physical, cognitive, and psychological demands of the job. **Job analysis** includes a formal methodology that details the interaction between the worker and the equipment of a system. It defines the performance requirements of the worker by a detailed description of the human task requirements. Job **task analysis** is the specific assessment of a particular task or procedure. A thorough job analysis includes employer and worker interviews; observation of multiple workers performing the task (if possible); measurement of the forces, frequencies, and durations of work tasks; postural requirements such as reaching and leaning; and the environmental and psychosocial conditions that are present in the workplace.

Methods

Before conducting a job analysis, it is imperative to discuss with management or the supervisor several issues regarding the assessment process. The employer will be able to provide information on the least disruptive methods for conducting the evaluation and the necessary safety precautions for the evaluator. Personal protective equipment, such as safety glasses, steel-toed shoes, hearing protection, or special clothing might be required while on the job site. There might be restrictions on interviewing workers while they are performing their work. Interviews might need to occur during the worker's lunch or break periods. In addition, the therapist should discuss and receive permission in advance for use of any audio, photographic, or video equipment.

Detailed, organized documentation of the information that is gained during the job analysis will be the most useful. Many checklists or forms are available to use as a starting point, allowing the therapist to highlight specific areas to target for more thorough analysis (Occupational Safety and Health Administration, 2002; Washington State Department of Labor and Industries, 2005). It is also helpful to use audiotape, photographic, or video equipment to record the worker or workers performing the job, allowing a more thorough analysis at a later time. Other common supplies that are helpful in job analysis are a tape measure, a force pressure gauge, a stopwatch, and a goniometer. In addition, specific tools can be investigated for measuring noise, heat, and vibration, as shown in Figures 51.1 and 51.2.

Supervisor and worker interviews provide valuable insight into all aspects of the job. According to OSHA (2002), "involving employees will help minimize oversights and ensure a quality analysis" (p. 9). The interviews can be a method of learning about routine and infrequent tasks and about flow patterns and sequences and to obtain workers' perspectives of physical and mental work stresses (Bohr, 1998; OSHA, 2002).

Formal Measurements

Job analysis involves measurements of many of the aspects of the job (Ellexson, 2000). This includes the dimensions of the workspace and the materials that are handled. Measuring the workspace includes measuring the dimensions of reach required for the various tasks, the distances required to transport items, and the heights of work surfaces. The weight of objects that are lifted or lowered is documented, as are the frequency, duration, distance, and quality of the task, such as the handholds, or the stability of the load. Other forces that the worker encounters are also measured, such as pushing and pulling, and use of tools, gloves, and other personal protective equipment is assessed. The body positions of the worker, such as leaning, reaching, or other postures, should be measured or

FIGURE 51.1 Instruments for measurement of noise levels. (Photograph provided by Quest Technologies.)

FIGURE 51.2   Instruments for measuring vibration. (Photograph provided by Quest Technologies.)

estimated, and the duration and frequency should be recorded. It might be possible to record only the initial and terminal postures for dynamic motions. Video recordings or photographic equipment aid in the assessment of body postures by allowing the evaluator to assess angles, frequency, duration, or other variables later (Bohr, 1998). Finally, the conditions of the workspace and environmental considerations such as the ambient temperature, surface temperatures, humidity, noise level, illumination, and vibration are also documented and measured. To assist the therapist in identifying the safe working levels, databases of acceptable working conditions are available. These are based on epidemiological, biomechanical, psychophysical, and physiological approaches (Eastman Kodak Company, 1983; Snook and Cirello, 1991; Washington State Department of Labor and Industries, 2005; Waters, Putz-Anderson, Garg, & Fine, 1993).

The job analysis is completed by preparing a summary that is specifically developed for the customer. Generally, the report will include an overview of the data that have been collected, the problems that have been identified, and recommendations for addressing the problems. "It is often a good idea to offer staged solutions for addressing the problems" (Bohr, 1998, p. 244). The therapist should prioritize solutions that will be the most effective in the short term to assist the employer in analyzing the cost-benefit ratio. The emphasis of the report will vary depending on the customer. When the customers are concerned about job placement for a client, the focus of the report will be on the individual. The report will highlight the necessary physical demands and rehabilitation needs such as strengthening, endurance and/or flexibility. When the focus is on workplace safety, the report will highlight hazardous conditions, with recommendations for safety, efficiency, and productivity. Regardless of the purpose of the assessment, the job analysis will identify factors that will either enhance or restrict participation in the occupation of work with

recommendations for the client, the rehabilitation team, and/or the employer. "Through observation, demonstration, participation, documentation and analysis, the skilled occupational therapist can develop a clear and concise picture of a specific job" (Ellexson, 2000, p. 6). Box 51.1 lists some resources that relate to job analysis.

Functional Capacity Evaluation

The **functional capacity evaluation** (FCE) is an integral assessment tool that is used for work injury prevention and rehabilitation. FCEs define an individual's functional abilities and/or limitations in the context of safe, productive work tasks. An FCE itself involves a process of systematically gathering and testing information and making and testing hypotheses about performance, often in relation to an occupation in context. The therapist begins by reviewing referral information related to a client's medical and work history. A series of test activities are then administered to measure whether the person has the abilities to meet the required job demands, to determine a level of disability, or to demonstrate the need for, and progress in, rehabilitation (Harwood, 2004). Physicians, employers, insurers, and benefits adjudicators often rely on FCEs to provide definitive answers in a variety of situations involving work. Results of these evaluations have significant implications for further rehabilitation efforts, employment, compensability determinations, and cash benefits.

FCEs include a wide range of evaluation activities. The simplest evaluations involve a series of standardized tasks with measured weights and distances and a trained observer; these are available for upper extremity as well as back and lower extremity activities. Other approaches use machines to measure average and peak forces, velocity, and range of motion in several different planes. In these situations, workers are generally asked to exert a maximal effort. Job simulation, using tasks and equipment that are specific to a particular job, has recently become more popular, in part because of the Americans With Disabilities Act (ADA) requirement that valid testing should be job-specific and focus on a comparison of capacity to actual job demands (Lechner, 1998).

The concept of matching job or workplace demands to the capabilities and limitations of a worker is a fundamental assumption underlying FCE application. One of the most important aspects of an FCE is that the measurement of capacity is specific to the demands that the job poses. The estimates of job demands are inexact generalizations that have not been scientifically validated. A formal job analysis is desirable for FCEs that are intended to measure the ability to work at a specific job. Discussions with employees and written company job descriptions are also helpful in obtaining accurate assessments of job demands.

FCE5 are usually performed in the clinic and may range from 2 to 4 hours in duration over the course of a

---

two-day period. Protocols often extrapolate from tasks that are stereotypical or performed at near-maximal levels for a short period of time to predict ability to sustain job activities for a full workday and workweek. Performance on FCE tasks are often compared with population or coworker norms, as actual job force requirements are not often estimated during this process. It is important for therapists to use good observational skills throughout the assessment to ensure a client's safe performance (King, 2004).

FCEs are generally classified into two broad categories: comprehensive and job-specific (Frings-Dresen & Sluiter, 2003; King, Tuckwell, & Barrett, 1998). When administering the comprehensive FCE, most evaluators use a complete battery of tasks that cover all 20 physical demands listed in the *Dictionary of Occupational Titles* (U.S. Department of Labor, 1977).

In job-specific testing, the evaluator tests only those tasks that are directly related to the job. The job-specific testing is more cost effective and is often used for disability determination. However, if the client cannot return to the former job, then additional testing might be required.

FCE reporting formats vary in length from one page to 35 pages or more. The primary objective is to describe the client's safe level of overall exertion ranging from sedentary to very heavy. A summary cover page is usually attached to the FCE data collection forms when FCE information is submitted to referral sources.

In these times of unprecedented workers' compensation costs and disability costs, there is a pressing need to return workers to gainful employment if possible and to make appropriate disability decisions for those who are unable to work. A well-designed FCE can provide

objective information on a wide range of functional activities for clinical decision making (Isernhagen, 1988; Lechner, Jackson, Roth, & Straaton, 1994; Lechner, Roth, & Straaton, 1991).

Preplacement Assessment

Preplacement assessments (PPAs) are used by employers to determine whether an individual is capable of performing the job. The results of these assessments help employers to make appropriate decisions related to the placement of individuals in jobs without hazards to the safety of themselves or others. Proper PPAs can reduce the number and costs of employee injuries as well as absenteeism attributed to ill health (Nachreiner et al., 1999).

Before passage of the ADA in 1990, prework screening was performed for the purpose of excluding individuals from employment if they presented an increased risk of any type of illness or injury (Andstadt, 1990). These screenings are no longer legal; PPAs have taken their place. Applicants must now be given a conditional offer of hire based on successful completion of the PPA. The preplacement screen is viewed as an injury prevention strategy, not as a means to screen out applicants. The employer's decision to withdraw a job offer must be based on the applicant's inability to perform the essential functions of the job with or without accommodations. A prospective employee can be denied the job only if he or she is at definite risk of specific injury or illness while performing the essential functions of the job. Employers are required to provide reasonable accommodation to mitigate these risks as much as possible (Nachreiner et al., 1999).

Occupational therapists design and administer preplacement screenings. The screening occurs after a conditional offer of hire, and it must apply to all applicants for a specific job position. First, the therapist requests a job description to ascertain the essential functions of the job. If a job description is not available, the therapist must perform a job analysis to determine the physical demands of the job. This entails observing job tasks, videotaping employees performing the job, and collecting workstation measurements to obtain accurate information to design an appropriate preplacement screen. Once the job description has been developed, the therapist develops a standardized test of the physical demands of the job. To verify that the preplacement screen tests what it is intended to test, a sample of current employees performing the particular job are selected to validate the job description and pilot the test. The therapist rates the performance of the individual according to the validated physical demands of the job. The applicant receives the scoring information. The evaluator does not make hiring interpretations. The ultimate decision to hire is in the hands of the employer.

Work Hardening and Work Conditioning Programs

The term *work hardening* came into being in the late 1970s as professionals used work as a treatment or evaluation modality. Other terms that are used synonymously are *work conditioning, work readiness,* and *work capabilities* (Isernhagen, 1988). In 1988, the Commission on Accreditation of Rehabilitation Facilities (CARF) officially defined **work hardening** as "a highly structured, goal-oriented, individualized treatment program designed to maximize the individual's ability to return to work" (CARF, 1988, p. 69). The guidelines recommended that work hardening programs be interdisciplinary and capable of addressing the functional, physical, behavioral, and vocational needs of the person who is being served. CARF suggested the use of real or simulated work activities in conjunction with conditioning activities to improve biomechanical, neuromuscular, cardiovascular/metabolic, behavioral, and vocational functioning (King, 1998). Work hardening programs usually employ exercise equipment, a work simulation area, and a quiet, private area for testing and evaluation.

Work conditioning programs emphasize physical conditioning, which addresses issues of strength, endurance, flexibility, motor control, and cardiopulmonary function (Helm-Williams, 1993). They are shorter in duration than work hardening programs; use exercise, aerobic conditioning, education, and limited work task simulation; and require less physical space than work hardening programs. Work conditioning programs usually involve only one or two disciplines and are usually half-day programs. Work hardening and work conditioning programs are increasingly being located in nonmedical settings such as industrial parks, strip shopping malls, and office complexes and at the worksite. Programs that are implemented at the worksite provide a more realistic environment and place the employee back at work and in close communication with the employer.

The work hardening and work conditioning evaluation and treatment process consists of entrance criteria whereby clients are unable to return to work due to pain or dysfunction following injury and the clients agree to participate in the program. The clients must also have a reasonably good prognosis for improvement of employment capacity and a job-oriented goal (King, 1998). The occupational therapist initially interviews the client to gather valuable information related to his or her medical and work history. Insight into what procedures have worked or failed in the past, as well as the client's beliefs or misperceptions about his or her condition, can be ascertained. Job history, before and after the injury, and how long the client has been off work or on light duty are important pieces of information to have in designing a work rehabilitation program. An evaluation of a client's functional capabilities is performed before performance of any conditioning and/or work-related activities. The purpose of this evaluation is to

become familiar with the client's current functional status, behaviors associated with work activity, potential latent symptom responses after activity, and body mechanics techniques. This information is compared with the client's job demands and goals for progress.

The client's length of time in work hardening and work conditioning programs depends on his or her individualized treatment needs and the treatment protocols that have been established by the program. Typically, clients are started in programs for two hours per day, eventually progressing to four hours as tolerated. This requires highly focused and well-managed treatment plans. Most programs start with warm-up exercises, followed by strengthening and job simulation activities. Education on risk factors to injury and prevention of injuries with use of proper body mechanics and work methods is woven into the program. Clients are discharged when (1) they meet their goals, (2) progress has stopped or slowed to an imperceptible level, (3) the client has medical complications, or (4) the client is noncompliant with the program.

Case Management

An increasing number of occupational therapists are assuming case management roles. Case management is not a profession; it is an area of practice within a profession. Therapists, nurses, social workers, and rehabilitation counselors may all serve as case managers. Their goal is to achieve a successful, cost-effective method of returning clients to work.

The nonprofit organization Case Management Society of America (CMSA) was established in 1989. Its *Standards of Practice for Case Management* defines **case management** as "a collaborative process which assesses, plans, implements, coordinates, monitors, and evaluates options and services to meet an individual's health needs through communication and available resources to promote quality cost effective outcomes" (CMSA, 1995, p. 8). A certification process was established to monitor professional conduct and provide standards of practice to those who perform case management functions. Certified or not, a successful case manager must be skilled in communication, diplomacy, and relationship building. He or she must demonstrate skill in identifying cost-effective resources and make appropriate referrals to promote case closure.

In a work injury case, in which workers' compensation is involved, the case manager will usually interact with several players: the injured employee, the employer, the insurance carrier, and the physician. Each player has a different perspective on the injury. Case management services are not restricted to workers' compensation cases, however. Case management services are just as important in other areas of work rehabilitation, such as those that involve individuals who have mental illness and developmental disabilities. The primary difference in case management practice with different populations is the team of players and the

resources that are investigated to facilitate a successful outcome. Regardless of the population that is being served, case management requires the ability to coordinate a complex mix of resources and services. These skills are dependent, at least in part, on clinical experience.

SETTINGS

Work programs in occupational therapy are evident in a variety of different settings. Traditional settings include hospitals, clinics, schools. Nontraditional occupational therapy settings include on-site programs in industry, fitness centers, and community rehabilitation programs. Regardless of the setting, the focus on the therapeutic value of work is a key aspect of occupational therapy.

On-Site Rehabilitation and Injury Management

The industrial rehabilitation movement in the 1980s provided the impetus for the development of on-site rehabilitation programs in industry. Although therapists working on-site in industry represent only a fraction of those who are involved in occupational rehabilitation, the many benefits of these programs foster their continued growth (Jundt & King, 1999; Tramposh, 1998). Occupational therapists working on-site or consulting with industry have many roles that include prevention, assessment, and rehabilitation programming. The benefits of on-site programming are decreased overall costs and improved quality care (B. A. Larson, 2000; Melnik, 2000). Therapists working on-site in industry enjoy improved communication with the employer, increased autonomy, and the ability to assess and intervene from an informed perspective, consistent with the holistic philosophy of occupational therapy. The clients benefit from on-site programs in several ways. On-site programs can reduce the waiting time for appointments, enhancing recovery through immediate care. The integration of the on-site therapist into the culture of the industrial setting can improve reasonable restricted duty placement and progression toward full-duty work. Awareness of the job demands and the worker's physical capacity can prevent re-injury while allowing the worker to safely continue in productive employment.

The employer also benefits from on-site programming. Successful programs allow the employer to oversee an employee's path through rehabilitation. Communication is improved through on-site interactions between the employee, the supervisor, and the practitioner. Improved communication speeds the rehabilitation process, reducing overall workers' compensation costs (Tramposh, 1998). The costs that are associated with travel to and from off-site clinics are also reduced by keeping the workers on-site for their therapy visits.

On-site therapists enjoy immersion in the culture of the industry, enhancing their realistic programming for

the client and adding the benefits of early rehabilitation. Therapists who work on-site often work autonomously and require a thorough understanding of work injury assessment, rehabilitation, prevention, and the psychosocial aspects of disability (B. A. Larson, 2000; Tramposh, 1998). In addition, knowledge of the rehabilitation system, the ability to analyze tasks and the ability to creatively adapt the physical environment are all important skills. The setting requires skills in decision making and in dealing with people from various socioeconomic and cultural backgrounds. The therapist's role is often that of an intermediary between the injured worker, the employer, and the workers' compensation carrier, each bringing forth their own perspectives and issues.

On-site prevention programs include educational offerings such as back schools, stretching programs, fitness programs, and other health promotion or wellness activities (Melnik, 2000). Prevention can also include worker symptom surveys, hazard assessments, ergonomic assessments, writing job descriptions, and participation in safety teams and committees (Rothman, 1998). Prevention programs must be continually adapted to the constantly changing industrial environment. Successful programs require management support, supervisor buy-in, employee participation, and ongoing support and reinforcement (Melnik, 2000).

Assessment and rehabilitation of injured workers in on-site clinics include a vast array of services. Early intervention assessments may involve screening, education, and prevention activities for workers who have experienced mild symptoms or discomfort (Olson, 1999). Comprehensive assessments include worker evaluations for specific injuries as well as functional capacity evaluations. Rehabilitation programming can include the management of a specific injury, such as carpal tunnel syndrome, or more intensive work hardening and work conditioning programs. On-site therapists have the advantage of integrating services within the context of the worker's physical job demands. On-site therapists may also be involved in job analysis, ergonomic analysis, job placement, and the design of restricted duty programs (see Figure 51.3). The occupational therapist's role on-site in industry is to provide prevention, assessment, and intervention services to enhance a safe, efficient, and productive work environment for the worker and the employer.

Work Clinics

Throughout the history of occupational therapy, participation in valued occupations, including work, has provided the foundation of rehabilitation (Lysaght & Wright, 2005). In the late 1970s and 1980s, many industrial rehabilitation clinics emerged, providing services that focused on return to work as the outcome of intensive rehabilitation programs. (Jacobs & Baker, 2000; Tramposh, 1998)

FIGURE 51.3   A therapist conducting a worksite job analysis.

The individualized therapy programs included functional capacity evaluations and progressive strengthening based on simulating the critical aspects of the client's work. Rehabilitation included creating workstations that represented the client's actual work tasks. The integrated services were designed to safely identify a client's tolerance for work tasks and to progress toward returning the client to productive employment. Although the primary focus of work has been obvious in these "end-of-rehabilitation programs," it has been no less evident in other rehabilitation settings. Safe, productive return to work has been included to some extent in all contexts of occupational therapy.

Hospital-Based and Freestanding Clinics

Traditional occupational therapy programs exist in hospitals and clinics providing inpatient and outpatient services to individuals with illnesses or injuries. Work, as a focus of rehabilitation, can be enhanced by the occupational therapist who analyzes the multidimensional issues faced by these individuals. Standardized rehabilitation assessment tools are available and can be customized to assess the physical, cognitive, and behavioral abilities of the individual in relation to the demands of the workplace. These skills are measured within the framework of productivity, interpersonal skills, and safety (Chappell, Higham, & McLean, 2003; Jackson, Harkess, & Ellis, 2004). Treatment programs address the identified deficit areas in performance and simulate the unpredictable nature of actual workplace demands. Studies have shown that use of a formal tool for addressing work abilities improved the decisiveness and clear recommendations by the therapist and provided a clear standard for formatting reports, and the clients expressed satisfaction that alternatives

CASE STUDY: *An Injured Sheet Metal Worker*

Thomas is 42 years old and employed as a sheet metal worker. He is married and has two sons, and he is the primary source of income for his family. Two months ago, a machine malfunctioned and crushed his right hand. He has had multiple surgeries to structurally restore the hand. He continues to experience problems in sensation, muscle strength, and coordination in his hand. Workers' compensation is providing him financial assistance in the form of income and medical expense coverage, but he is concerned about his job and when and whether he will be able to return to work. His physician has referred him to a work rehabilitation program. His occupational therapist, Sandy, addresses the many dimensions that affect his rehabilitation.

Questions

1. What is the occupational therapy process for Thomas's rehabilitation?
2. How does Sandy determine Thomas's functional abilities to return to work?

Discussion

Sandy should review Thomas's work, social, and medical history. Sandy's intake interview information will likely reveal Thomas's desire to return to his previous job. A job description from the employer should be obtained, and Sandy should ask Thomas to describe his usual work duties by talking through a usual day at work. If needed, a job analysis or job task analysis will provide objective information about the essential duties Thomas will need to perform to return to his previous job. Sandy will need to conduct an initial musculoskeletal assessment to determine the extent of Thomas's impairments. Sandy can then establish a work rehabilitation program to address the identified impairments. This program should include job simulation tasks to address the functional capabilities needed to perform his job. Sandy will need to communicate with the employer and/or case manager to promote an early return-to-work plan. The employer might be willing to accept Thomas back sooner if the employer understands Thomas's abilities and Sandy articulates job accommodation measures.

were suggested that included alternative work, further education, and voluntary work options (Jackson et al., 2004). Also, use of a standardized assessment resulted in increased client participation in hobbies and leisure pursuits.

Occupational therapists must consider barriers to employment when designing rehabilitation programs. Awareness of problem areas can guide assessment, training, and intervention. Lack of transportation, concerns about loss of financial benefits, and lack of awareness of social and federal programs have been cited as barriers to employment among the disabled (Fiedler et al., 2002). Occupational therapy interventions focus on overcoming barriers through specifically designed rehabilitation programs and education that is presented in a timely fashion. In a study of individuals with spinal cord injuries who were discharged from an inpatient rehabilitation unit, Fiedler and colleagues (2002) found that information on vocational services was presented too early in the rehabilitation process, limiting retention and usefulness. Although provision of the vocational information was a standard aspect of care, the majority of the study participants were unaware of federal vocational programs that were available to them.

The rehabilitation phase provides multiple opportunities for occupational therapists to explore issues and barriers to participation in work activities. The comprehensive occupational therapy program for individuals who receive services in hospital or clinic settings should include a work-focused standardized assessment, individualized intervention guided by the assessment, and education and training in areas that are informed by awareness of the barriers to employment.

Community Work Programs

Occupational therapy practitioners play major roles in using and developing the social context for vocational exploration and placement of people who have mental illness and developmental delays. Therapists are instrumental in developing community programs that are built on strong support networks and relationships with employers and other community job service agencies and health personnel. To influence the social context, practitioners use various management skills: needs evaluation, program development, worksite development, evaluation and monitoring of placements, and advocacy at the community level (Ramsey, Starnes, & Robertson, 2000).

Occupational therapy practitioners who are involved in vocational programming must be knowledgeable about work incentive issues that help people to make the transition to work. Supplemental Security Income, Social Security Disability Insurance, Welfare-to-Work incentives, and other public assistance programs must be well understood in order to adhere to the policies that qualify recipients to continue receipt of benefits while making the transition to gainful employment.

Many different program models exist to address vocational needs of individuals with serious mental illness and developmental delays. Overall, program models fall into two categories: programs that train and programs that both train and place.

Training Programs

Both simulated and actual work settings are used in training programs that are designed to train the client for general work habits and specific work skills. These programs encourage clients to obtain employment that pays at least minimum wage. Integrated environments provide for additional learning opportunities with individuals without mental illnesses or developmental disabilities.

Place and Train Programs

Place and train programs put clients into actual work environments that require them to learn to solve problems and adapt to work styles in a real work environment. Initially, the occupational therapist will evaluate the client's vocational potential by assessing medical and work history, work skills, social skills, specific job stresses, transportation needs, and the like to determine an appropriate job placement. No best way exists for designing work programs that meet all clients' needs. Instead, occupational therapy programs that offer a range of services best respond to client and employer needs.

Vocational programs require a continuum of services. The developer of these programs must help clients to build work habits and skills at one end of the continuum and locate independent part-time or full-time paid employment at the other end of the continuum.

Sheltered Workshops

Sheltered workshops are noncompetitive employment settings intended to provide many of the positive benefits of a work atmosphere for individuals with disabilities. A longstanding model of vocational rehabilitation, sheltered workshops strive to provide a protected work environment while developing vocational competency and providing behavioral interventions if needed (Siporin, 1999). Some individuals with physical or mental disabilities struggle with many issues in competitive employment settings, such as social skills, personal hygiene, and appearance. Difficulties in these areas can further isolate individuals rather than foster inclusion (Krupa, Lagarde, & Carmichael, 2003). Siporin suggested that the occupational therapist is ideally suited to work in the sheltered workshop setting by assisting clients to build on existing skills or train for new skills aimed at successful employment. The occupational therapists' role in sheltered workshop settings includes assessment and training in activities of daily living, sensorimotor skills, cognitive abilities and social skills. Although the protected environment of the sheltered workshop remains a successful option for some individuals with disabilities, studies have indicated that supported employment has proved to be a better option for many to enhance quality of life while allowing clients to earn competitive wages in the community (Bond, 2004; Siporin & Lysack, 2004).

Supported Employment

Supported employment is competitive work in an integrated work environment that is consistent with the strengths, resources, priorities, concerns, abilities, capabilities, interests, and informed choice of the individual (Rehabilitation Act Amendments, 1998). The Rehabilitation Act Amendments of 1986 provided the initial springboard for the transition from sheltered workshops into supported employment programs. These amendments were intended to foster inclusion and integration of people with disabilities into the economic, political, social, cultural, and educational mainstream of American society. They were based on the premise that work is a valued activity for everyone, including people who have disabilities. They stated that work fulfills the individual's need to be productive, promoted independence, enhanced self-esteem, and allowed for participation in the mainstream of life in the United States, which included earning competitive wages. The three essential characteristics of supported employment are paid work, employment in an integrated work setting, and ongoing support services that are available to meet continuous or periodic training needs. The ongoing services may include a job coach, a job trainer, a work-study coordinator, and/or an employment counselor. Studies have shown that participation in supported employment improved the quality of life for people with disabilities (Bond, 2004; Siporin & Lysack, 2004). Greater benefits were realized by consumers who held their competitive jobs for sustained periods of time, when they worked in jobs that reflected their choices, and when clients were placed directly into the work environment rather than undergoing training prior to placement. Strong evidence supports the integration of rehabilitation and vocational services (Bond, 2004). The occupational therapist in many different practice settings can play an integral role in preparing a client for supported employment, such as the client shown in Figure 51.4. School systems, mental health settings, and rehabilitation units all promote work as a valued outcome of occupational therapy intervention. The occupational therapist is ideally positioned to include motor skills function, cognitive function, social skills, activities of daily living, and adaptive equipment as part of the comprehensive treatment program. "Occupational

FIGURE 51.4 Courtney's supported employment began with several hours per week with a job coach who was provided by the local school system. Courtney has progressed to needing less than one hour with the coach every other week. Courtney plans to work full-time after high school and eventually to live independently in the community.

therapists can contribute to closing the gap between the impairments of individuals with developmental disabilities and the complex demands of supported employment and even the competitive workplace" (Siporin & Lysack, 2004, p. 463).

PRACTICE DILEMMA

ISSUES IN WORK PRACTICE

Imagine that you are an occupational therapist in the following practice settings, and describe the assessments and interventions that you would pursue for your clients.

◆ You are a school-based therapist working with a 16-year-old boy who has spasticity of the upper extremities due to cerebral palsy.
◆ The factory where you provide on-site services employs many workers over the age of 50.
◆ You are working in a homeless shelter with a 27-year-old single mother who has two small children and an eighth-grade education.
◆ The inpatient rehabilitation unit is well known for treatment of individuals with spinal cord injuries. Your caseload includes individuals between 16 and 35 years of age.

FUNDING AND LEGAL ISSUES

There are specific laws that govern and influence practice in work programs. Therapists should become familiar with this legislation and how it affects practice and the various populations they serve.

Workers' Compensation

The workers' compensation law is actually a system of individual state workers' compensation laws. These laws were designed to (1) cover the medical expenses and wage loss of workers who are injured or develop illnesses on the job and (2) shield employers from costly negligence lawsuits. Most states require employers to carry workers' compensation insurance. The states differ in respect to employers' insurance arrangements and the benefits that are offered to employees. However, most states cover medical expenses (including rehabilitation), disabilities (partial, total, temporary, permanent), and survivors' benefits (Business and Legal Reports, 1997).

Virtually all workers' compensations systems are fundamentally a no-fault mechanism through which employees who incur work-related injuries and illnesses are compensated with monetary and medical benefits (Box 51.2). Either party's potential negligence is usually not an issue as long as there is an employer-employee relationship. Employees are guaranteed a percentage of wages (usually two thirds) and full payment for their medical costs when they are injured on the job. Employers are guaranteed a reduced monetary cost for these injuries or illnesses and are provided with protection from additional or future legal action by the employee for the injury.

Americans With Disabilities Act

The ADA was passed in 1990 to prohibit discrimination against qualified individuals with physical or mental disabilities in all employment settings. The ADA is divided into five titles. Table 51.1 provides an outline of the areas of coverage.

Rehabilitation Act of 1973

Many of the concepts that the ADA contains have as their origin the Rehabilitation Act of 1973. By its terms, the Rehabilitation Act of 1973 was limited in scope. It prohibited discrimination only by federal agencies, entities that have contracts with the federal government, and recipients of federal financial assistance. Three major classes of recipients of federal funds are public school systems; colleges and other institutions of higher learning; and health, welfare, and social service providers (Domer, 1998).

In 1992, the Rehabilitation Act of 1973 was amended so that its terms would conform to those set forth in the ADA. State plans were developed that allowed each state

BOX 51.2 FEATURES OF WORKERS' COMPENSATION SYSTEMS

- Coverage of workers' compensation is limited to employees who are injured on the job.
- Workers' compensation is automatic.
- Employees' injuries and illnesses that arise out of the course of employment are usually considered compensable.
- Most workers' compensation systems include wage-loss benefits, which are usually between one half and three fourths of the employee's average weekly wage.
- Most workers' compensation systems require payment of all medical expenses, including such expenses as hospital, rehabilitation, and prosthesis expenses.
- Administration of workers' compensation is usually assigned to a commission or board within each state.

- In accepting workers' compensation, injured employees waive the right to take any common law action to sue the employer.
- When an injury is of a permanent nature, a dollar value for the percentage of loss to the injured employee is assigned and known as permanent partial disability or permanent total disability.
- In most states, employers with one or more employees are normally required to possess workers' compensation.
- Workers' compensation benefits are generally separate from the employment status of the injured employee.
- The workers' compensation commission or board in each state normally develops administrative rules and regulations for the administration and hearing procedures (Schneid & Schumann, 1997).

to submit to the commissioner of the Rehabilitation Services Administration a plan for vocational rehabilitation and assign a state agency to administer or supervise the plan. The 1992 amendments to the act emphasized individual written rehabilitation programs that were designed to achieve an employment objective consistent with the individual's unique strengths, resources, priorities, concerns, abilities, and capabilities and include a statement of the long-term rehabilitation goals. The term *disability* was substituted for *handicap* in the statute.

TABLE 51.1   THE FIVE TITLES OF THE AMERICANS WITH DISABILITIES ACT

Title	Area	Description
I	Employee provisions	Protects employees with disabilities from discrimination with regard to job applications, hiring, advancement, discharge, compensation, training, and other terms, conditions, and privileges of employment.
II	Public services	Prohibits discrimination against people with disabilities by public entities. This covers all governmental programs, services, activities, and employment but not the private sector. Requires that public transportation entities make a good faith effort to obtain or make vehicles accessible to people with disabilities.
III	Public accommodations	Extends the requirements in Title II to private sector public facilities. Requires that all goods, services, privileges, advantages, or facilities of any public place be offered to people with disabilities.
IV	Telecommunications	Requires telecommunication services to provide individuals with speech-related disabilities with the ability to communicate with hearing individuals through the use of telecommunication devices for the deaf.
V	Miscellaneous provisions	Addresses insurance related issues, such as allowing insurance providers to continue to use the preexisting condition clause, but prohibits denial of health insurance coverage to individuals on the basis of their disability. Does not limit or invalidate other federal or state laws that provide equal or greater protection to persons with disabilities.

The act provided for training and community rehabilitation programs. It authorizes grants and contracts to ensure that skilled personnel are available to provide rehabilitation services to individuals with disabilities through vocational, medical, social, and psychological rehabilitation programs and through supported employment programs, independent living services programs, and client assistant programs (Domer, 1998). The grants and contracts exist to provide training and information to individuals with disabilities and to their parents, families, guardians, advocates, and authorized representatives.

Social Security Disability

In the mid-1950s, the Social Security Act (SSA) established a social insurance program that was designed to provide guaranteed income to individuals with disabilities when they are found to be generally incapable of gainful employment. Its purpose is to provide a basic level of financial support for people who cannot support themselves because of disability. The SSA provides for disability benefit programs administered by the SSA, including Social Security Disability Insurance (SSDI) and Supplemental Security Income (SSI) programs. The SSDI program provides benefits to disabled workers, dependents, and widows and widowers if the worker is insured under the provisions of the program. The SSI program provides benefits to disabled individuals whose incomes and assets fall below a specified level (Domer, 1998).

SUMMARY

Occupational therapists address work issues for clients as young as 14 years old in school-based transition programs and across the life course to older adults who continue to benefit from work activities. The practice settings are varied including both traditional and nontraditional environments. Work-related assessments and interventions require the occupational therapist to integrate medical, psychological, behavioral, and philosophical dimensions to address the specific needs of the client, the population, the setting, and the system. Communication and collaboration with the clients, their families, and the team members enhance the success of work programs in all settings. The basic premise of work as a meaningful occupation provides the foundation for occupational therapy in work programs.

PROVOCATIVE QUESTIONS

1. What assessment and intervention activities would you design for a 23-year-old man who is considered to have moderate to severe mental retardation, is living in a group home, and wants to work?
2. If you were hired as an on-site therapist in a manufacturing plant and knew that the majority of the workers in the plant are over age 45, what types of services could you provide as a benefit to the employer and employees?

Play and Leisure

LOREE A. PRIMEAU

Learning Objectives

After reading this chapter, you will be able to:

1. Describe four definitions of play and leisure.
2. Describe guidelines and parameters for evaluation of play and leisure.
3. Identify selected assessments that can be used to develop an occupational profile and to evaluate play and leisure.
4. Describe three purposes of play and leisure in intervention.
5. Define play and leisure as lures or rewards, as means, and as ends.
6. Explain how play and leisure as means can be used for intervention.
7. Describe three types of occupational therapy intervention to facilitate play and leisure as ends.

WHAT ARE PLAY AND LEISURE?

Occupational therapy practitioners have a long tradition of considering play and leisure in the lives of people with whom they work (Parham & Primeau, 1997). In the founding years of the profession, the "play spirit" was seen as essential for living a worthwhile life (E. B. Saunders, 1922; Slagle, 1922; Ziegler, 1924). Over time, as occupational therapy practitioners became increasingly concerned with scientific and technical aspects of intervention, play and leisure were thought to be unscientific and inappropriate for use in practice. Late in the 20th century, scholars in occupational therapy and occupational science reclaimed play and leisure (Bundy, 1993; Canadian Association of Occupational Therapists [CAOT], 1996; Parham, 1996; Parham & Fazio, 1997; Primeau, 1996; Reilly, 1974; Suto, 1998).

Although multiple definitions of *play* and *leisure* have been proposed in the literature, consensus has not been reached on how to define these terms. Lack of definitional clarity for these terms, however, should not prevent occupational therapy practitioners' consideration of their clients' performance in these areas of occupation. From a pragmatic point of view, play and leisure are powerful tools for practice, but single, precise, and all-purpose definitions that are responsive to the needs of an entire profession might not be required or desired, even if they were possible (Parham & Primeau, 1997). Nevertheless, definitions of play and leisure in the literature tend to converge into four major categories: (1) play and leisure as discretionary time, (2) play and leisure as context, (3) play and leisure as observable behavior or activity, and (4) play and leisure as disposition or experience (Gunter & Stanley, 1985; Rubin, Fein, & Vandenberg, 1983).

Play and Leisure as Time

The category of play and leisure as discretionary time views them as leftover or residual time after obligatory activities, such as paid or unpaid work and self-maintenance tasks, have been completed (Gunter & Stanley, 1985; Tinsley & Tinsley, 1982). Play and leisure are defined by what they are not: They are not work or school activities; they are not activities of daily living or instrumental activities of daily living. By definition, play and leisure are quantified as the time that is spent by the individual who is engaged in them. This view of play and leisure lends itself easily to measurement and is often the focus of evaluation in occupational therapy through the use of activity configurations as an assessment tool (Suto, 1998). Although practitioners need to know about their clients' use of time and its relationship to their health and well-being, equally important for evaluation of play and leisure are the contexts in which they occur, the clients' activities, and their experience of those activities.

Play and Leisure as Context

The category of play and leisure as context identifies and describes them in terms of the conditions under which they occur. Contexts that are friendly, safe, and comfortable with a variety of materials, objects, people, and activities and that also denote cultural sanctions for play and leisure are more likely to elicit them (Figure 52.1). Freedom of choice to engage or not to engage in play and leisure and freedom from hunger, fatigue, illness, or other stressors are also identified as conditions that are conducive to play and leisure (Rubin et al., 1983). Beliefs held by people in a specific culture will determine what is and is not considered to be play and leisure and the con-

FIGURE 52.1 The definition of play as context can be seen in this boy's enjoyment of conditions that support his engagement in play.

ditions under which they will occur. Practitioners often draw from this category when they evaluate supports and barriers in their clients' contexts that facilitate or hinder their engagement in play and leisure. One problem with the view of play and leisure as context is that although the conditions described above are necessary for play and leisure, they are not sufficient, meaning that producing such a context does not ensure that play and leisure will emerge in it (Rubin et al., 1983). Because play and leisure are transactions between clients and their contexts (Bundy, 2001b), clients' play and leisure activities and their experience of them must also be considered.

Play and Leisure as Activity

The category of play and leisure as activity views them as behaviors or activities that can be observed and named. Taxonomies are used to identify and describe types of play and leisure activities. For example, Primeau and Ferguson (1999) named children's play using the following taxonomy: sensorimotor play, object play, social play, motor play, imaginative play, and game play. Such taxonomies are useful because they provide descriptive criteria for observation and evaluation of clients' play and leisure behaviors (Rubin et al., 1983), including their interests (Primeau, 1996). This view of play and leisure as activity is also easily quantified and measurable. It is familiar to practitioners in the form of many assessments, including checklists used to identify interests as well as strengths and problem areas in performance of play and leisure activities (Suto, 1998). A drawback to the view of play and leisure as activity is lack of consideration of the experience of the activities themselves (Primeau, 1996; Suto, 1998).

Play and Leisure as Experience

The category of play and leisure as experience views them as the overall experience of a client's engagement in play and leisure. Disposition, attitude, or state of mind while participating in play and leisure are of primary importance (Iso-Ahola, 1979; Tinsley & Tinsley, 1982). Personal meanings of play and leisure arise from these subjective experiences (Primeau, 1996). Several qualities of play and leisure as experience have been identified in the literature, including freedom from obligation or constraint, freedom of choice, enjoyment, fun, intrinsic motivation, low work-relation, flow, self-expression, active engagement, aesthetic appreciation, relaxation, internal locus of control, and suspension of reality (Bundy, 1997; Csikszentmihalyi, 1975; Iso-Ahola, 1979; Rubin et al., 1983; Samdahl, 1988; Shaw, 1985; Tinsley, Hinson, Tinsley, & Holt, 1993). Of all these qualities, freedom from constraint and freedom of choice are most often identified as defining characteristics of play and leisure as experience (Henderson, Bialeschki, Shaw, & Freysinger, 1996). Practitioners recognize the importance of evaluation of play and leisure as experi-

ence by gathering data on clients' experiences through interviews, participant observations, and specific formal assessments.

The view of play and leisure as experience holds the most promise for occupational therapy practice (Bundy, 1993; Primeau, 1996; Suto, 1998). Although evaluation of play and leisure as time, context, and activity are necessary, they are not sufficient to understand clients' participation in play and leisure. Best practice dictates that evaluation of play and leisure as experience must also be conducted to obtain the clearest picture of clients' engagement in play and leisure.

EVALUATION OF PLAY AND LEISURE

Guidelines for Evaluation of Play and Leisure

Evaluation of play and leisure should be client-centered and should follow a top-down approach. Client-centered evaluation is a collaborative process that combines the perspectives, expertise, and experiences of clients and practitioners to determine what is evaluated, how it is evaluated, and what will be the focus of intervention. To be truly client-centered, evaluation of play and leisure should occur in clients' natural settings (home, school, work, and community) whenever possible (Townsend, 1997). For practitioners who work with children, clients can "include the child, parents, siblings, other family members, peers, teachers, and other adults who are responsible for the child" (Primeau & Ferguson, 1999, p. 470). As the practitioner considers the child in each setting, a new group of individuals may become central to the collaborative process.

A top-down approach to evaluation begins with the client's occupational profile, including the client's participation in play and leisure in home, school, work, and community settings (American Occupational Therapy Association [AOTA], 2002; Trombly, 1993). The client and the practitioner collaboratively identify what the client wants to do, needs to do, or is expected to do (Law et al., 1990) and the extent to which the client is able to engage in play and leisure in these settings (Coster, 1998). Analysis of the client's occupational performance follows, with a specific focus on performance in the areas of occupation that were identified in the occupational profile (AOTA, 2002). Evaluation of play and leisure addresses the following issues: (1) how the client's contexts facilitate or inhibit his or her engagement in play and leisure, (2) how the client's performance in the areas of occupation of play and leisure is enhanced or limited by the types of play and leisure activities in which he or she engages and his or her experience of these activities, and (3) how limitations or impairments in performance skills and client factors affect the client's ability to engage in play and leisure activities.

Parameters for Evaluation of Play and Leisure

Client-centered and top-down approaches to evaluation guide practitioners in the process of evaluation, or *how* to evaluate play and leisure. The client's overall pattern of participation in play and leisure across home, school, work, and community settings is the content, or *what* needs to be evaluated. The four definitions of play and leisure described above provide parameters for evaluation that are aligned with the two substeps of the evaluation process: occupational profile and analysis of occupational performance (AOTA, 2002). Play and leisure as time aligns with the substep of the occupational profile, whereas play and leisure as context, as activity, and as experience are addressed in the substep of analysis of occupational performance. Specifically, play and leisure as context aligns with the domain area of contexts, and play and leisure as activity and as experience align with the domain area of performance in areas of occupation (AOTA, 2002). Also evaluated during the analysis of occupational performance are the domain areas of performance skills and client factors; however, parameters for evaluation of these areas are drawn from general occupational therapy assessments used to evaluate clients in these areas and are not necessarily specific to play and leisure assessments. Table 52.1 lists assessments that can be used to develop the client's occupational profile and to evaluate play and leisure in the areas of contexts, performance in areas of occupation, performance skills, and client factors.

Occupational Profile: Play and Leisure

When developing an occupational profile, occupational therapy practitioners gather information about the client's past and current play and leisure participation (AOTA, 2002). **Play and leisure participation** is defined as the client's engagement in play and leisure occupations that are typically expected of and available to a person of the same age and culture in home, school, work, and community settings (Coster, 1998; Primeau & Ferguson, 1999). This profile is used to determine clients' **characteristics of play and leisure participation** (nature, quality, frequency, and duration) in these settings.

Play and leisure participation may be restricted in nature, quality, frequency, or duration. Restrictions are relative to typical participation in each setting. Practitioners compare their clients' participation to that of individuals without participation restrictions to determine the clients' degree of participation or participation restriction (World Health Organization, 2001). They draw from their knowledge base about play and leisure as it occurs naturally in home, school, work, and community settings and from their observations of a typical person engaged in play and leisure in a particular setting to understand the play and leisure of people without restrictions in that setting (Dunn, 1998). Then they may interview their clients

and/or observe them to gather data on their participation in play and leisure, including their personal preferences, and compare this information to that of a person without participation restrictions.

The focus of evaluation is on the nature, quality, frequency, and duration of clients' play and leisure participation. The nature and quality of participation can be addressed by answering the following questions (Coster, 1998): Is the client's participation in play and leisure positive? Does it support the client's physical, cognitive, and psychosocial growth? Is it personally satisfying? Does the client have access to the same opportunities for play and leisure as others of the same age and culture do? Is the client's participation in play and leisure acceptable to others in his or her settings? Frequency and duration of participation are related to definitions of play and leisure as time. Does the client participate in play and leisure to the same extent as others in that setting? One study that asked this question found that boys with developmental dyspraxia participated in games on school playgrounds less often and for shorter time periods than did boys without developmental dyspraxia (Primeau, 1989), indicating a gap between typical participation and that of children with developmental dyspraxia. When gaps in nature, quality, frequency, or duration of participation are found, practitioners must evaluate the client's play and leisure contexts to identify ways to bridge these gaps (Dunn, 1998).

Analysis of Occupational Performance: Play and Leisure

EVALUATION OF PLAY AND LEISURE CONTEXTS.   Evaluation of play and leisure contexts is related to definitions of play and leisure as context. Contexts may be cultural (customs, beliefs, values), physical (built and natural environments, objects), social (individuals, groups, organizations, systems), personal (age, gender, socioeconomic status), spiritual (greater or higher purpose, meaning), temporal (time of day/year, stage of life), and virtual (chat rooms, simulated environments) (AOTA, 2002). Practitioners identify **contextual features** in their clients' settings of interest and then determine whether these features facilitate or hinder participation in play and leisure in those settings. Gathering objective data on contextual features is not sufficient; practitioners must assess the impact of these features on their clients' engagement in play and leisure (Dunn, 1998). Interviewing and observing clients in natural settings are optimal methods for doing this. For example, physical accessibility to a restaurant does not ensure that a client living with severe physical disabilities will dine out with friends. Cultural and social features can affect the client's comfort level in that setting, thereby restricting his or her participation. The practitioner would need to ask questions to discover the source of this client's restriction.

EVALUATION OF PERFORMANCE IN AREAS OF OCCUPATION: PLAY AND LEISURE.   Definitions of play and leisure as

activity and as experience are central to evaluation of performance in these areas of occupation. Evaluation focuses on clients' play and leisure performance (what they actually do and their experience while doing it). Practitioners assess clients' play and leisure activities and their experience while engaged in these activities to identify performance limitations and determine how to enhance performance. Evaluation of **play and leisure activity** considers **activity interests** and **activity choices**, whereas evaluation of **play and leisure experience** explores **subjective experience**, **personal meaning**, and **satisfaction with experience**.

EVALUATION OF PLAY AND LEISURE ACTIVITY.

◆ **Activity interests.** *Interests* are defined as "dispositions to find pleasure and satisfaction in occupations and the self-knowledge of enjoyment of occupations" (Kielhofner, Borell, Burke, Helfrich, & Nygard, 1995, p. 47). When this definition of interests is applied to play and leisure activities, it addresses clients' affective responses to play and leisure activities (often expressed as preferences or as likes, dislikes, and indifferences) and their perceptions and awareness of themselves and their environments (Matsutsuyu, 1969). Assessments of play and leisure activity interests provide information in two areas: preferences and self-knowledge as they relate to play and leisure activities. Clients are asked to identify their preferences for a variety of play and leisure activities. On the basis of their responses, practitioners can determine the extent and quality of clients' self-knowledge and awareness of these interests. For example, a client living in a cold, landlocked area who identifies scuba diving, surfing, and snorkeling as leisure interests displays limited preferences (he identifies only three) and a lack of awareness of the leisure activities that his environment offers him, indicating that he will most likely encounter limitations in his performance of leisure activities.

◆ **Activity choices.** Activity choices consist of the activities in which the client engages during play and leisure. Assessments in this area examine what clients do, with whom, and how often. Play and leisure activities are characterized as general categories (e.g., object play, games, hobbies, sports) or specific activities (e.g., play with blocks, board games, woodworking, soccer). Other areas to explore include whether the activity is done alone or with others, including friends, family, or coworkers, and how often a particular play and leisure activity is performed. This indicator of frequency differs from that evaluated in the occupational profile because practitioners are concerned here with the client's individual performance of a specific play and leisure activity, regardless of the setting in which it occurs, as an indicator of the client's history and familiarity with it. Recall the example of the boys with developmental dyspraxia who exhibited decreased frequency and duration of participation in games on the school playground.

Evaluation of their activity choices would focus on their history and familiarity with games (whether they had played games before and, if so, what types, with whom, and how often) rather than on their overall participation in play on the school playground.

EVALUATION OF PLAY AND LEISURE EXPERIENCE.

◆ **Subjective experience.** Subjective experience refers to two aspects of engagement in play and leisure activities: state of mind with which these activities are approached and the affective experience of engagement in them. State of mind, often termed playfulness, is characterized by freedom from constraint, freedom of choice, intrinsic motivation, internal control, active engagement, and freedom to suspend reality (Bundy, 1997; Henderson et al., 1996). The affective experience of engagement in play and leisure is a positive one, marked by feelings of fun, enjoyment, happiness, satisfaction, and pleasure (Csikszentmihalyi, 1988). Assessments of subjective experience explore these two areas: playfulness and affective experience. Practitioners must remember that the subjective experience of play and leisure transcends cultural definitions of play, leisure, work, and activities of daily of living (Primeau, 1996). For example, a mother describing her experience of playing with her children while doing housework as "play-work" stated, "It's like work with an *attitude.* It's my way to get things done in a *fun way.* . . . No, [it] isn't exactly what I want to do right now, . . . but I'm getting it done and *we're all enjoying it* at the same time." (Primeau, 1995). Although she recognizes that she is restricted in her choice of activity, her use of the words "attitude" and "fun way" demonstrate a playful approach, and her statement that "we're all enjoying it" refers to a positive affective experience, suggesting that her subjective experience is one of play and leisure.

◆ **Personal meaning.** Personal meaning derives from the subjective experience of play and leisure performance. Satisfaction of conscious or unconscious needs and benefits attributed to this experience create personal meanings, which often become motivation for clients' future engagement in play and leisure activities. Personal meanings can be categorized as physiological (e.g., physical fitness, stress reduction and recovery), educational/cognitive (e.g., learning, intellectual stimulation), social (e.g., social interaction, companionship), psychological (e.g., self-identity, self-expression), aesthetic (e.g., appreciation of beauty, arts, and symbolic systems of meaning), and spiritual (e.g., heightened awareness, transcendent experiences) (Beard & Ragheb, 1980; Driver, Brown, & Peterson, 1991). Evaluation of personal meaning becomes particularly important when practitioners want to increase their clients' repertoire of play and leisure activities (Bundy, 2001b) or substitute a new activity for one that is no longer viable (Bundy, 1993). Clients' identified personal meanings can be matched with play and leisure activities that provide those meanings in the form of benefits derived from them, offering new play and leisure options. For example, a study found that bingo, bowling, ceramics, dancing, and volunteer activities were all rated as providing high levels of the benefit of companionship by elderly adults living in the community (Driver, Tinsley, & Manfredo, 1991). Practitioners could suggest these activities, or others that provide a similar benefit, for their elderly clients who have expressed a desire for companionship.

◆ **Satisfaction with experience.** Satisfaction with experience refers to clients' overall feelings and perceptions related to their play and leisure experiences. Feelings and perceptions can be positive (contentment and satisfaction) (Beard & Ragheb, 1980) or negative (boredom and dissatisfaction) (Iso-Ahola & Weissinger, 1990). Satisfaction with play and leisure experience is thought to have powerful consequences for clients' physical health, mental health, life satisfaction, and personal growth (Driver, Tinsley, & Manfredo, 1991). Evaluation must capture clients' range of feelings and perceptions about their play and leisure satisfaction across all activities and settings in which they participate (Figure 52.2). For example, elderly clients' decreased participation in and access to leisure activities did not translate into dissatisfaction with their leisure experience, suggesting that, although their range of activity choices were restricted, even infrequent participation in valued activities added meaning and satisfaction to their lives (Griffin & McKenna, 1998).

EVALUATION OF PERFORMANCE SKILLS AND CLIENT FACTORS. Practitioners can choose from many general occupational therapy assessments and some specific play and leisure assessments that are designed to assess performance

FIGURE 52.2 Participation in valued leisure activities, even if it is infrequent, adds meaning and satisfaction to people's lives.

skills and client factors. Practitioners can also make informal observations during clients' engagement in play and leisure activities. Specific assessments and observations ensure that practitioners are examining clients' performance skills and body functions and structures that are actually used in play and leisure activities (Bundy, 2001b), thereby increasing the likelihood that their intervention will be focused on outcomes related to clients' participation in play and leisure. For example, practitioners often observe children at play with their peers to assess how the children's motor, process, and communication/interaction skills as well as their physical, cognitive, and psychosocial abilities affect their play with others.

Summary of Evaluation of Play and Leisure

Evaluation of play and leisure is guided by client-centered and top-down approaches and is focused on clients' overall patterns of participation in play and leisure across home, school, work, and community settings. The occupational profile gathers information related to clients' play and leisure participation, specifically characteristics of their participation (nature, quality, frequency, and duration). Analysis of occupational performance of clients' play and leisure consists of evaluation of their play and leisure contexts and their performance in the areas of occupation of play and leisure, including play and leisure activity (activity interests, activity choices), and play and leisure experience (subjective experience, personal meaning, satisfaction with experience). Evaluation of performance skills and client factors related to play and leisure is conducted by using general occupational therapy assessments, specific play and leisure assessments, and observation. Practitioners who use this conceptual framework to evaluate play and leisure will be able to design and implement interventions that are directly related to their clients' participation in play and leisure in home, school, work, and community settings.

PLAY AND LEISURE INTERVENTION

To understand play and leisure in intervention, a conceptual framework based on the work of Blanche (1997) and Pierce (1997) is presented. Play and leisure in intervention may be (1) lures or rewards, (2) means to achieve intervention goals, and (3) ends or intervention outcomes. This conceptual framework guides how occupational therapy practitioners use play and leisure in intervention. The occupational therapy intervention approaches (create/promote, establish/restore, maintain, modify, and prevent) within the Occupational Therapy Practice Framework (AOTA, 2002) direct the use of play and leisure toward specific intervention outcomes. Examples below highlight their application.

Play and Leisure as Lures or Rewards

Practitioners use **play and leisure as lures or rewards** to motivate clients to participate in therapeutic activities or to reward them for their participation in intervention (Blanche, 1997; Pierce, 1997). The use of play and leisure in this manner corresponds to the therapeutic use of self (personality, attitude, tone of voice, body language) as a type of occupational therapy intervention (AOTA, 2002). A survey of 222 occupational therapists working with preschool-aged children indicated that all respondents regarded play as important in motivating children to participate in intervention; 91% reported that it was very important (Couch, Deitz, & Kanny, 1998). Pierce (1997) describes the use of play with a toy as a therapy lure when it is presented out of reach of a child. The child is then encouraged to move toward the toy and, when successful, is allowed to play with it. Another example of play and leisure as lures is practitioners' frequent use of a playful attitude in their interactions with clients in order to draw them into intervention activities. Practitioners have historically attended to this affective aspect of therapy by creating intervention settings that are infused with feelings of cheerfulness, an esprit de corps, and hope (Kielhofner & Burke, 1983). Of 77 occupational therapists who reported using leisure assessments to plan their intervention, 32% reported using leisure activity to motivate their clients and facilitate their interest and participation in intervention (Turner, Chapman, McSherry, Krishnagiri, & Watts, 2000).

Play and leisure as rewards are also frequently employed in intervention. Of 203 occupational therapists working with preschool-aged children, 99% reported their use of play as a reinforcer; 40% indicated this use in over 50% of their caseload (Couch et al., 1998). Play as reinforcer is typically used when practitioners provide an opportunity for children to engage in free-play activities during, or at the conclusion of, an intervention session. Blanche (1997) urges those who use play to reinforce children's specific actions to allow time for play consistently throughout a session, rather than banishing it to the end of a session. The common practice of timing opportunities for free play at the end of a session leaves it open to interruption or postponement, suggesting that it is less important than other intervention activities and disregards children's view of play as one of primary importance (Blanche, 1997). Leisure is also used as a reinforcer, particularly when participation in specific leisure activities is the culmination of intervention sessions in which clients planned and organized these activities.

Play and Leisure as Means

Play and leisure as means refers to their use as a type of occupational therapy intervention (therapeutic use of occupations and activities) to achieve specific intervention goals (AOTA, 2002). Clients' engagement in play and

COMMENTARY ON THE EVIDENCE

Play and Leisure in Evaluation and Intervention

The occupational therapy literature provides numerous rationales for the use of play and leisure in evaluation and intervention in occupational therapy practice; however, few studies exist that provide direct evidence of their use and effectiveness in practice. Rationales for use of play and leisure in occupational therapy include descriptions of their general use in practice (Bundy, 1993; CAOT, 1996; Di Bona, 2000; Parham & Primeau, 1997; Primeau, 1996; Read, 1996; Rigby & Huggins, 2003; Stagnitti, 2004; Stagnitti & Unsworth, 2000; Sturgess, 1997; Suto, 1998) as well as their use with specific populations, such as children with autistic spectrum disorder (Desha, Ziviani, & Rodger, 2003; Ziviani, Boyle, & Rodger, 2001), juvenile idiopathic arthritis (Hackett, 2003), and other special needs (Segal, Mandich, Polatajko, & Cook, 2002); adolescents (Passmore & French, 2003); adults with mental illness (Ivarsson, Carlsson, & Sidenvall, 2004; Pieris & Craik, 2004), dual diagnoses (Hodgson, Lloyd, & Schmid, 2001), and physical disabilities (Sandqvist, Akesson, & Eklund, 2005; Specht, King, Brown, & Foris, 2002) and those in forensic settings (Gooch & Living, 2004); and elder adults living in extended care facilities (Atwal, Owen, & Davies, 2003). The majority of these papers are either review articles (Gooch & Living, 2004; Segal et al., 2002; Ziviani et al., 2001) or qualitative studies (Atwal et al., 2003; Hackett, 2003; Hodgson et al., 2001; Passmore & French, 2003; Pieris & Craik, 2004; Specht et al., 2002) that describe play and leisure participation of specific population groups (in some cases, including environmental facilitators and barriers) and make recommendations for use of play and leisure in occupational therapy practice. The remaining three studies use combinations of interviews, observations, questionnaires, and formal assessments to describe population-specific play behaviors and preferences (Desha et al., 2003) or levels of low satisfaction with leisure performance and/or leisure participation (Ivarsson et al., 2004; Sandqvist et al., 2005), leading to recommendations for occupational therapy practice.

Studies that provide direct evidence of the use and effectiveness of play and leisure in occupational therapy practice can be organized according to their focus: (1) play

and leisure evaluation in specific populations and (2) support for use of play and leisure as means or ends in intervention. Four studies found in the literature evaluated play behaviors in children using specific play assessments, including the Test of Playfulness (Leipold & Bundy, 2000; Okimoto, Bundy, & Hanzlik, 2000) and the Child-Initiated-Pretend Play Assessment (Stagnitti, Unsworth, & Rodger, 2000), or other structured, formal play observations conducted in clinical settings (Ziviani, Rodger, & Peters, 2005). Each study had small sample sizes ($n \leq 82$), used a control group of typically developing children, and found differences in play behaviors between the control groups and children with autistic spectrum disorder (Ziviani et al., 2005), those with attention deficit/hyperactivity disorder (Leipold & Bundy, 2000), those with cerebral palsy and developmental delays (Okimoto et al., 2000), and those experiencing preacademic problems (Stagnitti et al., 2000). In all cases, the children with disabilities exhibited problematic play behaviors when compared to the control groups.

Seven studies supporting the use of play as means to address client factors and performance skills were found in the literature. Four studies examined the use of games to enhance prone extension (Sakemiller & Nelson, 1998), promote arm reach (Sietsema, Nelson, Mulder, Mervau-Scheidel, & White, 1993), increase standing tolerance (Hoppes, 1997), and enhance motivation (Harris & Reid, 2005). Although sample sizes were small ($n \leq 20$), these studies indicated that play in the form of games had positive effects on these client factors. Additionally, a systematic review of eight studies that investigated the effect of leisure activity on depression or self-esteem in elder adults suggested that leisure activity does have a positive effect on depression and self-esteem (Fine, 2000). Finally, two correlational studies found significant relationships between playfulness and coping skills in both preschool children and adolescents, suggesting that the use of play as means can positively affect coping skills in these groups (Hess & Bundy, 2003; I. Saunders, Sayer, & Goodale, 1999).

Only two studies were found in the literature that investigated play and leisure as ends in occupational therapy

Continued

COMMENTARY ON THE EVIDENCE *Continued*

(O'Brien et al., 2000; Okimoto et al., 2000). One study (*n* = 8) used play as means to examine the effects of intervention on playfulness in children with developmental disorders; no differences were found between the play as means group and the control group that received a home program to promote playfulness (O'Brien et al., 2000). The second study (*n* = 38) compared the effects of the consultation process to improve mother-child interactions with a neurodevelopmental treatment (NDT) session on playfulness of children with cerebral palsy and developmental delays (Okimoto et al., 2000). Although the ToP scores of the children whose mothers received the consultation were higher after the intervention than

before, they were not significantly higher than those of the children who received direct NDT.

The state of the evidence in the literature for the use of play and leisure in occupational therapy practice is problematic. While numerous rationales are provided for their use, direct evidence of their use and effectiveness is lacking because too few studies have been reported in the literature, and those that have been reported are limited by methodological weaknesses and small sample sizes. The evidence indicates an urgent need for systematic and methodologically rigorous studies that examine the use of play and leisure in evaluation and intervention in occupational therapy.

---

leisure is the method or process through which change occurs (Gray, 1998; Trombly, 1995). Practitioners employ play and leisure as means to target change in client factors and performance skills (underlying all areas of occupation) and performance in two specific areas of occupation (play and leisure).

Means to Address Client Factors and Performance Skills

Play and leisure as means are frequently used to address impairments in clients' body functions and structures and limitations in their performance skills. Using the intervention approach of *establish/restore* (AOTA, 2002), practitioners engage their clients in play and leisure activities that are designed to facilitate their achievement of intervention goals related to these impairments and limitations. Survey results indicated that 100% of 212 occupational therapists working with preschool-aged children used play as a therapeutic modality to enhance motor, sensory, or psychosocial outcomes; 92% indicated this use in over 50% of their caseload (Couch et al., 1998). These results resonate with occupational therapy literature in which play is typically described as means to facilitate children's development of their physical, cognitive, and psychosocial abilities and their acquisition of motor, process, communication, and interaction skills (Blanche, 1997; CAOT, 1996; Morrison & Metzger, 2001; Parham & Primeau, 1997; Pierce, 1997).

Although descriptions of leisure as means in the occupational therapy literature are limited (Bundy, 1993;

Suto, 1998), other literature indicates that it is used to achieve physical, cognitive, psychological, social, and spiritual benefits (Driver, Brown, & Peterson, 1991). Occupational therapy practitioners often employ leisure activities, such as games or crafts, as means to improve their clients' manual dexterity, increase their attention to task, develop their social skills, or enhance their feelings of self-efficacy and self-esteem. Of 77 occupational therapists who reported using leisure assessments to guide their intervention, 38% said that they used their clients' leisure interests to address their clients' development of skills (Turner et al., 2000).

Means to Enhance Performance in Areas of Occupation: Play and Leisure

Play and leisure as means can target change in performance in two specific areas of occupation: play and leisure. They are used to address limitations in clients' play and leisure performance (what they actually do and their experience while doing it). Practitioners engage their clients in play and leisure activities to achieve intervention goals related to their competence in and experience of these activities. Intervention provides opportunities for clients to practice specific play and leisure activities, explore new ones, or enhance their experience while engaged in them (Bundy, 2001a; Gray, 1998; Morrison & Metzger, 2001). For example, a Saturday morning group called Kids' Club, an occupational therapy intervention focusing on play and social participation, uses play as means in the form of games with rules to provide opportunities for children with

developmental disorders to practice playing familiar games with their peers, explore games that are new to them, and experience fun and enjoyment during their participation in these games (Box 52.1).

When clients demonstrate problems with competence in their chosen play and leisure activities, practitioners can provide opportunities for them to practice play and leisure activities in a positive and safe environment or to explore alternate play and leisure activities in which they can experience higher levels of competence. For example, intervention for a boy with developmental dyspraxia who has difficulty playing soccer with his peers can include therapy sessions in which he and the occupational therapy practitioner actually play soccer so that he can

practice the skills and tasks required for success in a safe and positive environment with no serious consequences for failure (Morrison & Metzger, 2001). In addition, on the basis of evaluation of this boy's activity interests and activity choices, the practitioner can address the mismatch between his interest in and choice of soccer and his limited competence in it by engaging him in other sport activities that might provide a better match. Here, the practitioner uses the intervention approach of *prevent* to mitigate the effects of the boy's feelings of incompetence in soccer, thereby enhancing his performance in sports activities and reducing his risk for restricted participation in play and leisure activities.

When clients report problems with their experience of play and leisure, practitioners can design and adapt play and leisure activities and the environments in which they occur (Bundy, 2001a; Morrison & Metzger, 2001) to facilitate their clients' experience of playfulness, positive affect, personal meaning, and overall satisfaction with their play and leisure experience. For example, an elderly woman reported that the leisure experience she had previously obtained through cooking was no longer satisfying and personally meaningful because of her physical impairments related to a cerebrovascular accident (Bundy, 2001a). Using the intervention approach of *modify,* the practitioner adapted the leisure activity of cooking to facilitate the client's performance in such a way that her leisure experience during cooking was enhanced. Specifically, the practitioner demonstrated and taught the client adapted procedures that she could use to compensate for the mild weakness and abnormal muscle tone in her affected arm, such as sliding pans onto and off the cooktop rather than lifting and carrying them. Instead of focusing intervention on her body functions and structures and performance skills in the context of remediation of motor control, the practitioner used the client's leisure activity of cooking as means to enable her to regain the experience of leisure.

Play and Leisure as Ends

Play and leisure as ends refers to clients' participation in play and leisure as the goal or outcome of intervention (Gray, 1998; Trombly, 1995). Intervention focuses on their ability to engage in play and leisure occupations that are typically expected of and available to people of the same age and culture in home, school, work, and community settings (Box 52.2) (Coster, 1998; Primeau & Ferguson, 1999). Practitioners who address clients' play and leisure as ends promote clients' play and leisure participation for its own sake, not as a means to some other end (Blanche, 1997; Bundy, 1993; Parham & Primeau, 1997).

Although occupational therapy claims to value play and leisure as ends, the literature does not support this claim. Practitioners who address play as ends are rare (Pierce, 1997), as indicated by a survey finding that only 2% of 205 occupational therapists focused on preschool-aged

---

BOX 52.1 **CRAIG AND THOMAS**

The occupational therapist uses play as means in the form of a game with rules in an intervention session with Craig and Thomas (Figure 52.3). Client factors (e.g., orientation, attention, motivation, and muscle power) and motor, process, and communication/interaction performance skills (e.g., stabilizes, aligns, coordinates, calibrates, grips, attends, handles, heeds, gazes, orients, shares, sustains, focuses, and responds) are all addressed through their engagement in this game. Additionally, the boys' performance in the area of occupation of play is enhanced by the opportunity to play this game in a safe environment and by their positive and enjoyable experience of it.

FIGURE 52.3 Play as means is used to address these boys' client factors and performance skills and to enhance their performance in the area of occupation of play.

BOX 52.2   KIDS' CLUB

An occupational therapist in private practice offers a Saturday morning program called Kids' Club, a group intervention for children with developmental disorders focusing on play as ends, that is, the children's engagement in play and social participation as the outcome of intervention. She uses play as means, in the form of games with rules, to address client factors, performance skills, performance in the area of occupation of play, and play as ends. The power of the use of occupation of play as means to facilitate play as ends is demonstrated by two children's stories as told by their mothers.

Fredrick, a 6-year-old boy who was adopted from an Eastern European country, is nonverbal and demonstrates physical and social delays. He had been coming to Kids' Club for a few weeks. His mother called the therapist one night during the week to tell her excitedly about Fredrick's behavior that night in the waiting area outside his sister's karate class. She stated that Fredrick had, for the first time ever, approached a peer (who was also waiting for a sibling) and took his hand to lead him over to the area where Fredrick had been playing. His mother was very happy to see Fredrick initiate play with a peer in this everyday setting, and she attributed it directly to his participation in Kids' Club.

Daryll, a 6-year-old boy diagnosed with pervasive developmental disorder (NOS), had been coming to Kids' Club for about six months when his mother told the therapist that she and her husband had gotten up that Saturday morning to find that Daryll was out of bed and fully dressed. He had also already gotten himself his breakfast of cold cereal and milk. He was ready to leave for Kids' Club, and he was waiting for them to get up and take him there. She said that he had never before shown this kind of motivation to go anywhere. Clearly, Daryll's experience in Kids' Club was more than a means to an ends. His behavior suggested that he enjoyed his participation in Kids' Club as an ends and for its own sake.

children's participation in play as an outcome of intervention (Couch et al., 1998). Additionally, a search of two major North American occupational therapy journals from the 1980s and 1990s identified fewer than eight articles related to leisure (Suto, 1998). A similar search of these journals for the past eight years (1999–2006) revealed no new articles related to the use of leisure in occupational therapy. Literature outside occupational therapy, dating back to the 1970s, demonstrates a high correlational relationship between leisure satisfaction and overall life satisfaction (Parker, Gladman, & Drummond, 1997). Even though issues of causality in these studies are inconclusive (Headey, Veenhoven, & Wearing, 1991), they indicate that leisure participation can have significant repercussions on overall life satisfaction and quality of life (Brown & Frankel, 1993; Lloyd, 1996; Marans & Mohai, 1991), leading some authors to suggest that participation in play and leisure has a direct role in prevention, health promotion, and population health initiatives (Caldwell & Smith, 1988; Coleman & Iso-Ahola, 1993). Practitioners promote clients' play and leisure as ends through their use of the following types of occupational therapy intervention: therapeutic use of occupations and activities, the education process, and the consultation process (AOTA, 2002).

Therapeutic Use of Occupations and Activities

Therapeutic use of occupations and activities (play and leisure as means) can be used to facilitate clients' play and leisure as ends. As was described previously, they are means to address clients' impairments and limitations in body functions and structures, performance skills, and performance in the areas of occupation of play and leisure. A survey indicated that 35% of 77 occupational therapists reported using leisure activity as means in intervention to promote their clients' future participation in leisure as ends (Turner et al., 2000). Performance in other areas of occupation are also means to enhance play and leisure as ends. For example, practitioners may engage in their clients in activities of daily living, such as dressing or toileting, or in instrumental activities of daily living, such as driving or money management, to improve their ability to participate in play and leisure in home, school, work, and community settings. In fact, older people's ability to live active and healthy lives, including participation in the area of occupation of leisure, can be negatively affected by limitations in their community mobility (Iwarsson, Stahl, & Carlsson, 2003). Occupational therapy practitioners who work with their older clients to facilitate their community mobility can also enhance their ability to participate in leisure in community settings.

Education Process

The education process is a type of occupational therapy intervention (AOTA, 2002) that is used with clients, family members, friends, teachers, coworkers, or other people of significance to clients. Practitioners employ a variety of strategies to promote skill acquisition and structure the teaching-learning situation (Poole, 1995). They teach their clients skills that are required for play and leisure participation, such as how to throw and catch a ball or how to access leisure opportunities in the community. They teach other people (parents, other family members, teachers, and peers) how to facilitate clients' play and leisure participa-

tion by modeling playful interactions (CAOT, 1996). Practitioners also teach clients and others how to use adaptive equipment in play and leisure, such as computer games, toys with switches, and adaptive sports equipment (Deitz & Swinth, 1997). Leisure education programs educate clients about leisure, its potential benefits, and personal and community resources for and barriers to leisure and how to access or overcome them (Bundy, 2001a). These programs exemplify the occupational therapy intervention approach of *maintain* by supporting clients' continued participation in leisure in community settings.

Consultation Process

The consultation process is a type of occupational therapy intervention (AOTA, 2002) through which practitioners collaborate with clients and others in their home, school, work, and community settings to identify issues that affect their successful participation in play and leisure and then to plan solutions that address those issues (Barris, Kielhofner, & Watts, 1988). The focus is on clients' participation in play and leisure outside of therapy in the context of their daily lives (Kielhofner, 1997). Leisure counseling is a specific form of consultation that helps clients to identify and clarify leisure values, interests, and attitudes; determine their abilities and skills for leisure participation; improve or refine their skills as needed; and locate and access community resources for leisure (Barris et al., 1988; Caldwell & Smith, 1988).

Practitioners also use the consultation process to address contextual features that facilitate or hinder clients' successful participation in play and leisure in home, school, work, and community settings. As consultants and advocates for change (Law, Stewart, & Strong, 1995), practitioners advise, coordinate, educate, and collaborate with clients and others to remove barriers and shape supportive environments that facilitate clients' access to and inclusion in play and leisure opportunities (CAOT, 1996; Rigby & Huggins, 2003). For example, using the intervention approach of *create/promote,* practitioners advocate for accessible community playgrounds and collaborate with parents, teachers, and other adults to facilitate children's inclusion in play with peers and ensure protected play time (Blanche, 1997). Additionally, practitioners use the intervention approach of *prevent* to advise employers on the requirement of the Americans with Disabilities Act of 1990 to include clients with disabilities in all employment-related activities, including holiday parties, sports events, and business trips (Figure 52.4) (Crist & Stoffel, 1992).

Summary of Play and Leisure Intervention

Play and leisure in intervention may be lures or rewards, means, or ends. As lures, they motivate clients to engage in therapeutic activities; as rewards, they reinforce their participation in intervention. They are therapeutic means to achieve intervention goals related to clients' impairments

and limitations in body functions and structures, performance skills, and play and leisure performance. Play and leisure as ends are the goals or outcomes of intervention when practitioners promote clients' play and leisure participation for its own sake, not as means to some other end.

FIGURE 52.4   Play and leisure at work, such as participation in holiday parties and special events, is a significant feature of adults' participation in play and leisure.

CASE STUDY: *Putting it All Together: Evaluating and Designing Interventions for a Child's Participation in Play*

Alvin is a 4-year, 6-month-old boy with a diagnosis of autism. He has a fraternal twin brother who does not have autism. During the occupational therapy evaluation, the occupational therapist asks Alvin's parents about his play behaviors. They report that he essentially ignores other children and rarely engages in play with them. He prefers to play alone, choosing toys such as animal figurines or computer games. When he is around other children, he is likely to interact with those who are younger than he and is most comfortable interacting with others in structured play situations, such as preschool activities, and outdoor activities, such as tag, hide-and-seek, and jumping on the trampoline in their backyard. They also report that Alvin does not have any friends outside of structured play situations that occur in his preschool or that they set up for him at home. Although they state that he demonstrates playfulness, he rarely engages in the play behaviors that they observe in his twin brother's interactions with his peers. They report that

Alvin is unable to make or keep friends, yet that is their wish for him: to have friends outside of the structured activities in which they involve him.

Questions and Exercises

1. What do you know about Alvin's characteristics of play participation, his play contexts, and his play activity and experience? Organize this information according to the parameters for evaluation of play and leisure provided in this chapter.
2. What do you need to know to develop and implement an intervention plan to address Alvin's performance in play and how will you obtain this information? Refer to Table 52.1 for specific assessments that you could use.
3. How could you use play in your intervention with Alvin and what types of intervention would you use?

Therapeutic use of occupations and activities, the education process, and the consultation process are types of occupational therapy intervention that facilitate clients' play and leisure as ends. Practitioners choose among these purposes of play and leisure as lures or rewards, means, or ends to design interventions that lead to outcomes directly related to clients' participation and occupational engagement in home, school, work, and community settings.

ACKNOWLEDGMENT

I acknowledge Janice M. Ferguson, MS, OT(C), for her contributions to our previous conceptualization of occupation as ends that is the basis for this discussion of play and leisure as ends.

PROVOCATIVE QUESTION

1. Occupational therapy practitioners work in a variety of practice settings with different systems of payment for occupational therapy services (see Unit XVI and Chapter 69). How can practitioners address their clients' problems in play and leisure participation within the funding parameters of each setting? Describe how this might occur for the following settings and payment systems:
   a. Skilled nursing facility funded by Medicare
   b. Private, community-based center for children funded by individual health insurance plans
   c. Adult day care program funded by for-profit business

   d. Group homes for adults with developmental disabilities

OT Evaluation and Intervention: Personal Factors

" In order to understand anything well, you need at least three good theories. "

William Perry

" What we understand the world to be like is determined by many things: our sensory organs, our ability to move and to manipulate objects, the detailed structure of our brain, our culture, and our interactions with the environment. . . "

George Lakoff & Mark Johnson

Overview of Personal Factors Affecting Performance

BARBARA A. BOYT SCHELL,
ELLEN S. COHN, AND
ELIZABETH BLESEDELL CREPEAU

Learning Objectives

After reading this chapter, you will be able to:

1. Discuss how personal factors are related to occupations.
2. Discuss how knowledge and theories about personal factors are used in occupational therapy evaluation and intervention.
3. Identify examples of body functions and structures that are considered in the occupational therapy process.

INTRODUCTION

The chapters in this unit discuss various personal factors that affect occupational performance. The term **personal factors** is a broad term that we use here to encompass several aspects of the human condition. In part, personal factors include our **body structures**, which are the anatomical parts of our bodies, such as bones and organs (World Health Organization, 2001). In part, personal factors include our **body functions**, which are the physiological processes of the body (WHO, 2001). Chapters in this unit focus on body functions and structures and how those two sets of personal factors influence us as we engage in occupations. Our bodily structures and functions play an important role in how we conduct our daily lives. This becomes strikingly evident when our bodies and related abilities are different from those of our peers, become impaired, or otherwise change from

what we have come to expect. It is important to understand body functions and structures in order to use occupation as therapy.

We also use the term *personal factors* to refer to the characteristics of the social and cultural context that each individual absorbs into his or her identity as a person. Because many of the chapters in Unit I addressed how social and cultural contexts affect individuals, these factors are only briefly summarized here as a reminder before we discuss body functions and structures.

THE WHOLE IS GREATER THAN THE SUM OF THE PARTS

Personal factors do not operate in isolation. People rarely take their arms and legs anywhere that their brains, eyes, and ears don't go as well! Anyone who has tried to maneuver in unfamiliar space in the dark (such as finding the bathroom in a dark hotel room in the middle of the night) can attest to the importance of vision to movement. All bodily factors work synergistically, which is why it is difficult to generate a definitive list of factors for practition-

ers to attend to. That is the case in this chapter as well, and the selected lists of factors and descriptions are presented to prompt your thinking. The categorizations that are presented here are not, nor can they be, a complete list of all the factors that affect human behavior. They are, at best, suggestions of factors to consider in analyzing occupational performance.

Practitioners can consider all of these factors from an **objective** standpoint or as **subjectively experienced** by the client. When considering personal factors objectively, practitioners observe or measure body functions and structures in ways that other observers can replicate. (Unit IX addresses the importance of using reliable and valid measures.) Although objective approaches are undeniably useful for informing professional reasoning, the client's subjective experience is also important. Skilled practitioners consider both. Box 53.1 provides some examples of objective and subjective reports related to body functions and structures.

Our job as occupational therapy practitioners is twofold. First, we must understand how bodily structures and functions support humans as they engage in occupations and, simultaneously, how occupational engagement can

---

BOX 53.1 **OBJECTIVE AND SUBJECTIVE REPORTS OF BODY FUNCTIONS AND STRUCTURES**

"I Didn't Have a Clue"

In a study seeking to understand the subjective experience of regaining self-care skills after a stroke or spinal cord injury, Guidetti, Asaba, and Tham (2007) reported numerous examples of what it felt like for the study participants to attempt familiar tasks with various impairments. For instance, one participant who was recovering from a stroke appears to have had what objectively might be documented as a sensory loss, along with neglect of the affected upper extremity (a perceptual impairment). She described her experience this way: "I didn't have a clue where it [her hand] was, it was behind my back and like this, so the first night it could have been anybody's hand" (Guidetti et al., 2007, p. 3).

"When You're Sitting There by Yourself, You're Just Eating"

In a study examining supported socialization for people with mental illness, Davidson and his colleagues (2004) argued that people with persistent mental illness are lonely and isolated, not by choice (or objective impairments) but because of lack of opportunity and encour-

agement. When viewed solely from an objective perspective, people with persistent mental illness have been described as having impairments in volition, self-awareness, or coping (affective and cognitive impairments) and are thought to no longer desire human connection, with a preference for being alone. In a randomized control trial of supported socialization intervention, Davidson and colleagues found that people with mental illness desire friendships. One participant in the study commented that eating with her friend was better than eating alone at Burger King: "I'm alone. I sit down at the table, I eat a hamburger. But when I go with somebody else, and I'm sitting there at the table and eating it, she'll say 'Oh, is your hamburger good?' Then it becomes, the hamburger becomes noticeable, and then your mind starts to think about the taste. But when you're sitting there by yourself, you're just eating" (Davidson et al., 2001, p. 380).

This woman's description of eating with a friend illustrates the importance of considering clients' subjective experience. Without consideration of the subjective experience, intervention could run the risk of negating what was meaningful to this woman.

be disrupted by impairments. Second, we must go beyond the generic labeling and understandings of diagnostic conditions to a deeper and more personal understanding of how clients feel in their specific situations. As an acquaintance once noted to the first author, when describing her experience with occupational therapy, "Occupational therapy is such an intimate profession. My OT really understood how this whole thing affected me."

REASONING ABOUT PERSONAL FACTORS: OCCUPATIONAL THERAPY AS A BRIDGE

Occupational therapy practitioners like to say that they treat the "whole person," While other professions (such as nursing) legitimately make a similar claim, occupational therapy is unique in its focus on how daily occupations are the synergistic product of personal factors within the individual and factors that are external to the person in the larger context.

Another way to think about occupational therapy and how we consider the factors under discussion is to contrast occupational therapy with other professions. Think of occupational therapy as a bridge between the medical world and the life world. In the medical world, there are many professions that focus on particular sets of body structures and functions. The field of medicine has obvious examples, with specialties in dermatology, endocrinology, gynecology, and the list goes on and on. But other professions can also be examples. For instance, ophthalmologists focus on the visual system, physical therapists focus on the neuromuscular and musculoskeletal systems, nutritionists focus on the digestive system, and speech-language pathologists focus primarily on the cognitive and oral-motor systems as they relate to communication. Although all of these professionals are interested in improving an individual's function, their contribution is very specific and their knowledge about body functions and structures within their specific scope is typically quite extensive. In general, people in the medical professions focus primarily on disease and reduction of impairment (Fleming, 1991) and secondarily on the use of devices or techniques to compensate for impairments related to their chosen scope of practice.

In contrast, other professions organize themselves around major roles or tasks of life. For instance, vocational evaluators and rehabilitation counselors focus on work-related concerns, educators focus on helping people learn to become productive citizens, recreation professionals focus on play and leisure, and social workers focus on family and community life. These professionals may attend to the impact of personal factors. Special educators, for example, are particularly aware of the impact of cognitive abilities and limitations for students in the classroom. However, for the most part, people in these professions are very different from those in the medically oriented

fields in that they typically have little or no background related to anatomy, physiology, and the specific impact of different health conditions on performance. Rather, they have broad working knowledge about the skills and social demands that are required for their area of interest. So, for example, practitioners with a work focus know a great deal about job demands, employer requirements, and government standards related to work. Similarly, recreation therapists are quite knowledgeable about recreational spaces and places, the value of leisure in life, and the kinds of equipment that individuals might use to pursue leisure interests.

Complexity: An Asset and a Challenge

Occupational therapy is unique as a profession in its willingness to consider all personal factors along with all contextual factors as they shape engagement in the daily activities and routines of life. It is this appreciation of the transactional nature of occupational performance that makes occupational therapy so customized and effective for helping to solve complex problems of daily life. This uniqueness is a tremendous asset. However, for new practitioners and even some experienced ones, it can be challenging not to get absorbed in one aspect and thus lose sight of the larger picture. It is tempting, because there is so much to know. When this happens, you start to see practitioner refer to themselves by the particular aspect—for instance, hand therapy, cognitive therapy, or vision therapy. Recognizing that depth of knowledge about the personal factors is very important to expert practice; we maintain that our clients are best served when we view these factors in relation to the use of occupation as a means for intervention. Examples of such reasoning are provided through the practitioners' narratives in Unit XIII. All of these practitioners indicate a deep understanding of body functions and structures that are relevant to their clients, but they view these personal factors in relation to performance. Furthermore, occupational therapy practitioners grade their use of interventions in a way that is mindful of the person's development, impairments, potential for recovery, and/or need for adaptive approaches. Practitioners also are very in tune with how social and cultural contexts influence their clients' lives. Thus, occupational therapy practitioners specialize not in body parts or body functions, but in supporting health and participation in life through engagement in occupation.

Intertwining Knowledge and Theories

For occupational therapy practitioners to work effectively with people who have impairments or developmental conditions that affect their performance, practitioners must intertwine knowledge about occupation with knowledge about the client's particular health problems. Thus, the quotation from William Perry that opened the unit, stat-

ing that you "must have at least three good theories" to understand anything, seems written for occupational therapy practice. The therapists' narratives in Unit XIII provide examples of using different theories to guide practice. Readers might want to look at those chapters for examples of how to integrate theories about body functions and structures into an occupational therapy intervention. For instance, Mary Muhlenhaupt (Chapter 63) first obtained information about Davey, a third-grade student (occupation), from his teachers and parents and from her direct observation of him (occupational performance) in a variety of school settings (physical and social context). On the basis of his occupational abilities and performance problems, she suspected that a sensory processing problem (neurological system) was affecting his performance. Winifred Schultz-Krohn (Chapter 64) demonstrates an understanding of how many factors, both personal and contextual, contribute to stressful living for individuals in homeless shelters and uses her understanding as the basis for group programming. Karen Garren (Chapter 65) helped Dan to recover from a devastating hand injury (body

structure) in order to regain coordinated use (musculoskeletal function) of his hand so that he could return to being a master carpenter (occupation). Coralie Glantz (Chapter 66) received information from a family member (social context) who was worried about her mother's memory (cognitive function). As it turned out, the client had Alzheimer's disease (neurological impairment). Coralie's knowledge of the typical course of this disease helped her to anticipate and deal with the client's occupational performance problems. The professional reasoning processes that these four practitioners describe demonstrate the complexity and the richness of the occupational therapy process.

PERSONAL FACTORS THAT ARE COMMONLY CONSIDERED

In this section, we provide several tables that readers might find helpful to prompt consideration of one or more personal factors (see Tables 53.1, 53.2, and 53.3). Readers

---

TABLE 53.1.   EXAMPLES OF PERSONAL FACTORS (EXCLUDING BODY FUNCTIONS AND STRUCTURES) THAT ARE CONSIDERED IN OCCUPATIONAL THERAPY

Factor	Common Categories or Descriptors
Age	Historical cohort (e.g., people who lived through the Depression and how that experience affects their worldview) Internalization of societal expectations regarding development and achieving a particular developmental milestone at a given time in the life course Personal expectations about age-related behavior
Gender	Personally adopted social/cultural norms regarding gender
Values	Meanings associated with physical and social spaces Importance of family Standards of conduct
Beliefs	Knowledge that is held to be truth Beliefs about causes and interventions related to illness Perceived locus of control
Spirituality	Beliefs about the meaning of life Religious and sacred beliefs
Family and significant others	Internalized family experiences that shape worldview Internalized expectations about relationships
Socioeconomic status	Financial status Work status Educational attainment
Ethnicity	Internal beliefs about membership in groups of common descent; can include race, culture, language, religion, and politics
Sexual orientation	An individuals sexuality, usually related to the sex or gender of the person the individual finds sexually attractive

TABLE 53.2.	EXAMPLES OF BODY STRUCTURES CONSIDERED IN OCCUPATIONAL THERAPY
Structure	**Common Categories or Descriptors Addressed Within OT Process**
Nervous system	Central (brain, spinal cord) Peripheral Autonomic (sympathetic, parasympathetic)
Eye, ear, nose, throat	Eye (retina, cornea, lens) Ear (inner, middle, outer) Mouth (lips, cheek,tongue, teeth) Nose Pharynx, esophagus Larynx
Cardiovascular, immunological, respiratory	Heart Veins Arteries Lungs Trachea Bronchial tubes Lymph system
Digestive, metabolic, endocrine	Esophagus Stomach Intestine Many glands
Genitourinary, reproductive	Bladder, ureters, urethra Reproductive structures, including glands
Movement-related structures	Bones Joints Muscles Tendons Ligaments Fascia
Skin and related structures	Skin layers Skin glands Hair Sensing organs in skin

Source: AOTA (in press), WHO (2001), Sloan, E. (1994)

will likely find the language useful in communicating about personal factors. As was discussed earlier, there is no practical way to make a comprehensive list, so we make no claim that the tables are all inclusive. Information for these tables was drawn primarily from the International Classification of Function (WHO 2001), the Occupational Therapy Practice Framework (American Occupational Therapy Association, in press), and topical areas that are addressed in this unit as well as chapters from Unit I. The factors that are listed in the tables provide a starting place. Occupational therapy practice, by nature, requires ongoing inquiry

to gain needed knowledge to respond to the challenges of practice.

Cues to personal factors that could be affecting performance are gained from at least three sources:

◆ **Reason for referral.** Referral information may contain a medical, psychological, or educational diagnosis and sometimes precautions to consider during intervention. Even when precautions, symptoms, or other descriptors are not included, knowledge about typical body structures and functions that are affected

TABLE 53.3.	EXAMPLES OF BODY FUNCTIONS ADDRESSED BY OCCUPATIONAL THERAPISTS

Source: Based on AOTA (in press), Dunn (2000), WHO (2001), chapters in this text (J. Poole, Chapter 54; C, Guiffrida & M. Rice, Chapter 55; B. White, Chapter 56; J. Toglia, K. Golisz, & Y. Goverover, Chapter 57; W. Dunn, Chapter 58; S. Smith Roley & E. Jacobs, Chapter 59.).

by the condition can guide practitioners about factors to consider.

◆ **Client self-report.** Clients themselves, their families, and other key people in their social environments (e.g., teachers, employers, caregivers) often give practitioners information about factors that they believe are affecting client performance.

◆ **Observation of client.** Observations of the client engaging in occupations often prompt practitioners to consider one or more factors that are affecting performance.

Skillful intervention requires that practitioners respond to these cues and then use credible resources to obtain needed objective information. This information, combined with the subjective data provided by the client, is then synthesized to develop interventions that enable clients' occupational performance

CONCLUSION

Occupational therapy practitioners routinely consider body functions, structures, and other personal factors during intervention. By integrating knowledge and theories about these factors with theories that relate to occupation and occupational contexts, practitioners provide a unique contribution to society and to the clients they serve.

Musculoskeletal Factors

<div style="float:right">**54**</div>

JANET L. POOLE

Learning Objectives

After reading this chapter, you will be able to:

1. Identify assessments for individuals with musculoskeletal impairments.
2. Recommend intervention approaches for individuals with musculoskeletal impairments.
3. Evaluate the evidence for interventions for individuals with musculoskeletal impairments.

Musculoskeletal impairments can be present in individuals of all ages as a result of an injury or disease or during a recovery stage after surgery (e.g., hip precautions after a total hip replacement) or immobility (e.g., fracture). These impairments can include an injury or amputation of the upper extremity or extremities, amputation of the lower extremity or extremities, arthritis, fractures, joint surgery, or repetitive motion disorders. Regardless, musculoskeletal impairments can limit performance of basic activities of daily living, productivity, and/or leisure activities.

THEORIES

The traditional approaches to evaluation and treatment of individuals with musculoskeletal problems include the biomechanical and the rehabilitative frames of reference. The biomechanical frame of reference is used to assess and treat individuals who have activity limitations due to musculoskeletal impairments such as limited range of motion and strength and decreased dexterity and endurance (James, 2003). The main tenet of this frame of reference is that occupational performance can be regained through addressing the underlying impairments that limit performance of daily activities (Hagedorn, 1997; James, 2003; Trombly, 1995). Thus, assessment would focus on the impairments that appear to be the causes for the deficits in occupational performance and on intervention aimed at reducing these impairments. For example, if decreased upper extremity range of motion is noted and determined to be the reason why an individual with arthritis is having difficulty with bathing, then intervention would consist of a variety of stretching and range of motion exercises and exercises to increase joint motion. Other interventions that use a biomechanical frame of reference include **splints** and **orthotics**, range of motion exercises, strengthening and endurance exercises, stretching, **physical agent modalities**, and edema reduction

techniques. However, what is not clear is whether a reduction in a biomechanical impairment corresponds to an improvement in occupational performance.

For individuals who have musculoskeletal impairments, the rehabilitative frame of reference aims to achieve maximum function in the performance of daily tasks. Through assessment, the client's goals are identified, and intervention focuses on compensatory methods, assistive devices, and environmental modifications (Seidel, 2003). Therefore, for the person with arthritis who is having difficulty bathing because of limitations in joint motion, the occupational therapist, using a rehabilitative frame of reference, might provide a long-handled sponge and a wash mitt to eliminate holding a washcloth and might suggest a hand-held shower. A rehabilitative frame of reference might be appropriate when an underlying impairment cannot be reduced. In addition, the introduction of potentially new strategies, techniques, and/or equipment involves the teaching-learning process. Box 54.1 lists strategies that therapists can use to facilitate learning of new skills (Poole, 1991, 1995).

<div style="border:1px solid #000; padding:10px;">

BOX 54.1

STRATEGIES FOR TEACHING AN OCCUPATION BASED ON PRINCIPLES OF MOTOR LEARNING

1. Make sure the client understands the goal and critical aspects of the occupation.
2. Provide feedback.
3. Organize practice of an occupation, strategies, techniques, and/or equipment so that clients will retain and generalize the information to other occupations or new environments.
4. Assess whether material or techniques have been learned correctly.

</div>

These strategies may also be useful in teaching clients biomechanical inventions such as home exercise programs. Following are some examples of these strategies in use:

- **Make sure the client understands the goal and critical aspects of the occupation.** For example, in teaching a person with a total hip replacement to put on pants using a reacher, the critical aspects are adhering to the hip precautions and making sure the reacher has a good grip on the pants. In teaching a person to use an upper extremity **prosthesis** to use utensils for eating, the critical aspects of the occupation are to look for the flat surface of the utensil before deciding how to preposition the **terminal device**. In teaching a client techniques for behavioral changes, such as **joint pro-**

tection, **energy conservation**, total hip precautions, or body mechanics, make sure the client understand why these are important for him or her.

- **Provide feedback.** When a client is first learning a new technique or to use a piece of adapted equipment or a new exercise program, feedback should be given fairly frequently so that the learner understands the correct performance. However, wait a few minutes after the task is completed so that the person can process internal feedback. As the client becomes more proficient, feedback should be withdrawn so that the client does not become dependent on the feedback.

- **Organize practice of an occupation, strategies, techniques, and/or equipment use so that clients will retain the information and be able to generalize to other occupations or new environments.** For example, a client transfers to and from a toilet and a wheelchair several times. This is called **blocked practice**, in which the same occupation is practiced over and over again. Or a client transfers from the wheelchair to a toilet, tub bench, chair, and bed in succession. This type of practice, referred to as **random practice**, involves practicing variations of an occupation. Studies have shown that blocked practice can be helpful when someone is learning something new but that random practice results in better retention and generalization (Hanlon, 1996; Lee & Magill, 1983; Shea & Morgan, 1979).

When specific strategies for behavior change are taught, practice is also necessary. Sometimes clients are just given verbal or written instructions on body mechanics, joint protection, and energy conservation, for example. Clients need to pick up objects to use proper body mechanics and actually practice principles of joint protection. Hammond and Freeman (2001) have shown that supervised practice of joint protection principles in addition to verbal and visual instruction results in actual incorporation of these principles during daily tasks. Furthermore, principles of **motor learning** can be used in educating clients' families and/or caregivers. The therapist should direct families to practice the intervention they are being taught, such as a transfer, pushing a wheelchair up a curb, or putting on a splint with the therapist present and giving feedback.

- **Assess whether material or techniques have been learned correctly:** The therapist should ask the client, family, and/or caregiver to demonstrate what they have learned so that the therapist can determine whether they can apply this new technique to other situations.

Chapter 55 provides more information about motor control and motor learning theories.

ASSESSMENT

As is discussed in Units IX and X, the occupational therapy evaluation is guided by attention to those activities that the person wants or needs to perform. Additionally, in dealing

with individuals with musculoskeletal impairments, it is critical that the occupational therapist follow appropriate precautions. For instance, individuals who recently had joint replacements might need to avoid resistive or weight-bearing activities for a period of time. Further, as part of the assessment, the therapist will likely need to determine whether and how musculoskeletal factors are inhibiting the performance. Important musculoskeletal factors to consider are joint motion, muscle strength, dexterity and endurance. Finally, in deciding what assessment to use to with people with musculoskeletal conditions, consider the ability of the assessment to detect change when it has occurred. Activity or occupation level outcome measures have been found to be more sensitive to short-term changes than are impairment (i.e., personal factor) level assessments such as range of motion and strength (Amadio, Silverstein, Ilstrup, Schleck, & Jensen, 1996).

Range of Motion

Range of motion for a joint is the arc of motion through which a joint moves. The motion at a joint is determined by the structure of the joint and the integrity of the surrounding capsule (Flinn, Trombly Latham, & Podolski, 2007; Killingsworth & Pedretti, 2006a;). There are two types of range of motion: **passive range of motion (PROM)** and **active range of motion (AROM)**. PROM is the motion available in a joint when it is moved by an outside force. PROM provides information about the extensibility of the joint capsule, associate ligaments, and muscles (Norkin & White, 1995). AROM is the range through which a client can move a joint using his or her muscle power; it provides additional information about muscle strength and functional ability. Range of motion is measured by a **goniometer**. Detailed instructions for placement of goniometers to measure each joint and norms for range of motion can be found in several sources (Flinn et al., 2007; Kohlmeyer, 2003; Norkin & White, 2005; Killingsworth & Pedretti, 2006a).

Range of motion is evaluated to determine limitations that affect function and whether additional motion is needed; to determine the need for splints, assistive devices, or both; to determine limitations that might produce deformity; and to document progress (Kohlmeyer, 2003). AROM can be observed during activities of daily living or performing a functional range of motion assessment in which a client moves through various positions (Killingsworth, 2006). All joints can be moved though their respective motion to briefly assess PROM.

Not every client needs a formal assessment of joint motion. However, certain diagnoses may result in deficits in range of motion such as arthritis, fractures, stroke, and spinal cord injury, and a formal assessment would be warranted. When range of motion measurements are below the norms and interfere with the performance of activities of daily living and other occupations, the therapist should determine the cause of the decreased range. Causes may include pain, edema, muscle weakness, skin adhesions, spasticity, bony obstruction or destruction, or soft tissue contractures (Kohlmeyer, 2003). If the cause is modifiable, therapy might be able to increase the active motion or prevent further loss of motion by stretching, strengthening, orthotics, casts, or physical agent modalities such as heat or neuromuscular electrical stimulation. If it is determined that it might not be possible to increase the joint motion, therapists might want to consider adaptive techniques or equipment to perform daily tasks (Flinn et al., 2007).

Muscle Strength

Muscle strength, or the power of a muscle to resist movement, is evaluated by manual resistance, **isokinetics exercises**, pinch meters, and **dynamometers**. Resistance can be provided by a therapist, who scores the strength of a muscle on the basis of the amount of resistance and whether the movement is against or with gravity (Daniels & Worthington, 1986; Flinn et al., 2007; Kendall, McCreary, & Provance, 1993; Killingsworth & Pedretti, 2006b). Hand strength can also be assessed by using an adjustable handle dynamometer, and pinch strength can be measured with a pinch meter. Generally, three types of pinch are tested: thumb to index finger (palmar pinch), thumb to lateral side of index finger (lateral pinch), and thumb to tips of index and middle fingers (three-point pinch). Standardized procedures for using a dynamometer and a pinch meter and normative data are provided in the occupational therapy literature (Flinn et al., 2007; Killingsworth & Pedretti, 2001b; Mathiowetz, Kashman, Volland, Weber, Dowe, & Rogers 1985).

Muscle strength is evaluated to do the following:

- Facilitate diagnosis in some neuromuscular conditions (e.g., spinal cord injury, peripheral nerve injury)
- Establish a baseline and assess intervention effectiveness
- Determine whether weakness is limiting performance
- Determine the need for compensatory measures or assistive devices on a temporary or long-term basis
- Identify muscle imbalances that might require strengthening, if possible
- Determine appropriate orthotic intervention to prevent deformity (Kohlmeyer, 2002).

Muscle weakness is often seen in people with lower motor neuron disorders, primary muscle diseases, neurological diseases, and conditions that result in muscle weakness through disuse or immobilization such as burns, arthritis and amputations (Flinn et al., 2007; Pedretti, 2001b).

Dexterity

Several tests are available to evaluate dexterity or fine motor coordination (Table 54.1). The majority of these tests are

TABLE 54.1   FINE MOTOR COORDINATION TESTS

Dexterity Assessment	Description and Features
Crawford Small Parts Dexterity Test	◆ Measures eye-hand coordination and manipulation of small hand tools ◆ Designed for teenagers and adults ◆ Uses pins, collars, screws, tweezers, screwdriver ◆ Client is timed on tasks such as inserting a pen in a hole in a metal plate with tweezers, covering with a collar, threading screws
Erhardt Developmental Prehension Assessment	◆ Measures components and skills of hand function development ◆ Designed for birth to 6 years ◆ Uses a variety of objects (e.g., small suitcase, plastic pail, toy hammer, key, beads, aluminum can, rubber ball, stacking rings) to measure grasp, reflex, and manipulation skills
Fine Dexterity Test	◆ Assesses fine finger movements of adults
Grooved Peg Board Test	◆ Measures eye-hand coordination and finger dexterity ◆ Client places grooved pegs in a 25-hole peg board in various random positions ◆ Measures speed of eye-hand coordination and color matching for all age groups
Purdue Peg Board Test	◆ Measures movements of arms, hands, fingers, and fingertip dexterity ◆ Norms for adults and children ages 5–15 years, 11 months ◆ Client places pins in a peg board; assembles pins, washers, and collars
Box and Block Test	◆ Tests manual dexterity ◆ Norms for children ages 7–9 years, adults, and adults with neuromuscular involvement ◆ Client picks up one block at a time and places it in an attached compartment
Nine Hole Peg Test of Fine Motor Coordination	◆ Measures fine dexterity ◆ Norms for adults older than 20 years ◆ Timed score to place nine 11/4-inch pegs in a 5×5-inch board and remove them
Jebsen-Taylor Hand Function Test	◆ Evaluates functional capabilities ◆ Subtests include writing, card turning, picking up small objects, simulated feeding, stacking checkers, and picking up light and heavy objects
Minnesota Rate of Manipulation Test	◆ Measures dexterity ◆ Assesses placing, turning, displacing, one-hand turning and placing, and two-hand turning and placing of round blocks
Arthritis Hand Function Test	◆ Functional capabilities plus grip and pinch strength ◆ Items: peg board dexterity, cut putty, lace and tie bow on shoe, use coins, pour water, lift tray of cans, open and close safety pins, unbutton and button buttons
TEMPA	◆ Evaluates routine daily tasks ◆ Tasks: pick up and move jar, open jar and spoon coffee, pour water from pitcher, open lock and take top off pill box, write and affix stamp, put scarf around neck, shuffle and deal cards, use coins, pick up and move small objects

Source: Reprinted and adapted from Kohlmeyer, K. (2003). Sensory and neuromuscular function. In E. B. Crepeau, E. S. Cohn, & B. A. B. Schell (Eds.), *Willard & Spackman's occupational therapy* (10th ed., pp. 365–426). Baltimore: Lippincott Williams & Wilkins. See appendix A for author, source, and descriptions of assessments.

timed and involve object manipulation, grasp and release, prehension patterns, and hand posture. Many are standardized and have norms. However, the majority of them do not assess fine motor function as occurs in daily tasks. The Arthritis Hand Function Test (Backman, Mackie, & Harris, 1991) and the Test d'Évaluation des Membres Supérieurs des Personnes Agées (TEMPA) (Desrosiers, Hébert, Dutil, & Bravo, 1993) are two more recently developed tests that do use tasks in daily living but are not commercially available and require assembly and fabrication to simulate daily tasks.

Endurance

Endurance is the ability to sustain a given activity over time. It can be compromised by inactivity, immobilization, cardiorespiratory deconditioning, muscular deconditioning, and diminished flexibility (Kohlmeyer, 2003). Table 54.2

TABLE 54.2 MET VALUES FOR SOME OCCUPATIONAL PERFORMANCE AREAS

METs	Oxygen Consumed (mL/kg/min)	Level of Activity	Self-Care Activities	Instrumental Activities of Daily Living and Work Activities	Play and Leisure Activities
1.5–2.0	4–7	Very light, minimal	Eating, shaving, grooming, getting in and out of bed, dressing, undressing, standing, walking 1 km/h or 1.6 mph	Working at desk, typing, writing	Playing cards, sewing, knitting
2–3	7–11	Light	Showering in warm water, level walking 2 km/h or 3.25 mph	Ironing, light woodworking, using riding lawnmower	Level bicycling 8 km/h or 5 mph, playing billiards, bowling, golfing with power cart
3–4	11–14	Moderate	Walking 5 km/h or 3.5 mph	Cleaning windows, making beds, mopping floors, vacuuming, bricklaying, doing machine assembly	Bicycling 10 km/h or 6 mph, fly fishing standing in waders, horseshoe pitching
4–5	14–18	Heavy	Showering in hot water, walking 5.5 km/h or 3.5 mph	Scrubbing floors, hoeing, raking leaves, doing light carpentry	Bicycling 13 km/h or 8 mph, table tennis, doubles tennis
5–6	18–21	Heavy	Walking 6.5 km/h or 4 mph	Digging in garden, shoveling light earth	Bicycling 16 km/h or 10 mph, canoeing 6.5 km/h or 4 mph, ice skating or roller skating 15 km/h or 9 mph
6–7	21–25	Very heavy	Walking 8 km/h or 5 mph	Shoveling snow, splitting wood	Bicycling 17.5 km/h or 11 mph, light downhill skiing, ski touring 4 km/h or 2.5 mph

mL/kg/min = milliliters per kilogram body weight per minute; km/h = kilometers per hour; mph = miles per hour.

Source: Data from Ainsworth et al., 1998; Wilmore & Costill, 1999. Reprinted from Kohlmeyer, K. (2003). Sensory and neuromuscular function. In E. B. Crepeau, E. S. Cohn, & B. A. B. Schell (Eds.). *Willard & Spackman's occupational therapy* (10th ed., p. 390). Baltimore: Lippincott Williams & Wilkins.

provides a summary of cardiorespiratory endurance, metabolic equivalent capacity values, and biomechanical and neuromuscular endurance (Kohlmeyer, 2003). For occupational therapists, observation of endurance, or how long clients can participate in daily activities, is probably the most pertinent clinical assessment (Kohlmeyer, 2003).

INTERVENTION

Much like assessment, the intervention process is one that blends attention to the client's occupational performance and to the underlying musculoskeletal factors affecting performance. The time and sequencing of these interventions are related to the acuity or chronicity of the impairment as well as to client priorities.

Splints and Orthotics

Splints and orthotics are external devices that are applied to the body to immobilize, restrain, or support injured tissues; align or correct deformities; and improve function (Anderson, Anderson, & Glanze, 1998; O'Toole, 1997). With regard to musculoskeletal conditions, splints and orthoses may be used to support healing. Basic anatomical and biomechanical considerations for fit and fabrication of splints are provided in Box 54.2.

In some musculoskeletal conditions, such as arthritis and cumulative trauma disorders, splints can be used to reduce stress on joints such as wrist support splints for

carpel tunnel syndrome and arthritis pain. Thumb splints may be indicated for CMC arthritis or deQuervain's tendinitis. Splints can also be used to align or correct deformities; for example, ulnar deviation splints can be used for clients with rheumatoid arthritis (Figure 54.1).

Range of Motion and Strength Exercises

Although it is nice to think that performing everyday occupations maintains motions in the joints of the extremities, full range is usually not achieved during everyday tasks. Therefore, individuals who have deficits with joint motion might need passive, active assistive, or active range of motion exercises. To improve range of motion, activities must be graded by positioning materials and equipment to demand greater reach. However, compliance with exercise programs also needs to be considered. Self-efficacy, or the belief that one can perform the exercises, and the convenience of fitting an exercise program into one's daily routine are important factors to consider (Chen, Neufield, Feeley, & Skinner, 1999). For example, it might be easier for a mother with two young children to do her shoulder exercises in the morning during a shower where she can walk her fingertips up to a point on the shower wall, before her children wake up. On the other hand, a person who is retired might choose to do her exercises in the middle of the morning after a leisurely breakfast. Support from family and friends can also help with compliance. Therefore, therapists should make sure clients and families or caregivers understand the exercises and should provide them with written or picture instructions. Setting realistic weekly goals and reviewing them on a regular basis have been shown to be important factors in compliance with exercise programs (Chen et al., 1999).

For some clients, if the underlying reasons for the decreased motion are scar tissue or pain, physical agent modalities such as ultrasound or heat (e.g., a paraffin bath) may also be indicated (see Table 54.3). Physical modalities should be used as an adjunct to therapy, and therapists are encouraged to pursue professional education, including supervised use of modalities before using them (American Occupational Therapy Association, 2003).

A rehabilitation approach would be to provide an individual with long-handled assistive devices such as reachers or built-up handles on tools to compensate for range of motion deficits. Numerous assistive devices are available to compensate for decreased range of motion, such as long-handled utensils, shoehorns, combs and brushes, dressing sticks, reachers, sock aids, and long-handled sponges. The use of these items and other strategies are discussed in Chapter 49.

However, in determining which frame of reference to use, therapists must consider the reason for and duration of the joint limitation and the goals. It might not be possible to increase joint motion in a person who has had rheumatoid

---

BOX 54.2

BASIC ANATOMICAL AND BIOMECHANICAL CONSIDERATIONS WHEN MAKING A SPLINT

- ◆ Preserve palmar arches.
- ◆ Use hand creases as landmarks for splint design and molding.
- ◆ Maintain antideformity position.
- ◆ Properly position and tighten straps to allow blood flow or venous return.
- ◆ Properly contour splints.
- ◆ Avoid or minimize pressure over bony prominence.
- ◆ Allow motion out of the splint when possible.

TABLE 54.3 PHYSICAL AGENT MODALITIES

Modality	Indications	Contraindications/ Precautions	Evidence for Effectiveness of the Modality
Superficial heat Hot packs, heating pads Paraffin wax Fluidotherapy Whirlpool	Prior to active exercise, passive stretching, and joint mobilization Before traction and soft tissue mobilization Reduce pain and muscle spasms After acute inflammation to increase tissue healing	Decreased circulation Decreased sensibility Altered cardiorespiratory status Open wounds or recently healed burns (paraffin) Significant areas of edema Over tissue during acute inflammation	Limited evidence for fluidotherapy Some evidence that superficial heat and paraffin wax reduce pain and increase motion in persons with arthritis (Minor & Sanford, 1993; Steultjens et al., 2002)

TABLE 54.3   PHYSICAL AGENT MODALITIES   *Continued*

Modality	Indications	Contraindications/ Precautions	Evidence for Effectiveness of the Modality
Deep heat Ultrasound	Soft tissue tightness Subacute and chronic inflammation (e.g., tendinitis) Bone fracture Wound healing	Do not use over or near the eyes, ears, heart, pregnant uterus, testes, known or expected malignant tumor, pacemaker, joint replacements or metal implants, or insensate areas	Review by Robertson and Baker (2001) found eight articles that showed ultrasound to be no more effective than placebo in promoting tissue healing and decreasing pain, and two studies showed ultrasound to be beneficial. For people with rheumatoid arthritis, ultrasound to both surfaces of the hand increased grip strength (Casimiro et al., 2002).
Therapeutic cold Cold packs and cold baths Ice massage	Minimize acute inflammation associated with therapeutic intervention Reduce edema and bleeding Reduce spasticity	Temperature sensation deficits Circulation deficits Altered cardiorespiratory status Cold hypersensitivity such as Raynaud's phenomenon	Inconclusive evidence. Several systematic reviews (Bleakley, McDonough, & MacAuley, 2004; Hubbard, Aronson, & Denegar, 2004; Hubbard & Denegar, 2004) report some evidence for physiological responses to cold on blood flow, tissue temperature, and swelling, but few studies document a return to participation in valued occupations. Studies vary in duration, intensity, and mode, which limits conclusions that can be made.
Contrast baths	Promotes tissue healing	Cardiovascular problems as fluctuations in pulse and blood pressure may occur Peripheral vascular diseases Loss of sensation Pregnancy Cold hypersensitivity such as Raynaud's phenomenon	Inclusive evidence
Electrotherapy Iontophoresis	Modulate pain Decrease inflammation (e.g., bursitis, tendinitis) Reduce edema	Do not use over or near the eyes, ears, chest of person with cardiac disease, pregnant uterus, wounds or skin breaks, known or expected malignant tumor, pacemaker, blood vessels susceptible to hemorrhage, thrombosis or embolus, or insensate areas	Few studies available

ETHICAL DILEMMA

How Much Knowledge is Needed to Use Modalities?

You are an occupational therapy student at a hand rehabilitation center. Your supervisor is at a meeting at the moment, and you are to treat her client. The client has arrived, and the first intervention is ultrasound to the scar tissue on the client's hand. You had a brief lecture in school on ultrasound and tried it on one of your classmates. The technician in the room says that she has set the client up several times with ultrasound and can help you get started. What do you do?

---

arthritis for many years and has joint destruction; for this person, the goal might be to prevent further deformities and functional limitations and use compensatory methods. Similarly, for an adolescent who was recently diagnosed with rheumatoid arthritis, the goal would be to prevent joint limitations and destruction. On the other hand, for a person who has undergone recent surgery or has been in a cast because of a fracture, the decrease in joint motion is due to temporary immobilization and is probably amenable to change. For this person, more aggressive therapy using a physical agent modality (i.e., a hot pack) along with activities or exercise would be indicated to improve motion. Shiraishi, Fujii, and Kobayashi (2002) found that despite aggressive occupational therapy intervention to improve strength and motion after reconstructive surgery of the shoulder joint, a rehabilitative frame of reference was necessary to help clients maximize use of the contralateral intact upper extremity, as was education regarding use of assistive devices.

Strengthening and Endurance

In designing an intervention program for a person who needs strengthening, the occupational therapist must consider the role of resistance, the effect of gravity, and the type and speed of muscle contractions. Resistance is often used to stimulate muscle contractions and increase the firing of additional motor units to increase strength. In addition, muscles have to work harder to move a body part against gravity than to move in a gravity-eliminated or horizontal plane (O'Mahony, 2003). Most occupations require a combination of **isometric** (holding contractions) and **concentric** (shortening) contractions against a force. Thus, the occupational therapist must consider the strength of a muscle or muscles, precautions for movement, prognosis, and occupational demands (O'Mahony, 2003). See Table 54.4 for descriptions of

specific exercise programs including passive exercise, isotonic active assistive exercise, **isotonic** active exercise, isotonic resistive exercise, and isometric exercises. The occupational therapy practitioner can structure the exercise program using active motion by adding resistance as indicated. The resistance can be weights; Thera-Band, Thera-Tubing, or Theraputty; or springs. The therapist can also structure an occupation to grade the type of muscle contractions or amount of resistance, such as wiping off a table in a gravity-eliminated plane (isotonic active exercise), putting cans of food away on a cupboard shelf that is above shoulder height (isotonic resistive exercise), or cleaning a mirror above shoulder height (holding the shoulder in flexion and wiping from right to left would be isometric resistive exercise for the deltoid muscle). The resistance may be a weight, a spring, Thera-Tubing or Theraputty, or simply the weight of a limb. Therapists can also increase resistance by using tools of differing weights (e.g., a light versus a heavy hammer or sanding blocks of different weights or grade of sandpaper) or varying the resistance of a material (stiff versus soft cookie or bread dough or Theraputty).

In occupation-based approaches, relevant activities can be graded to increase strength, or assistive devices can be provided to compensate for the strength or endurance deficits. An individual might vacuum with a heavy or lightweight vacuum cleaner or use electric appliances to open cans and jars. However, the resistance offered by the occupation is often not great enough to increase strength in larger or stronger muscles. For example, a young man with a spinal cord injury at the C6 level needs to have enough strength in his shoulders, biceps, and wrist extensor muscles to be able to move and lift his body and legs for dressing and transferring his body to different surfaces. Although he can practice these occupations repetitively, which will lead to greater strength, actual strengthening exercises will

TABLE 54.4   EXERCISE PROGRAMS

Type	Definition	Resistance	Muscles Grades	Precautions
Passive exercise	Involves passive range of motion and passive stretch, usually done by a practitioner	None Stretch may be held 15–30 seconds	Zero Trace	Inflammation Limited sensation for pain Prolonged immobilization
Isotonic active assistive exercise	Client moves the joint as far as possible, then an outside force such as a practitioner or equipment assists with moving the joint through the rest of the range	None	Trace Poor minus Fair minus	None
Isotonic active exercise	Client moves the joint through available range of motion without any assistance. The muscle shortens and lengthens.	None	Poor Fair	Poor muscles: Move in gravity eliminated plane Fair muscles: Move in against gravity plane
Isometric without resistance	Client contracts the muscle, increasing the tension, and holds the position for 5 seconds. Used when motion of a joint is prohibited.	None	Trace Poor Fair Good	Clients with cardiac conditions and high blood pressure
Isotonic resistive exercise	An isotonic contraction against resistance	Resistance provided by wrist weights, dumbbells, Thera-Band, Theraputty, elastic bands, springs, weights	Fair plus Good	Inflammation Unstable joint Recent or unhealed fracture Use with caution with conditions that are exacerbated by fatigue
Isometric resistive exercise	An isometric contraction against a load	Resistance could be an immovable surface (e.g., pushing the palm against a wall).	Fair plus Good	Clients with cardiac conditions and high blood pressure
Isokinetic exercise	Exercise that uses a machine that controls the speed of contraction within the range of motion	Resistance controlled by machine and is variable in proportion to the change in muscle length throughout the range of motion	Fair plus Good	Inflammation Unstable joint Recent or unhealed fracture Use with caution with conditions that are exacerbated by fatigue

improve his strength faster and lead to faster achievement of independence and could preserve independence (Nyland et al., 2000). In these situations, optimum therapy thus involves both exercise and engagement in desired occupational activity.

Other compensatory approaches to treat strength and endurance impairments might consist of using lighter-weight tools; using electric appliances; and client education regarding joint protection, energy conservation, and work simplification (Tables 54.5 and 54.6).

TABLE 54.5 PRINCIPLES FOR JOINT PROTECTION	
Principles	**Examples**
1. Respect pain.	If pain persists more than 2 hours after performing an activity, modify the activity by spending less time on it, using adaptive equipment, or resting during activity.
2. Use proper body mechanics and use joints in good alignment.	Lean forward to put weight over the feet, and use armrests on chairs to come to standing. Use the palms of the hands on the armrests to push up to standing. Push or pull objects, rather than lifting. Avoid bending, reaching, and twisting.
3. Avoid holding one position for a long time and prolonged repetitive motions.	Alternate sitting and standing during an activity, or shift around. Relax and stretch the hands every 5 minutes when doing an activity that requires holding objects or tools such as holding cards, pencils, telephone, knitting or crochet needles, garden, kitchen, or hand tools. Avoid kneeling to scrub the floor or to garden; instead, sit on a stool and use longer-handled tools
4. Avoid positions and stress that cause deformity.	Avoid pressures along the lateral (thumb) side of fingers that encourage ulnar deviation such as turning keys, doorknobs, and screwdrivers. Avoid pressure against the back of the fingers and wrist, such as propping the chin on the back of the hand. Avoid excessive and constant pressure against the pad of the thumb. Avoid positions of ulnar deviation of the wrist, such as cutting with scissors or cutting with knives.
5. Use the larger and strongest muscles and joints.	Carry a briefcase or purse over one or both shoulders instead of holding it with the fingers. Use the palm of the hands to lift pots and pans. Lift objects using leg muscles instead of back muscles.
6. Balance rest and activity.	Exercise and activity are important for joint mobility and strength, but leisure and work should be balanced with periods of rest.
7. Never begin an activity that cannot be stopped immediately if needed.	Preplan and pace activities. Try to slide, push, or pull objects rather than lifting. Also see energy conservation principles.

Dexterity

In designing an intervention program to improve dexterity, key factors are practice and repetition. In addition, during practice, the occupational therapist might want to consider changing the level of difficulty or complexity of the occupation or activity. Retraining a client's ability to keyboard might require practice using only a few fingers at a time to relearn finger placement. In the beginning, a client might type only individual letters or three- to four-letter words and then progress to longer words, sentences, and paragraphs. In this particular activity, speed might be an important factor to be considered, so another way to grade the activity would be to increase speed requirements of keyboarding. For other types of clients, the size or shape or even texture of the objects might also be

altered. For example, in training a person to use a prosthesis, the therapist might start by having the client pick up one-inch cubes with flat sides and then progress to round objects such as pegs and then to flat objects such as checkers. The size of each of these objects could be decreased, and the texture could be changed by using a cube of cheese, a paper cup, or a flat cracker.

Compensatory approaches to dexterity impairments might consist of using adapted equipment such as button hooks, zipper pulls, and elastic laces to help manage fasteners during dressing. A therapist might also suggest that clients eliminate fasteners altogether by wearing pullover shirts, pants with an elastic waistband, and/or slip-on shoes. Other suggestions might include utensil holders or universal cuffs, weighted utensils if stability is needed, plate guards, stabilizers for plates and glasses, wash mitts,

TABLE 54.6   PRINCIPLES AND EXAMPLES OF ENERGY CONSERVATION

Principles	Examples
1. Plan ahead.	Gather all items needed before an activity. Spread heavy and light tasks throughout the day and week.
2. Pace yourself.	Perform energy-demanding tasks earlier in the day. Plan the day to balance rest and activity. Break activities into smaller units that can be done over a number of days. Pace yourself during activities, and do not rush. Take frequent rest breaks.
3. Prioritize.	Decide activities that are important to be completed and ones that can be completed later or eliminated. Delegate tasks to other family members.
4. Sit when possible.	Use a seat in the shower. Sit on the bed or a chair to get dressed. Consider using a high stool.
5. Use work simplification techniques.	Eliminate unnecessary tasks (e.g., buy permanent-press clothes, precut vegetables). Work in a well-lit and well-ventilated environment.
6. Maintain good posture.	Avoid a prolonged stooped posture. Avoid excessive reaching and bending by prearranging work centers to be at an appropriate height and keeping frequently used items at comfortable heights.

electric razors instead of safety razors, and voice-operated computer systems. See Chapter 48 for more ideas for compensation.

Activities of Daily Living

Assisting individuals to improve occupational performance or resume their occupations is the primary objective for occupational therapists working with individuals with musculoskeletal impairment (see Case Studies pp. 670–671). In conjunction with the suggestions provided in Chapter 48, the following should be considered in working with people who have musculoskeletal impairments:

◆ Application and removal of splints, orthoses, and/or prosthetics
◆ Use of long-term splints and prostheses
◆ Performing tasks with adaptive devices
◆ Developing adaptive techniques for temporary use following a recoverable injury
◆ Understanding precautions relevant to the impairment, such as encouraging a client to use total hip precautions
◆ Energy conservation and work simplification procedures, especially for people with arthritis or when endurance is an issue, such as with older adults

◆ Principles of motor learning, especially in training or retraining activities of daily living (see Box 54.1).

Table 54.7 lists musculoskeletal conditions of the lower extremities, back, and pelvis that are commonly treated by occupational therapists and describes intervention considerations and equipment. Dohli and colleagues (2003) stated that for these conditions, the areas of occupation that should be addressed include bed mobility, lower body bathing and dressing, transfers, home management, care of others or pets, childrearing, community mobility, meal preparation and cleanup, safety procedures and emergency responses, sexual activity, shopping, work or school, play, leisure, and social participation.

Table 54.8 shows musculoskeletal conditions of the upper extremities and intervention considerations and equipment. Since upper extremity and hand use is critical to the performance of occupations, limitations or loss of independence will be a primary concern. Individuals might experience a temporary or permanent change in hand dominance and need to compensate with the less involved extremity. Bilateral capabilities are compromised, and safety and speed of performance are therefore affected. Work and social participation can be disrupted, leading to anxiety and depression. Depending on the condition, deformities, amputations, or severe scarring can result in changes in appearance.

CASE STUDY: *Marita: A Client with a Total Hip Replacement*

Occupational therapy referral: The occupational therapy consult is "status post left total hip replacement as a result of degenerative joint disease."

Occupational profile: Marita is a divorced 63-year-old who resides alone in a two-story home. Premorbidly, she completed all housekeeping independently, including cooking, cleaning, and shopping. She attends weekly group activities at the senior citizens' center and engages in church activities.

Treatment setting: Inpatient rehabilitation hospital.

Disposition setting: Home.

Occupational therapy goals: While observing hip precautions and weight bearing as tolerated, Marita will, in 1 week, be able to:

◆ Prepare a frozen food entrée in the microwave with minimal assistance while ambulatory using a standard walker and walker basket.

◆ Independently don and doff shoes and socks using adaptive equipment while seated in an armchair.

◆ Develop a plan with minimal assistance for securing temporary help from others for obtaining groceries and mail.

Source: Reprinted from Dohli, C., Leibold, M. L., & Schreiber, J. (2003). Adult orthopedic dysfunction. In E. B. Crepeau, E. S. Cohn, & B. A. B. Schell (Eds.), Willard & Spackman's occupational therapy *(10th ed., p. 791). Baltimore: Lippincott Williams & Wilkins.*

CASE STUDY: *Joy: A Client with a Lower Extremity Amputation*

Occupational therapy referral: The occupational therapy consult is "status post left below the knee amputation because of diabetes." The client is in the prosthetic training phase.

Occupational profile: Joy is a widowed 78-year-old who lives alone in a third-floor apartment; she receives Meals-on-Wheels. She is a retired high school teacher who enjoys TV game shows and reading the Bible. Her two adult daughters reside out of state.

Treatment setting: Skilled nursing facility (while endurance is low).

Disposition setting: Inpatient rehabilitation center (when she is able to tolerate 3 hours of treatment per day).

Occupational therapy goals: Joy, in 1 week, wearing the prosthesis will be able to:

◆ Complete her morning grooming activities while standing at the bathroom sink with moderate assistance for maintaining standing balance.

◆ Complete lower body dressing while seated in an armchair at bedside with moderate assistance using adapted methods.

◆ Inspect her left lower extremity residual limb with a mirror and correctly identify areas of potential skin breakdown to the therapist with minimal assistance.

Source: Reprinted from Dohli, C., Leibold, M. L., & Schreiber, J. (2003). Adult orthopedic dysfunction. In E. B. Crepeau, E. S. Cohn, & B. A. B. Schell (Eds.), Willard & Spackman's occupational therapy *(10th ed., p. 792). Baltimore: Lippincott Williams & Wilkins.*

CASE STUDY: *Joe: A Client with a Hand Injury*

Occupational therapy referral: The occupational therapy consult is "for a right hand splint to increase flexion of fractured fourth and fifth metacarpals as a result of an injury at work." His cast for his right hand has been removed.

Occupational profile: Joe is a single 25-year-old who worked in construction. He lives alone and enjoys watching TV and playing games on the PlayStation.

Treatment setting: Outpatient clinic
Disposition setting: Home
Occupational therapy goals: Joe, in 1 week, will be able to:
◆ Independently don and doff hand splint.
◆ Complete morning grooming and hygiene activities independently using right hand to hold tools.
◆ Demonstrate an increase of 5 pounds of grip strength in order to hold a pair of pliers.

CASE STUDY: *Lee Ann: A Client with Arthritis*

Occupational therapy referral: The occupational therapy consult is "diagnosis of rheumatoid arthritis."

Occupational profile: Lee Ann is a 41-year-old who is married and has two children, aged 11 and 13 years. She lives in a one-story, three-bedroom home and works part time as an educational assistant at her daughters' school. She loves to bake. The pain in her hands makes it difficult for her to write and cut with scissors, tasks that she needs to do for her job. She fatigues easily.

Treatment setting: Inpatient rehabilitation setting

Disposition setting: Home
Occupational therapy goals: Lee Ann, in 1 week, will be able to:
◆ Utilize joint protection techniques 80% of the time while performing a baking task.
◆ Identify 2 styles of writing tools and adapted scissors in order to write and cut without pain.
◆ Utilize energy conservations techniques 80% of the time during daily living skills.

CASE STUDY: *Michelle: A Client with Tendinitis of the Abductor Pollicis Longus and Extensor Pollicis Brevis Tendons of the Thumb (DeQuervain's)*

Occupational therapy referral: The occupational therapy consult is "pain and swelling of the abductor pollicis longus and extensor pollicis brevis tendons."

Occupational profile: Michelle is a 37-year-old who is married. She works as a beautician 20–25 hours a week. In the last few weeks, she has scheduled all her appointments into three days because she started another part-time job in a store with home furnishings and accessories. The second job is "just for fun," as she really loves to work on hair. The pain in her thumbs is so bad that she can hardly cut hair.

Treatment setting: Outpatient setting

Disposition setting: Home
Occupational therapy goals: Michelle, in 1 week, will be able to:
◆ Wear her forearm-based thumb spica splint while performing her second job and in the evenings.
◆ Apply ice for 5–10 minutes between hair appointments if possible and rest her thumb.
◆ Identify two types of ergonomic scissors in order to cut hair without pain.
◆ Develop a schedule to spread out the time spent in both jobs more evenly throughout the week.

TABLE 54.7   OCCUPATIONAL THERAPY CONSIDERATIONS FOR CLIENTS WITH ORTHOPEDIC CONDITIONS OF THE BACK AND LOWER EXTREMITIES

Condition	Description	Precautions	Intervention Considerations and Equipment
Hip fracture with closed reduction	Break in any portion of femur that can be manipulated into its natural position without major surgery	Weight bearing established by physician; hip precautions	◆ Eating, grooming, and upper body dressing typically require assistance from another person for gathering, setting up, and putting away needed supplies; client can then complete tasks either long sitting in bed with an over-the-bed table or seated on the edge of the bed, seated in a wheelchair, or seated in an armchair at a table or sink.
Total hip replacement or total hip arthroplasty	Surgical removal of a diseased or injured hip joint, which is replaced with a prosthetic appliance		◆ Lower body dressing can be accomplished with equipment or adaptations as needed (e.g., reacher, dressing stick, sock aid, long shoehorn, elastic shoelaces, and/or hook-and-loop tape shoe closures); oversize clothing may ease dressing; standing should be encouraged during dressing (client can alternate sitting and standing during activities). ◆ Toileting equipment must enable client to maintain hip precautions; options include standard elevated toilet seat (or model designed for hip injuries) with bilateral arm supports or bedside commode with adjustable legs for use alone or positioned over toilet. ◆ Bathing may be completed by using a transfer tub bench, hand-held shower, nonskid mat, and long-handled sponge; client may choose to sponge-bathe at the sink or bedside instead. ◆ Abduction wedge pillow can be used to prevent internal rotation of the affected hip while in bed or seated. ◆ Walker bag or basket and/or wheeled cart can be used to retrieve and transport items safely.
Hip fracture with open reduction and internal fixation	Surgical procedure that uses wires, screws, or pins applied directly to fractured bone segments to keep them in place	Weight bearing established by physician	◆ Clients often do not require strict hip precautions; treatment considerations as described above may be implemented to enhance performance and minimize pain; this may be especially beneficial immediately post surgery, and equipment can be loaned to the client.

TABLE 54.7   OCCUPATIONAL THERAPY CONSIDERATIONS FOR CLIENTS WITH ORTHOPEDIC CONDITIONS OF THE BACK AND LOWER EXTREMITIES *Continued*

Condition	Description	Precautions	Intervention Considerations and Equipment
Knee replacement	Implantation of device to substitute for damaged joint surfaces	Weight bearing established by physician	◆ Typically, active movement of the knee is encouraged during *all* activities; the client's ability or willingness to flex knee may initially be limited because of fear or pain; twisting motions that put undue stress on the joint should be avoided. ◆ All activities of daily living (ADLs) and instrumental activities of daily living (IADLs) can be completed in a manner selected by the client once safety has been demonstrated and knee flexion has been promoted. Completion without the use of adaptive equipment is encouraged to promote normal movement; however, it may be used initially in some instances to enhance performance, encourage participation, and minimize pain. ◆ Walker bag or basket and/or wheeled cart may be used to retrieve and transport items safely while the client uses an ambulation device. ◆ If needed, equipment may be used on a long-term basis for independence.
Vertebral compression fracture (without CNS involvement)	Fracture of vertebral body, often associated with osteoporosis	Rolling in bed restricted to log-rolling technique; orthotic device may be used to restrict vertebral mobility (e.g., corset type or rigid body jacket); wearing schedule determined by physician	◆ Eating, grooming, and upper body dressing typically require assistance from another person for gathering, setting up, and putting away needed supplies; client can then complete tasks either long sitting in bed with an over-the-bed table or seated on the edge of the bed, in a wheelchair, or in an armchair at a table or sink. ◆ If an orthotic device is worn only when out of bed, the following sequence is recommended: Client lies in bed without the device; completes upper body bathing while semireclined; dons a thin T-shirt or undershirt; resumes a supine position, log–rolls, and dons the orthotic device; returns to supine and fastens the orthotic device; the client is now ready to assume a seated position on the edge of the bed.

TABLE 54.7 OCCUPATIONAL THERAPY CONSIDERATIONS FOR CLIENTS WITH ORTHOPEDIC CONDITIONS OF THE BACK AND LOWER EXTREMITIES *Continued*

Condition	Description	Precautions	Intervention Considerations and Equipment
			◆ Lower body dressing can be accomplished with equipment or adaptations as needed (e.g., a reacher, dressing stick, sock aid, long shoehorn, elastic shoelaces, and/or hook-and-loop tape shoe closures); oversize clothing may help to accommodate an orthotic device. ◆ Standing should be encouraged during dressing; the client can alternate sitting and standing during activities. ◆ Use of an elevated toilet seat and bilateral arm supports for toileting may enhance performance by increasing safety, decreasing anxiety, and increasing confidence. ◆ Bathing is restricted to long sitting in bed without the brace or sitting in a chair with the orthotic device in place. ◆ A walker bag or basket and/or wheeled cart may be used to retrieve and transport items safely.
Pelvic fracture	Break in any part of the pelvic ring or acetabulum	Hip flexion limited to 60 degrees; non-weight-bearing for both lower extremities	◆ Eating, grooming, and upper body dressing typically require assistance from another person for gathering, setting up, and putting away needed supplies; the client can then complete tasks long sitting in bed with the bed inclined to 60 degrees to adhere to precautions. ◆ Lower body dressing and bathing can be accomplished long sitting in bed with the bed inclined to 60 degrees and with equipment and adaptations as needed (e.g., reacher, dressing stick, sock aid, long shoehorn, elastic shoelaces, hook-and-loop tape shoe closures, and/or long-handled sponge); the client typically requires assistance with lower extremity dressing and bathing in conjunction with long-handled equipment. ◆ Toileting is managed either in bed with a bedpan or using a bedside commode with drop arms and a backrest that allows the client to maintain hip flexion at 60 degrees.

TABLE 54.7   OCCUPATIONAL THERAPY CONSIDERATIONS FOR CLIENTS WITH ORTHOPEDIC CONDITIONS OF THE BACK AND LOWER EXTREMITIES   *Continued*

Condition	Description	Precautions	Intervention Considerations and Equipment
			◆ Bed mobility may be enhanced by use of a trapeze bar placed on a hospital bed. ◆ A reclining wheelchair is necessary for mobility to adhere to precautions; choice of proper wheelchair cushion is necessary to maintain skin integrity due to non-weight-bearing status. ◆ Completing functional transfers usually requires another person to assist with lower extremities during transfer; a sliding board may also be necessary to secure safe, confident transfers.
Lower extremity amputation: preprosthetic training phase	Loss of any part of the legs or feet (before artificial limb replacement)	Balance precautions owing to change in center of gravity; fall risk owing to phantom limb sensation and balance deficits	◆ Addition of antitipper bars and/or counterbalancing to the wheelchair to avoid tipping should be considered to accommodate for change in the center of gravity. ◆ All ADLs and IADLs can be completed in a manner selected by the client once safety has been demonstrated; the client completes tasks either from a wheelchair or ambulatory level, depending on a variety of factors (e.g., medical condition, balance, activity tolerance, cognition, and environmental accessibility). ◆ Use of an elevated toilet seat and bilateral arm supports for toileting may enhance performance by increasing safety, decreasing anxiety, and increasing confidence. ◆ Bathing may be completed with use of a tub transfer bench, tub seat, or sponge-bathing.
Lower extremity amputation: prosthetic training phase	Period in which client learns to use lower extremity prosthesis	Preprosthetic precautions as applicable; maintenance of skin integrity, especially during prosthetic use	◆ All ADLs and IADLs can be completed in a manner selected by the client once safety has been demonstrated; the client completes tasks either from a wheelchair or ambulatory level, depending on a variety of factors (e.g., medical condition, balance, activity tolerance, cognition, and environmental accessibility).

Continued

TABLE 54.7 OCCUPATIONAL THERAPY CONSIDERATIONS FOR CLIENTS WITH ORTHOPEDIC CONDITIONS OF THE BACK AND LOWER EXTREMITIES *Continued*

Condition	Description	Precautions	Intervention Considerations and Equipment
			◆ The following dressing procedures are recommended: Client with one prosthesis sits on the edge of the bed or in an armchair, dresses the prosthesis first, then dons the device and dresses the other leg; client with bilateral prostheses sits in an armchair or in bed, dresses both prosthetic devices, and then dons them; socks and shoes on a prosthesis should be inspected, cleaned, and changed as needed. ◆ Use of an elevated toilet seat and bilateral arm supports for toileting may enhance performance by increasing safety, decreasing anxiety, and increasing confidence. ◆ Bathing may be completed with the use of a tub transfer bench, tub seat, or sponge-bathing; cleaning of the prosthesis is done regularly as instructed by the prosthetist; the residual limb should be kept dry to maintain skin integrity and avoid skin breakdown; the client's bathing schedule should be arranged to allow a maximum amount of time so that the residual limb and prosthesis may dry thoroughly.

Source: Reprinted from Dohli, C., Leibold, M. L., & Schreiber, J. (2003). Adult orthopedic dysfunction. In E. B. Crepeau, E. S. Cohn, & B. A. B. Schell (Eds.), *Willard & Spackman's occupational therapy* (10th ed., pp. 793–795). Baltimore: Lippincott Williams & Wilkins.

TABLE 54.8 OCCUPATIONAL THERAPY CONSIDERATIONS FOR CLIENTS WITH SELECTED ORTHOPEDIC CONDITIONS OF THE UPPER EXTREMITIES

Condition	Description	Precautions	Intervention Considerations and Equipment
Shoulder: rotator cuff repair	Surgical repair of a tear in one of the rotator cuff muscles	Immobilized in sling PROM; progression to active-assist and isometric/isotonic	There might be a temporary change in hand dominance. Compensation with the less involved extremity. Bilateral capabilities affected. Sling and abduction pillow at night. Might need to wear front buttoning oversized shirts because they are easier to put on and can fit over the sling if necessary. Eliminating socks and wearing slip-on shoes will be easier initially; a long-handled shoes horn might help. Elastic waist pants might be easier to put on and remove, although usually the hand on the operated side is not enclosed by the sling. Bathing might require a long-handled sponge

TABLE 54.8 OCCUPATIONAL THERAPY CONSIDERATIONS FOR CLIENTS WITH SELECTED ORTHOPEDIC CONDITIONS OF THE UPPER EXTREMITIES *Continued*

Condition	Description	Precautions	Intervention Considerations and Equipment
Hand: laceration, penetration, compression	Direct trauma	Insensitivity Safety issue Pain Skin integrity Edema Immobility	There might be a temporary or permanent change in hand dominance. Compensation with the less involved extremity. Bilateral capabilities affected, so adapted equipment might be required to stabilize or compensate, such as elastic shoelaces, suction brush sponge, rocker knife, electric can opener, plastic disposable dental flossers. Client and/or family might have to be able to remove and apply a splint or orthotic device.
Repetitive use of upper extremity/ies	Inflammation of tendon cumulative effect of repeated stress on tissue	Inflammation Pain Swelling Sensory impairment Motor involvement	Ergonomic assessment modification of work station, job site, tools, and hand positions may be indicated. Splints may be needed in acute phase. An assessment should also be made of everyday activities to determine repetitive patterns.
Arthritis	Inflammation in joints	Sensory impairments Pain Swelling Deformities	Clients need to be instructed in and use principles of joint protection and energy conservation in all daily occupations. Adapted equipment should be used only to protect joints or improve function. A warm shower in the morning can help to loosen up joints, but client might need long-handled sponge. Dressing might be easier with pullover shirts, elastic waists on pants, slip-on shoes; however, assistive devices such as button hook, long shoehorns, dressing sticks may be used. Client and/or family might have to be able to remove and apply a splint or orthotic device. Involvement of the lower extremities might require a raised toilet seat and/or grab bars. Because of the chronic nature of the disease, psychological adjustment to the progressive disability and lifestyle changes may occur.
Upper extremity amputation	Loss of any part of the arm or hand	Insensitivity Pain Skin integrity Postural changes	Loss of any part of a limb can result in changes in body image. There might be a permanent change in hand dominance. Compensation with the unamputated limb. Bilateral capabilities are affected when the prosthesis is not worn, so adapted equipment might be required to stabilize or compensate, such as elastic shoelaces, suction brush sponge, rocker knife, electric can opener, plastic disposable dental flossers. Client and/or family might have to be able to remove and apply the prosthesis. Client must determine which occupations can be performed with and without the prosthesis.

COMMENTARY ON THE EVIDENCE

Interventions for Clients with Musculoskeletal Impairments

Although the effectiveness of interventions for musculoskeletal impairments is scarce in the occupational therapy literature, numerous studies do exist in the hand therapy and rheumatology literature that examine the effectiveness of range of motion and strengthening and endurance programs. Paraffin baths with and without a combined hand exercise program have been shown to be effective in increasing joint motion, strength, and hand function in people with rheumatoid arthritis (Buljina, Taljanovic, Avdic, & Hunter, 2001; Dellhag, Wollersjo, & Bjelle, 1992), osteoarthritis (Stamm, 2002), and scleroderma (Sandqvist, Akesson, & Eklund, 2004).

In a systematic review of hand exercises for people with rheumatoid arthritis, Wessel (2004) reported that of the nine studies that met her criteria for review, there were improvements in hand joint motion, strength, and dexterity. However, a number of different outcomes were studied, follow-up periods varied, therapist bias was present, power analyses were not done, and the impact on everyday activities was not studied. Michlovitz, Harris, and Watkins (2004) investigated the effectiveness of various interventions to increase joint range of motion in people with more varied types of diagnoses (fracture, fracture/dislocation, joint injury, or soft tissue injuries). The following interventions were reviewed for the above-mentioned diagnoses: splints and casts, joint mobilization, continuous passive motion, injection versus other therapist, and in-clinic versus home exercise. They reported moderate support for splints and casts and passive exercise and insufficient evidence to support continuous passive motion. They found no studies that assessed heat modalities such as hot packs, paraffin, fluidotherapy, ultrasound, or stretch for the diagnoses that were studied. Other studies have compared the effectiveness of exercise program versus activities or games and computer games in improving motion and strength (Jaris, Shavit, & Ratzon, 2000). Edema, motion, and grip strength improved after a five-week treatment for wrist movements regardless of which intervention was used.

The effectiveness of client-centered occupational therapy services for people with hand injuries showed improvements in functional measures after six to eight weeks of therapy (Case-Smith, 2003). The Canadian Occupational Performance Measure was used as an outcome measure and to identify individual functional goals. The interventions consisted of splints, therapeutic exercise and activities, manual therapy, activities of daily living, and physical agent modalities, primarily ultrasound. At the end of six to eight weeks, individuals made significant improvements in functional activities, and 80% of subjects returned to work (Case-Smith, 2003).

Steultjens, Dekker, Bouter, Van Schaardenburg, Van Kuyk, and Van Den Ende (2002) conducted a systematic review of controlled clinical and randomized control trials of occupational therapy intervention for people with rheumatoid arthritis. Studies were categorized into themes: comprehensive occupational therapy, training of motor function such as exercise, instruction in joint protection and energy conservation, assistive devices, and splints. They reported limited evidence for the effectiveness of comprehensive occupational therapy in functional ability, no evidence for the effects of exercises on pain and functional ability, limited evidence that joint protection leads to improvement in performing occupations, and insufficient data in the use of assistive devices. Evidence was found that splints reduce pain and increase grip strength but reduce dexterity. However, Steultjens and colleagues (2002) rated the overall methodological quality of studies as weak and without power.

CONCLUSION

Occupational therapists frequently encounter individuals who have musculoskeletal impairments that limit the performance of daily activities. An important factor to consider in working with individuals who have such impairments is to ensure that appropriate precautions are followed, especially after surgery. Regardless of what theoretical framework is used to evaluate and treat individuals with these impairments, the goal is to improve performance in desired occupations within the constraints of the precautions and musculoskeletal impairments themselves.

ACKNOWLEDGMENTS

PROVOCATIVE QUESTIONS

1. Compare and contrast frames of references for intervention for a person with rheumatoid arthritis who has had the disease for 15 years and has joint limitations and mild hand deformities versus a person who has had the disease for 1 year and has similar joint limitations and hand deformities.
2. Discuss how you might use principles of motor learning to teach transfers to a client who has had a recent hip replacement with a posterior approach.

Motor Skills and Occupational Performance: Assessments and Interventions

CLARE G. GIUFFRIDA
AND MARTIN S. RICE

Learning Objectives

After reading this chapter, you will be able to:

1. Discuss the emergence, control, and learning of motor skills from a systems perspective.
2. Identify the different terms that are used to describe movement organization and motor behaviors that contribute to skilled performance.
3. Identify the role of the occupational therapy practitioner in assessing and treating people with performance deficits in everyday skills and routines secondary to motor impairments.
4. Describe various types of motor dysfunction that are seen in people with central nervous system dysfunction and developmental disorders.
5. Identify the different strategies and measurement tools that are used to assess patients with deficits in skilled performance.
6. Discuss the influence of neuroscientific and movement scientific findings as well as evidence-based practices on occupational therapy assessment and interventions focused on everyday skill recovery and learning.
7. Discuss the strategies that are used by the neurophysiological and task-related systems approaches to intervention and the recovery of everyday skill.

Outline Continued

Occupational therapy practitioners assess and treat patients with a variety of neuromotor impairments that interfere with movement control and organization. These deficits are displayed by both children and adults with specific difficulties such as tone irregularities, loss of postural and or limb control, motor planning problems, and motor coordination deficits as well as by children and adults with delayed sensory motor development. From an occupational therapy perspective, movement problems can interfere with the individual's performance of everyday tasks and the organization of purposeful and meaningful activities into daily occupations.

This chapter focuses on identifying common elements of movement control and organization that are essential to an individual's motor development and attainment of fundamental motor skills as well as life skills.

THE EMERGENCE OF MOTOR SKILLS

Conceptually, the development of motor skills, regardless of one's age, is essential for success in any type of occupation that requires a motor component. This statement hints at the foundation on which much occupational therapy treatment is based. Numerous factors contribute to success in motor skills, not the least of which is an intact central nervous system (CNS). As the CNS develops from infancy through early adulthood, there are associated increases in **motor skill** ability. Although motor skills per se are not automatically developed, their age-appropriate emergence is limited to the maturational level of the various systems of the body, including the CNS. The integrity of the CNS is the ultimate rate-limiting factor in determining any potential success in acquiring motor skills. It has been proposed that motor skills are not actually *developed* at all; rather, they are *acquired.* For example, a child who is beginning to learn how to walk will make many attempts at taking his or her first step before actually being successful. In the process of these attempts, the child is learning consciously and subconsciously about the limits of his or her **stability**, **postural control**, and **balance**. Once these (and several other factors) have been at least marginally accounted for, the child will be successful in acquiring the ability to actually take that first step.

The development of motor abilities, however, is based on more than just CNS maturation. Many systems develop and change simultaneously along with the CNS, including, but not limited to, the muscular, skeletal, and endocrine systems. Each system within the body develops at its own rate and experiences periods of varying degrees of change across time. For any given motor skill, success with acquiring that skill rests on the critical maturation of any number of underlying systems (e.g., skeletal size, muscle strength, and postural stability). When each of the systems has reached a level of development that supports the acquisition of the new skill, the child then has the capability to acquire that new skill (Thelen, 1995). A large part of learning requires that the child learn what his or her body can and cannot do, given the constraints of the environment and the task at hand. Once the child's systems have the developmental maturity to allow the child to have the capability to learn a new skill and the child experiences the environmental constraints (physical constraints, social constraints, and task constraints), then all of the ingredients for successful learning are in place. Stated another way, once experimentation occurs, the child will learn how to succeed, given his or her developmental maturation and environmental constraints.

Reflexes, Myelination, and Maturational Processes in Motor Development

Interestingly, when a child is newly born, the number of neurons within the CNS is approximately 100 billion (Nolte, 2002). After birth, these neurons are believed to be unable to divide and reproduce themselves. Additionally, as a person traverses the decades of his or her life starting in the second decade, the CNS tends to lose neurons. This is considered to be a part of the normal aging process associated with the CNS. The point here, though, is that when a baby is born, it essentially has all of its neurons at the first day of its life. The question then becomes: If the infant has all of its neurons, then why does the child need to learn? Clearly, there are many processes involved in the development of the child. This is particularly true in the child's motor development.

Some of the earliest patterns of movement or positioning are in the form of **primary reflexes**. These primary reflexes are often conspicuous when one views the positioning of a child younger than six months of age. Two common primitive reflexes are known as the asymmetrical tonic neck reflex and the symmetrical tonic neck reflex. These two reflexes affect the position of the upper and lower extremities and are elicited or determined by the position of the head. Although these reflexes remain with us throughout life, their influence on the positioning of the body is not as apparent after the age of approximately six months. Sometimes these reflexes can emerge in older children or adults after an injury to the brain occurs.

There are several theories as to why these primitive reflexes become integrated. One of the most prevalent theories has to do with the rapid myelination of the brain within the first few years of life. The average mass of a human brain at birth is about 400 grams, and by the end of the third year, the mass has increased to approximately 1,200 grams (Nolte, 2002). Much of this increase is thought to come from the myelination of the CNS neurons. Myelination is thought to continue at least into the second decade of life. Further, it is believed that as the individual ages, the rapidity of myelination decreases.

Why is myelination so important? Once myelin is established, the ease of neuronal depolarization and the rate of the neuronal propagation increase dramatically. This results in the ability of the neurons to communicate with each other more efficiently. Simultaneously the establishment and proliferation of neuronal dendrites occur at a relatively intense rate during the early years of life. The more dendrites there are, the more connections there are to other neurons. Whereas the myelin facilitates the speed at which depolarization travels down the neuronal axon, the dendrites act as connections between other neurons. The increase in myelin and dendrites results in more efficient communication to many more neurons, which in turn means that the brain can process much more information much more efficiently. Pragmatically speaking, this results in being able to process more information, allows for greater coordination of movement, and facilitates the ability to learn new skills at a quicker rate.

As these neuronal changes are rapidly developing in typically developing children, growth charts provide some insight into the physical development in terms of height and weight. From birth to approximately age 20, there are two large growth spurts, which can be readily seen in Figure 55.1 and Figure 55.2. Specifically, the rate of
FIGURE 55.1 Centers for Disease Control weight-for-age percentile growth chart for boys from birth to 36 months.
FIGURE 55.2 Centers for Disease Control weight-for-age percentile growth chart for boys from 2 to 20 years.

weight increase is greatest from birth to approximately 18 months, when it begins to plateau. Weight tends to stay relatively stable until approximately age 10 or 11 years; that is, the increase in weight is not as dramatic as it was in the earlier months of life (Figure 55.2). The child continues to develop between the ages of approximately 18 months and age 11, and then a second dramatic weight increase occurs throughout the years of puberty. Much of this weight gain is due to a rapid increase in muscle mass and skeletal growth. Accompanying this weight gain during these pubescent years are substantial maturational changes within the endocrine system.

How Body Systems Change with Motor Development

Once the person has successfully navigated puberty and enters the twenties, many of the body's systems (i.e., muscle mass, skeletal size, CNS myelination) remain relatively stable for the next several decades. However, detrimental changes in muscle mass can been seen as early as age thirty, when loss of muscle fibers begins, continuing to decrease at least through age 75 years (Abrams, Beers, Berkow, Fletcher, & Besdine, 1995). Bone mass is another area that changes, especially for menopausal women, but both sexes normally experience slow progressive loss of bone mass beginning at about age 50 years. Brain mass tends to decline by approximately 10% between the ages of 25 and 90 years (Abrams et al., 1995). This reduction in brain mass is not necessarily associated with decreased cognitive function, though some cognitive changes do occur with the normal aging process. As an example, people with large ventricles can still function normally, while those with "normal" sized ventricles have been known to have severe dementia. Therefore, normal age-related loss of brain mass does not necessarily mean loss of cognitive function.

Although we just touched on three systems that change across the life course (bone mass, muscle mass, and brain mass), changes occur in every organ and system throughout the life course, including, but not limited to, the cardiovascular system, the kidneys, the gastrointestinal system, the skin, and the immune system. Just as when the development of the child's subsystems provides the potential to acquire skills, the opposite can be true as the person traverses the fifth and sixth decades (and beyond). For instance, as the individual ages and experiences age-related organ and system changes, the potential for either learning new skills or maintaining the ability to perform skills learned earlier in life may decline. Having discussed some developmental, growth, and maturational issues that occur throughout life, we turn in the following section to motor control concepts that are specific to functional movement and skills.

THE INTERACTION OF MOTOR TASKS WITH THE ENVIRONMENT AND THE PERSON

Movement, with all its exquisite manifestations, is essential to the performance of everyday activity and skills. Occupational activities, such as writing and typing, require developing and organizing movements or actions that adapt to the task demands. For example, writing on a piece of paper requires organizing several actions: (1) reaching for a pen, (2) orienting, (3) grasping and (4) holding a pen to write on the surface of a piece of paper, (5) generating thoughts to write with the pen on the paper, (6) forming and initiating the plan to write, (7) executing the action plan for writing, (8) completing and stopping writing. In current scientific thought, movement emerges from the interaction of the individual with the task and the environment (Shumway-Cook & Woollacott, 1995). How we write will depend on the tool we grasp, the surface we write on, the message we want to convey, and what we know about the act of writing. The organization of each movement we make varies depending on the person and the task and reflects the multiple influences of the physical, social, and cultural environment on the person and the task. Movements are task specific, context dependent, and constrained by factors inherent to the situation. For example, the act of reaching depends on the posture, position, location, and size of the person reaching, as well as the size and placement of the object being reached for and its location relative to the person reaching. If a person has a disability that interferes with or disrupts the ability to move, then that person's initiation and/or task performance is affected. All individuals generate movements in line with task demands, and each person's ability to adapt to changing task demands on a daily basis reflects his or her functional capabilities and limitations. Current thinking highlights the expression of movement as a function of the integrity of the individual, the task, and the environment and not solely as the expression of neuromotor and musculoskeletal processes within the person. The scientific thinking that guided therapeutic practice from the 1950s through the 1980s relied heavily on the understanding of movement as both neuromotor and musculoskeletal derived. However, contemporary thinking highlights a multidimensional systems approach to motor development and motor control. Figure 55.3 illustrates this fundamental thought about a systems and multifactorial approach to the organization of movement and factors controlling movement.

Motor Control and Individual Constraints on Movement

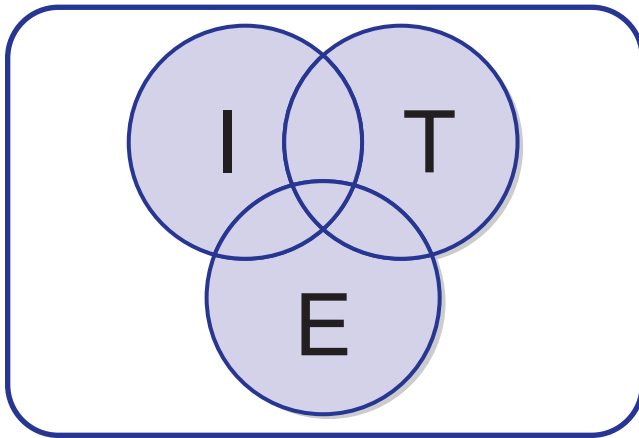
Motor control involves both the study and understanding of the nature and regulation of movement. Motor


FIGURE 55.3   Interaction of the individual, the task, and the environment. (I = individual, T = task, E = environment).

control is seen as the end product of a dynamic interaction between the person's cognitive-perception-action systems, the task at hand, and the environment (Heriza, 1991; Shumway-Cook & Woollacott, 2001). An overview of the different body systems within the individual that contribute to movement follows.

Movement and Sensation/Perception

Most motor control theories propose several roles for sensory input and feedback in movement regulation. The sensory channels provide information from the environment and the body that is useful in initiating and maintaining movement. Sensory input not only has a role in initiating movement, but also has a role as sensory feedback in controlling the movement as the movement occurs.

Perception is the integration of sensory impressions from the different sensory sources into psychologically meaningful information. Both the perceptual and sensory systems provide information about the state of the body and features of the environment that influence movement control. Sensation and perceptual information are important to action just as action is essential to perceptual information (Rosenbaum, 1991). We act on what we perceive, and we perceive and act on our perceptions. Therefore, understanding movement requires an understanding of the systems that control sensation and perception and how these systems influence and form action.

Movement and Action

Movements are housed within actions, and for the occupational therapy practitioner, the focus on movement control is to understand how the individual organizes movements into meaningful and purposeful actions, activities, and routines within different occupations. Also, movements are described and best understood within the context of accomplishing goal-directed actions. Movement control is studied within the context of an action, such as reaching, with the

assumption that the control processes that are involved in this function will provide insight into principles related to how similar movements are controlled.

Understanding the control of action implies understanding how the motor output is based on musculoskeletal and neuromuscular components, including movement synergies and the motor programming systems. The musculoskeletal system includes joint and muscle properties, such as joint and muscle lengthening flexibility, contributing to the organization of the movement. There are numerous joints and muscles in the body, and these must be controlled during the execution of coordinated, functional movement. The problem of coordinating many muscles and joints into a **coordinative structure**, called the **degrees of freedom** problem, is a major research issue for motor control researchers.

Another movement structure that is relevant to action are **synergies**, which are categories of movement that require the action of more than one muscle. As defined by Shumway-Cook and Woollacott (2007), synergies are functional couplings of groups of muscles constrained to act as a unit and reflect preferred strategies for moving. Examples include grasping an object and throwing a ball. Synergies are characterized by spatial and temporal characteristics that allow for both stability and flexibility in movement. Flexibility in synergistic patterns allows the coordinated structure to adapt to the environmental demands, while stability is evidenced by the reliability of the spatial and temporal ordering of the specific movement. In the standing position, lower extremity stability is provided by the distal-to-proximal muscle sequence activation, while flexibility allows for walking on an uneven surface (Shumway-Cook & Woollacott, 2007). In occupational therapy literature, atypical synergies associated with impaired movement control have frequently been described, particularly in populations with stroke and cerebral palsy. These atypical flexion- and extension-dominated synergies are groups of muscles acting as mass movement patterns that reflect the individual's response to reorganization of movement control subsequent to brain injury. Such synergies are marked by lack of flexibility and stability and can result in muscle shortening and musculoskeletal deformity as set postures emerge and normal reciprocal movements and sequences do not occur as part of movement control.

Motor Program and Plans

Motor programs and plans are also part of the action system that is hypothesized to influence movement control. Several definitions of motor programs have been offered in the literature. According to Brooks (1986), **motor programs** have been defined as "communications within the central nervous system that are based on past experiences and can generate planned postural adjustments and movements" (p. 7). Alternatively, in motor control literature,

motor programs are defined as abstract representations that when initiated result in the production of a coordinated movement sequence (Keele, Cohen, & Ivry, 1990; Schmidt & Lee, 2005). Much of motor control research has focused on examining the hypothesized invariant characteristics of motor programs and their role in movement planning and control. Invariant characteristics of motor programs include the relative timing, the order, and the relative force of an action. Such elements characterize categories of movements, such as throwing. Throwing is the motor programming action, and this action is generalized so that "throwing" can include throwing a football, throwing laundry into a hamper, or throwing a snowball at a friend. Several motor control theorists question the usefulness of the programming construct or the abstract representations of movements. However, the concept of a motor program or a stored representation of movement is central in cognitive approaches to movement planning and control. It is thought that the individual uses existing motor programs to organize motor behavior when faced with novel actions and tasks in the environment. Although there is neurobehavioral evidence to support the notion of motor programs in the individual, how motor programs develop and where they are stored in the individual remain controversial (Shea & Wulf, 2005). Along with movement plans and programs, an understanding of posture, stability, and postural control informs our understanding of movement.

Postural control involves controlling the body's position in space to maintain stability and orientation. Horak and Macpherson (1996) have defined *postural orientation* as the ability to maintain an appropriate relationship between body segments and between the body and the environment for a task. Postural stability or balance is the ability to maintain the body in equilibrium. Maintaining postural control requires two separate sensory motor processes: the sensory organization process and the motor adjustment process. The sensory organization process involves the interplay of one or more of the orientation senses (vision, somatosensory, and vestibular), their integration within the CNS, and their contributions to postural control. The motor adjustment process involves the ability to execute coordinated and properly scaled musculoskeletal responses. The motor responses are automatic processes that develop early in childhood, while the sensory processes develop over time in children and are not fully developed until a child is about 14 or 15 years of age. Both sensory and motor processes are essential to developing and maintaining postural control. Disruptions in these sensory or motor systems due to injury, disease or delay will result in inadequate postural control strategies.

The term *posture* is most often used to describe both the biomechanical alignment of the body and the orientation of the body to the environment. For example, the occupational therapy practitioner might describe the client's posture as sitting, standing, or lying down. When working with a client, the occupational therapy practitioner might focus on developing postural control and coordinative movements as part of the person's need to develop motor programs and plans. The practitioner considers the process of posture, action, and movement organization in relation to an individual's performance of a task and does not focus on the execution of a single movement or posture. What is essential is the therapist's supporting the organization of the client's movement relative to the task and the activity demands associated with different tasks.

Cognition and Action

Actions can occur as a result of external prompts, such as seeing a toothbrush and reaching for it, or reflexively in response to an external stimulus, or as a result of an internal intent or motivation, such as wanting to brush one's teeth in the morning and looking for and reaching for a toothbrush. Cognitive processes that are important to action include attention, memory, motivation, and the emotional aspects of motor control underlying the establishment of the person's intent or goals (Shumway-Cook & Woollacott, 2001). Also, the ability to attend to the relevant cues of a task and the performance environment and the ability to make task comparisons, to evaluate one's own performance, and to identify errors in movement planning are cognitive strategies that are useful in skill learning and relearning.

Reaction Time

One example of cognition and action that has been relatively well researched as a measure of cognitive processing is **reaction time**. Reaction time is considered to be a measure of how efficiently the CNS is working. Reaction time is defined as the time from when a stimulus is given to the time when a movement begins in reaction to the stimulus. There are different types of reaction time. For instance, *simple reaction time* is the reaction time when there is a single stimulus associated with a solitary specific response. For example, suppose that when a person sees a light turn on, he or she is required to reach forward; in this case, there is a one-to-one relationship between the stimulus and the response. *Choice reaction time* is somewhat more complex, occurring when a number of potential stimuli are present and the motor response is unique for each of the different stimuli. For example, there might be three potential stimuli involving a red light, a green light, and a blue light. The directions might be that when he or she sees the red light, the participant is required to lift his or her arm straight up; when he or she sees the green light, the participant is supposed to move his or her arm to the left; and when he or she sees the blue light, the participant is supposed to move his or her hand to the right. It has been shown that a person's choice reaction time performance is typically longer than

his or her simple reaction time performance. It has also been shown that the best reaction times occur during the late teens and early twenties and that the reaction time increases each decade thereafter. Men tend to have faster reaction times than women. It also appears that the more education a person has, the better is his or her reaction time (Fozard, Vercryssen, Reynolds, Hancock, & Quilter, 1994; Houx & Jolles 1993) Within the individual movement is the product of many systems that need to be examined as they interact and contribute to movement organization and control. Deficits in one system affect the function of other systems. To understand motor control and organization, the perceptual, cognitive, and action components of motor control must be considered and synthesized as part of the full picture of motor control. In addition to individual body factors affecting control, different tasks as well as the environment impose constraints on motor control (see Figure 55.3).

Task and Environmental Constraints on Movement

Essential to movement control is the nature of the task and the task requirements. Within occupational therapy, the practitioner's role is to help the client be successful with tasks that are important to the client's occupations from basic activities of daily living to complex work or leisure routines. For instance, a therapist might have a child catch a ball while standing still or have the child catch a ball while he or she is running.

In motor behavior research, tasks are categorized according to task features and activity demands. These classifications are based on task attributes that affect postural and movement control and learning. Also, **motor learning** research has focused on examining optimal practice environments and feedback conditions for the learning of different tasks according to task attributes. This framework is helpful for understanding movement control; however, the research that has been done in this area with patient populations while performing activities of daily living and functional tasks is limited.

Discrete, Serial, and Continuous Movement Tasks

Discrete tasks are those with a recognizable beginning and end. For example, going from a sitting to a standing position, lying down in bed, and turning on the ignition of a car with a key are examples of discrete movements. A series of discrete movements performed together are referred to as **serial tasks**. An example is the sequence of inserting contact lenses; the steps involved might include removing the contact lens from the case, rinsing it with solution, orienting the contact lens on the finger, and finally applying the lens to the cornea of the eye. According to Schmidt and Lee (2005), serial tasks are composed of an ordered set of discrete movements. Most actions in basic and instrumental activities of daily living such as hygiene and dressing are serial in nature. Continuous tasks are those that have no

recognizable beginning or end; these include walking, running, biking, and, in the realm of hygiene, brushing or combing the hair. In these cases, the beginning and the end of the task are determined by the performer. In all tasks, the nature of the task defines the action needed and the organization of the action. How one learns or relearns tasks is also affected by the type of task.

Open Versus Closed Tasks or Skills

Another task classification system that is used in motor behavior research is based on the task environment interaction defined by Schmidt and Lee (2005) and later elaborated on by Gentile (1992). In this classification system, closed movement tasks are characterized by fixed habitual patterns of movement that are performed in relatively fixed environments. **Closed skills** are somewhat stereotypical, show little trial variability, have low information-processing demands, and require less cognitive attention than open skills. **Open skills** are those that are performed in a constantly changing environment, require the performer to adapt his or her behavior to a constantly changing environment, have high information-processing demands, and are attention demanding. Most basic activities of daily living, such as turning on faucets to wash one's face, are closed skills, while instrumental activities such as driving or maneuvering a grocery cart in a crowded store are open skills. To be successful with open skills, the client must develop a repertoire of movements that allow for adaptation to changing environmental conditions, such as hitting a ball with a bat (Figure 55.4).

FIGURE 55.4   Open skill of batting a ball.

Stability Versus Mobility Tasks and Manipulation Demands

In classifying tasks and movement demands, Gentile (1992) also introduced a task dimension based on whether the person's base of support is still or in motion. Stability tasks such as sitting or standing are performed with a non-moving base of support. However, mobility tasks, such as walking or running, have a moving base of support. Also, Gentile (1992) took into account the amount of upper extremity manipulation involved in a task, as well as the degree of accuracy and speed necessary for functional performance of tasks. Manipulation tasks such as keyboarding that require speed and accuracy increase demands on the postural system, since body stabilization is critical to task performance.

Regulatory and Nonregulatory Environmental Constraints

As tasks are performed, environmental constraints can influence the person's performance in various ways. Some of these constraints directly regulate the movement, while others may affect performance more indirectly. For example, reaching is constrained by the size shape and weight of a glass that is to be used for drinking. The features of the glass regulate the movement. If the environment is noisy, however, reaching might not be directly affected; in this case, noise is a nonregulatory aspect of the environment. To plan effective interventions, it is necessary to understand the environment and its contribution to movement and to prepare patients to move in a variety of environments.

The Person, the Task, and the Environment

Skill acquisition is dependent on several factors. Practitioners help patients to learn skills, and these skills have multiple dimensions that influence reacquisition. Understanding the types and requirements of tasks as well as the regulatory features of the environment that affect task performance allows the practitioner to plan with the patient the optimal environment for skill learning. Also, understanding how movement control is affected in the client with a neurological disorder and what body systems have been affected helps the practitioner to plan effective multisystems interventions for skill learning.

Along with using task analysis, a task taxonomy can be useful for retraining functional movements in the patient with a neurological disorder. Using the three continuums of closed to open skills, stability to mobility, and no manipulation versus manipulation, the practitioner could assess a client's capability and skill level across many basic and instrumental activities of daily living. By systematically varying the regulatory features of the task and the environment, the practitioner, can help the patient to develop the motor program and plans that are necessary for rebuilding task routines. Now that we have reviewed some fundamental aspects of motor learning and control and its development

from a theoretical perspective, the next section focuses on defining and assessing motor skills and motor performance.

DEFINING AND ASSESSING MOTOR SKILLS AND MOTOR PERFORMANCE PROBLEMS

This section presents concepts from the **International Classification of Function (ICF)** to provide a framework for understanding motor skills and how neuromotor impairments that affect motor skills are defined and assessed. The ICF integrates medical and social models of disability by specifying the nature and parallels between functional ability and disability, as well as the impact of social and environmental factors on performance. According to the ICF, **function** reflects the composite of one's body functions, activity and participation, whereas **disability** reflects impairments, limitations of activity and function, and activity restrictions (Figure 55.5). Within the ICF classification, the person's achievement of a level of function that affords independence and quality of life is the determinant of a successful rehabilitation outcome. The ICF's focus on health and quality of life resonates with the focus of the occupational therapy profession on health and wellness, as well as its focus on the multi-faceted aspects of function and occupational performance.

In assessing, treating, and determining client outcomes, the practitioner focuses on understanding the client factors, the client's occupational activity demands, the client's occupational performance contexts, the client's occupational performance patterns, the client's occupational performance skills, and the client's actual performance of and participation in personal tasks and meaningful occupations. Also, in assessing and treating the client, the practitioner observes what the client can and cannot do and what enables or interferes with the client's performances of his or her occupations. In understanding motor control and organization, this means that the practitioner integrates his or her understanding of the individual, the task, and the environment as it relates to movement control and motor skill to address the client's motor issues that interfere with the ability for participation in occupation. It is this integration that uniquely defines the art of occupational therapy as a profession.

This section lists the primary motor terms that are used to explain motor skills Additionally, client factors, including body structures, functions, and impairments that interfere with motor skill acquisition and performance, are defined. This is so that the reader has an understanding of both typical motor skill and the impairments that interfere with motor performance and result in inefficient movements.

From the practitioner's perspective, motor skills are clients' skills in moving and interacting with task, objects, and environment specific to their engagement in the occupations that are meaningful and necessary to their life roles and participation and satisfaction with their life. Also, clients' skilled performance in their occupations will

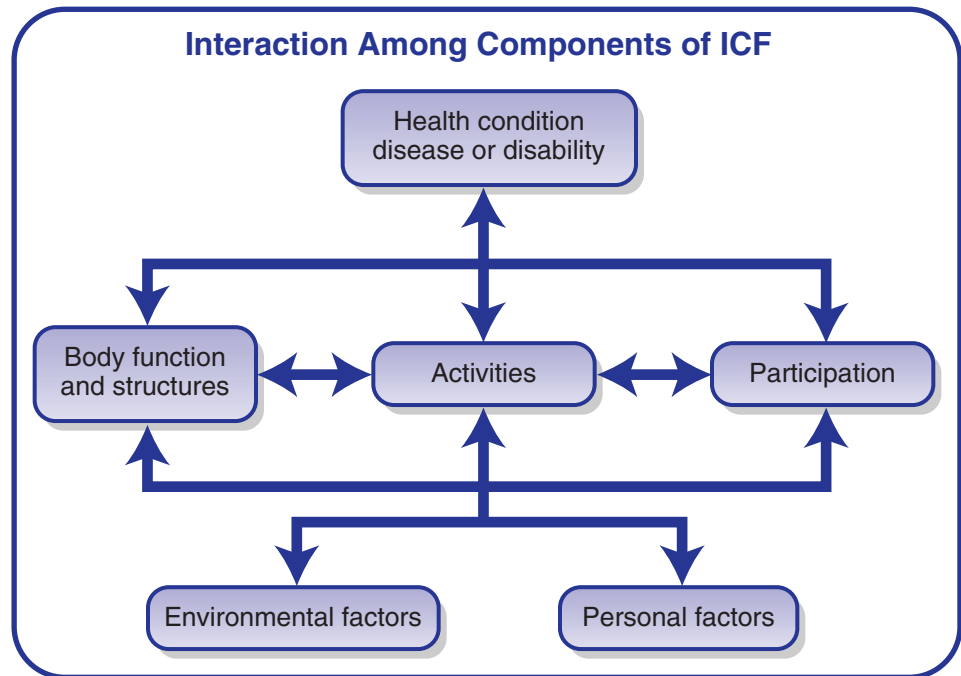
Interaction Among Components of ICF


FIGURE 55.5 International Classification of Function.

depend on the integrity of their different body systems (client factors), the composite of activity demands of their occupations, and the influence of and the contexts in which they function.

Motor skill is defined as a goal-related volitional movement that requires both motor and sensory input for success. Motor skills are learned and can wax and wane depending on practice and experience. There can be multiple client factors that interfere with the performance of motor skills, as motor control and organization are integrally involved with the body systems and mental functions contributing to task performance. Not the least of these are neuromotor factors or impairments at the neuromuscular and postural levels that can interfere with motor skill. For instance, in addition to problems with motor planning (e.g., problems with praxis), the disruption of skilled performance can result from postural instability and malalignment, limited functional trunk and limb mobility, dyscoordination of the upper extremities, problems with in-hand manipulation, limb and body weakness, the inability to grade and sustain muscle coactivation and force, and the inability to sequence muscle activity. The following discussion defines terms and impairments that help the practitioner to understand the components of posture, movement, and skill, as well as what neuromuscular impairments can interfere with efficient and skilled movement. The typical components of postural control include posture, alignment, and adaptation.

Posture is a composite of the positions of all the joints of the body at any given time. It is the static position that is assumed by any body part at any time. Therapists must evaluate spinal alignment and curves, pelvis, trunk, head, neck, and upper extremity posture alone and in relation to each other in positions of standing, sitting, and lying down and in the context of occupational performance.

Good body and **postural alignment** occurs when the center of gravity of each body segment is over the supporting base of the body. In the case of a child with cerebral palsy, postural alignment can be limited by the presence of interfering reflexes, such as an asymmetrical tonic neck reflex, which results in the child's body being dominated by more extensor tone on the side of the body to which the head is turned and more flexion tone on the other side of the body (Preston, 2006). Similarly, in a person who has sustained a stroke, atypical muscle synergies can result in an atypical and sustained increase of flexion and or extension tone in different groupings of muscles, leading to postural asymmetries as the client is sitting or standing.

Postural adaptation refers to the ability of the body to maintain balance automatically and remain upright during alterations in positions and challenges to stability. Normal control and adaptation involve the ability to produce movements through adequate ranges and to control movements throughout the ranges. Also, they involve the ability to differentiate and selectively control different body parts; to initiate, stop, and hold a limb in action; and to have normal tone in the body to stabilize the body and support limb movements while the body is stationary or moving. As defined by Howle (2002), **postural control** consists of (1) proactive reactions or postural orientation, which helps to anticipate the appropriate relationship between body segments that is task specific; (2) postural stability, which is the ability to maintain the center of mass within the limits of the base of stability; and (3) reactive postural adjustments, which are flexible and varied responses to perturbations from the environment, self-initiated movements or a moving surface.

When evaluating a client, the practitioner needs to observe the client's posture in the context of his or her everyday actions, such as sitting at a computer, standing,

pushing a grocery cart, or lying in bed. During these observations, the practitioner observes what is occurring in the client's body and whether the client is able to move efficiently and easily while also having a goal such as getting out of bed or typing while sitting. In this context, observations are made of the client's postural alignment, initiation of movement, selective and independent control of his or her limbs, and ability to terminate actions. Practitioners should look at the client's posture, alignment, and balance while the client is on stable, hard surfaces and when the client is on an unstable surface or a slippery surface. A difficulty in determining balance deficits is that balance has both sensory and motor components. Appropriate postural control depends on inputs from visual and somatosensory receptors and the vestibular system and

on the ability of the CNS to interpret the relative importance of each. To fully assess balance, the practitioner needs to evaluate all contributions to balance, including perturbations to balance and both sensory and motor influences on postural control. The client's ability to bend and tie shoes and to get into and out of the bathtub should also be assessed as part of the observation of the dynamic nature of postural control. Table 55.1 describes several clinical assessment tools that evaluate postural control.

Tone can be defined in several ways; varies from person to person; and can depend on age, gender, and occupation. Muscle tone is characterized by the stiffness or tension with which a muscle resists being lengthened. Both neural and nonneural mechanisms contribute to muscle tone (Lin, Brown, & Brotherstone, 1994). Normal tone

TABLE 55.1   POSTURAL CONTROL ASSESSMENTS

Assessment	Age Range	Description
Sensory Organization Test (SOT)	Adult	◆ Defines six different sensory conditions or environments to measure postural sway ◆ Assesses influence of vision and somatic and vestibular sensory information
Clinical Testing for Sensory Integration and Balance (CTSIB)	All	◆ A foam surface is used to disrupt somatic sensation ◆ A visual conflict done with dots or lines is used to disrupt vision ◆ Measures client's ability to maintain balance under six conditions
Functional Reach	Adults	◆ Measures the distance that can be reached in standing in a forward direction. It indicates the extent to which the center of the body mass can be moved in a forward direction toward the limit of stability
Timed "Up and Go" Test (TUG)	Adults	◆ Measures the time it takes to stand up from a seat, walk off, and sit down again. It indicates the ability to balance during body translation from one place to another, the ability to balance being interpreted as the time taken to perform the entire sequence
Tinetti's Balance and Gait Evaluation	Adult	◆ Client is asked to do a variety of tasks (e.g., move from sitting to standing and ambulate) ◆ Has high predictive validity for frail elderly at risk for falls
Berg Balance Scale	Adults	◆ Client is asked to complete 14 different tasks; each task is scored by using a four-point scale ◆ Client is asked to complete 14 different tasks; each task is scored using a four-point scale
Limits of Stability Test	Adult	◆ Client stands, and a computerized force plated center of gravity is calculated ◆ Client volitionally shifts weight toward a series of targets ◆ Monitors movement for smoothness and accuracy of postural movements
Fugl-Meyer Sensori-motor Assessment	Adults	◆ Balance subtest measures the amount of assistance and time tolerated using static standing balance and tilting reactions

is characterized by ability to move against gravity, shift between stability and mobility, use muscles in groups or selectively, and balance between agonist and antagonist tone (Preston, 2006). Tone in a muscle can be affected by damage to the nervous system and can increase and decrease as well as vary under different task and environmental conditions (Figure 55.6).

Hypotonia reflected in low-tone clients is a decrease in the sensation of a muscle's resistance to stretch as the joint is moved through the range of motion and the client's inability to recruit adequate force to move against gravity. Clinically, muscles appear soft, joints are lax as cocontraction around the joints is less than optimal because of inadequate force generation, and deep tendon reflexes are absent or diminished. Hypotonia is observed in lesions of the cerebellar pathways, primary muscle diseases, lower motor neuron disorders, and the acute phases of stroke and spinal cord injury. Hypotonia can also be observed as a transient phase in infants with cerebral palsy.

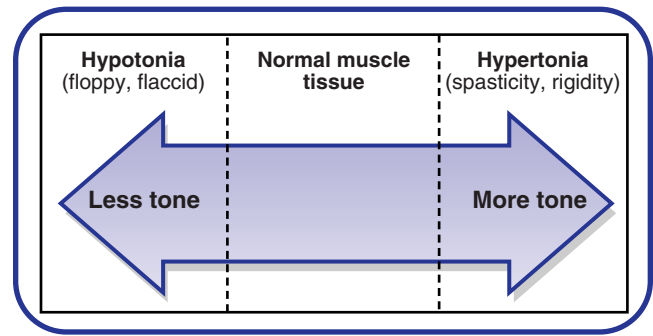
Hypertonia in contrast to hypotonia, is characterized by increased resistance to stretch, a feeling of stiffness, and limits to the range and variety of movements. **Spasticity** is a motor disorder that is characterized by a velocity dependent increase in tonic stretch reflexes with exaggerated tendon jerks resulting from a hyperexcitability of the stretch reflex. Clinically, spasticity is characterized by hypertonic muscles, hyperactive deep tendon reflexes, **clonus**, abnormal spinal reflexes, increased resistance to passive movement, and decreased coordination. Spasticity is influenced by the client's postural status and by extrinsic factors such as anxiety, pain, and temperature extremes. It can be mild, moderate, or severe.


FIGURE 55.6   Tone continuum.

Rigidity is defined as the simultaneous increase of muscle tone in the agonist and antagonist muscles that results in increased resistance to passive motion in any direction. Rigidity occurs in extrapyramidal system lesions such as Parkinson's disease, encephalitis, and tumors. Rigidity that is characterized by a feeling of constant stiffness throughout the range is called *lead pipe rigidity,* whereas rigidity that is characterized by alternating contraction and relaxation is called *cogwheel rigidity.* There are many challenges to assessing muscle tone, as tone can vary and depends on intrinsic and extrinsic factors.

Observation of tone can be evaluated directly by using the Ashworth Scale of Spasticity (Ashworth, 1964) and the Modified Ashworth Scale of Spasticity (Bohannon & Smith, 1987). These scales provide a way to loosely quantify the level of spasticity in muscle. The Modified Ashworth Scale of Spasticity is fairly commonly cited in the literature and is fairly straightforward in its application and interpretation (Table 55.2).

TABLE 55.2   ASHWORTH SCALE OF SPASTICITY AND MODIFIED ASHWORTH SCALE OF SPASTICITY

Ashworth Scale of Spasticity (Ashworth, 1964)	Description	Modified Ashworth Scale of Spasticity (Bohannon & Smith, 1987)
1	"Slight increase in muscle tone with a 'catch' when the limb is moved"	0
	"Slight increase in muscle tone, manifested by minimal resistance at the end of the range of motion when the affected part(s) is moved in flexion or extension"	1
	"Light increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the range of motion"	1+
2	"More marked increase in muscle tone, but the limb is easily flexed"	2
3	"Considerable increase in muscle tone"	3
4	"Rigid in flexion or extension"	4

Another scale for assessing spasticity is the Tardieu scale (Tardieu, Shentoub, & Delarue, 1954), later adapted by Held and Pierrot-Deseilligney (1969). This scale involves testing spasticity using three separate velocities (V1: as slow as possible, V2: velocity of limb as if it were falling under gravity, and V3: velocity of the limb as fast as possible, that is, faster than the effects of gravity). Under these various velocities, both the quality of muscle reaction ("X") and the angle of the muscle reaction ("Y") are recorded. The quality of muscle reaction uses a five-point scale from zero to four. Zero refers to "no resistance throughout the course of the passive movement." One refers to "slight resistance through the course of the passive movement, with no clear catch at a precise angle." Two refers to a "clear catch at a precise angle, interrupting the passive movement, followed by release." Three refers to "fatigable clonus (<10 seconds when maintaining pressure) occurring at a precise angle." Four refers to "infatigable clonuses (>10 seconds when maintaining pressure) occurring at a precise angle" (Gracies et al., 2000, p. 1555). The angle of muscle reaction is "measured relative to the position of minimal stretch of the muscle (corresponding to angle 0) for all joints except hip, where it is relative to the resting anatomic position" (Gracies et al., 2000, p. 1555.). **Gross coordination** is the combined activity of many muscles into smooth patterns and sequences of motion and is described as smooth, directed, and fluid actions supporting everyday activities. Also, coordinated movement is characterized by rhythm, appropriate muscle tension, appropriate postural tone, and refinement to the minimal number of muscle groups necessary to produce the desired movements and equilibrium. **Coordination** is an automatic response that is monitored primarily through proprioceptive sensory feedback. Visual and tactile sensory feedback, body scheme, and ability to judge and move the body through space also affect overall coordination. **Incoordination** is a broad term that is used for extraneous, uneven, or inaccurate movements. Neurological disorders and trauma such as muscle or peripheral nerve disease and lesions of the cerebellum, spinal cord, and frontal or postcentral cortex can cause unique disturbances in coordination. See Table 55.3 for examples of neurological disorders and their stereotypical coordination patterns.

TABLE 55.3 NEUROLOGICAL DISORDERS AND THEIR STEREOTYPICAL COORDINATION PATTERNS

Category	Description	Test
CEREBELLAR DYSFUNCTION		
Intention tremor	◆ Occurs during voluntary movement, is less apparent or absent during rest, and intensifies at the termination of the movement. ◆ Evident in multiple sclerosis.	◆ Finger-to-finger test, finger-to-nose test. ◆ May have trouble performing tasks that require accuracy and precision of limb placement (e.g., drinking from a cup or inserting a key in a lock).
Essential familial tremor	◆ Inherited as an autosomal-dominant trait, visible when client is carrying out a fine precision and accuracy task.	◆ Have the person reach for an item. Positive if tremors are present during the reach.
Adiadochokinesis	◆ Inability to perform rapid alternating movements, e.g. pronation/supination, elbow flexion/extension.	◆ Tests by counting how many cycles of alternating movements in 10-second time frame. Best to test unaffected/less affected side first, then compare performance to affected side.
Dysdiadochokinesia	◆ Decreased ability to perform rapid alternating movements smoothly.	◆ Supinate/pronate, flex/extend elbow, grasp/release hand, alternating bilateral tasks. Number of alternations within a time period and the differences between extremities are noted.
Dysmetria	◆ Inability to control muscle length results in overshooting when pointing to target objects. ◆ Inability to estimate range of motion necessary to reach a target. Two types include hypermetria (overshoot) and hypometria undershoot).	◆ Finger–to-finger or finger-to-nose tests.

TABLE 55.3	NEUROLOGICAL DISORDERS AND THEIR STEREOTYPICAL COORDINATION PATTERNS *Continued*	
Category	**Description**	**Test**
Dyssynergia	◆ Movements are broken up into their component parts and appear jerky. Jerky movements are due to lack of synergy between agonist/antagonist. ◆ Can cause problems in articulation and phonation.	◆ Alternating movement, finger-to-nose, finger-to-finger tests.
Ataxia	◆ Delayed initiation of movement responses, errors in range and force of movement, errors in rate and regularity of movement. Poor agonist/antagonist coordination, results in jerky, poorly controlled movements, poor postural stability.	◆ When reaching for object, shortest distance between the client and object is not a straight line.
Ataxic gait	◆ Unsteady, wide-based gait, tendency to veer or fall toward side of lesion. ◆ Staggering, wide-based gait with reduced or no arm swing, uneven step length and tendency to fall.	◆ Observation of walking, turning quickly, walking toe to heel along straight line.
Rebound phenomenon of Holmes	◆ Lack of a check reflex. ◆ Inability to stop a motion quickly to avoid striking something.	◆ Therapist releases resistance to client's elbow flexion unexpectedly, client's hand hits his or her own chest if unable to check motion.
Hypotonia	◆ Decreased muscle tone, decreased resistance to passive movement	◆ Can observe clinically and perform a quick stretch.
Nystagmus	◆ Involuntary (oscillating) movement of eyes. Interferes with head control and balance. Can occur as result of vestibular system, brainstem, or cerebellar lesions.	◆ Can observe by having the person look at a fixed object. Is positive if the eyes make small rapid oscillations (tremorlike movements).
Dysarthria	◆ Explosive or slurred speech caused by incoordination of the speech mechanism. ◆ Speech may vary in pitch, seem nasal or tremulous.	◆ Can observe if ability to articulate words due to the oral-motor and/or larynx musculature. This is a motor problem, not due to aphasia.
POSTERIOR COLUMN DYSFUNCTION		
Ataxia	◆ Wide-based gait results from loss of proprioception, but client can self-correct using vision by watching their feet (compare with cerebellar dysfunction).	◆ Can observe in any part of the body. Is characterized by "large" tremors.
Romberg sign	◆ Inability to maintain standing balance with feet together and eyes closed.	◆ The test is the same as the definition.
BASAL GANGLIA DYSFUNCTION		
Athetoid movements	◆ Continuous, slow, wormlike, arrhythmic movements that primarily affect the distal portions of the extremities. Occur in the same patterns in the same subject, not present during sleep. Co-occurrence with athetosis = choreoathetosis.	◆ Therapist should note proximal or distal involvement extremities involved, pattern of motions, and which stimuli increase/decrease abnormal movements. Its occurrence can be documented through observation.

TABLE 55.3	NEUROLOGICAL DISORDERS AND THEIR STEREOTYPICAL COORDINATION PATTERNS *Continued*	
Category	**Description**	**Test**
Dystonia	◆ A form of athetosis that causes twisting movements of the trunk and proximal muscles of the extremities, distorted postures and torsion spasms. ◆ Persistent posturing of the extremities (e.g., hyperextension of hyperflexion of the wrist and fingers) often with concurrent torsion of the spine and twisting of the trunk. Movements are often continuous and seen in conjunction with spasticity. Subtypes included segmental, generalized, focal, and multifocal.	◆ Its occurrence can be documented through observation.
Chorea	◆ Irregular, purposeless, involuntary, coarse, quick, jerky, and dysrhythmic movements of variable distribution. May occur in sleep.	◆ Its occurrence can be documented through observation.
Ballism	◆ A rare symptom produced by continuous, abrupt contraction of axial and proximal musculature of the extremity. Causes the limb to fly out suddenly. Occurs on one side (hemiballism) and is caused by lesions of the opposite subthalamic nucleus.	◆ Its occurrence can be documented through observation.
Resting tremors	◆ Stop at the initiation of voluntary movement, resume during holding phase of motor task (e.g., pill rolling tremor of Parkinsonism). ◆ Occurs at rest and subsides when voluntary movement is attempted. Seen in Parkinson's disease.	◆ Have the person reach for an item. Positive if tremors are present before initiation of the reach but stop when the reach begins.
Bradykinesia	◆ Movement is very slow or even nonexistent, with accompanying rigidity.	◆ Ask the person to move; on attempting to move, the person's motions are extremely slow, if at all. Tone appears to be high.

In addition to direct observation of the client's smooth and fluid movements during life activities and any notable deviations such as tremor at rest, lurching, and overshooting, there are several standardized tests that use speed and accuracy in functional tasks to determine performance, as shown in Table 55.4.

Fine coordination is defined as the smooth and harmonious action of groups of muscles working together to produce a desired motion, whereas **dexterity** is defined as a type of fine coordination that is mostly demonstrated in the use of the upper extremity. Coordination problems can be manifested in irregularity in rate of movement, excessive force, incorrect sequencing, and sudden corrective movements. Practitioners use several standardized tests to assess speed of object manipulation, grasp and release,

accuracy of movement, prehension patterns, writing skills, and hand posture, as shown in Table 55.5.

Besides standardized tests that are performance based, it is important to observe the client using the upper extremities in self-help tasks such as buttoning, keyboarding, manipulating change, and writing. The Assessment of Motor and Process Skills, a standardized test based on the client's preferred task to perform, is a tool that was developed by an occupational therapist, Dr. Anne Fisher. The therapist grades the client's performance across tasks according to process, motor, and communication skills. This partitions task performance across the dimensions of posture, mobility coordination, strength, and energy. However, to administer this test, special training is required, which limits the applicability of this tool across populations.

TABLE 55.4 STANDARDIZED TESTS OF MOTOR CONTROL AND SKILL

Assessment	Age Range	Description
Bruininks-Oseretsky Test of Motor Proficiency	4.6–14.5 years	◆ Assesses gross and fine coordination, dexterity, upper limb speed, visual motor control, muscle strength running, balance.
BOT-2: Bruininks-Oseretsky Test of Motor Proficiency, Second Edition	4–21	◆ Covers a broad array of fine and gross motor skills, providing composite scores in four motor areas and one comprehensive measure of overall motor proficiency. These composites are Fine Manual Control, Manual Coordination, Body Coordination, Strength and Agility, and a Total Motor Composite.
Movement ABC	4–12	◆ Identifies and evaluates the movement problems that can determine a child's participation and social adjustment at school and to plan programs for remediation and management. It provides a comprehensive assessment for those who are identified as being at risk, yielding both normative and qualitative measures of movement competence, manual dexterity, ball skills, and static and dynamic balance.
Miller Assessment for Preschoolers	Preschool	◆ Assesses 27 items (e.g., walking a line, stepping, hand-to-nose test) and gross motor assessment.
Quick Neurological Screening Test	5 years–adult	◆ Screens neurological integration (attention, balance, spatial organization, rate and rhythm of movement, motor planning, coordination).
Assessment of Motor and Process Skills	Adults, adolescents, and older children; there is also a school version.	◆ Measures both process and motor skills as they relate to task performance, provides information on how the person is performing in a given context, and is used to predict performance in activities of daily living.
Test of Motor Impairment	5–14 years	◆ Assesses motor deficits (static and dynamic balance, manual dexterity, speed of movement, eye-hand coordination, problem solving ability).

TABLE 55.5 STANDARDIZED TESTS OF UPPER LIMB FUNCTION AND FINE MOTOR COORDINATION

Dexterity Assessment	Age Range	Description and Features
Crawford Small Parts Dexterity Test	Adults	◆ Measures eye-hand coordination and manipulation of small hand tools. ◆ Designed for teenagers and adults. ◆ Uses pins, collars, screws, tweezers, screwdriver. ◆ Client is timed on tasks such as inserting a pin in a hole in a metal plate with tweezers, covering with a collar, threading screws.
Erhardt Developmental Prehension Assessment	Birth–6 years	◆ Measures components and skills of hand function development. ◆ Used for birth–6 years. ◆ Uses a variety of objects (e.g., small suitcase, plastic pail, toy hammer, key, beads, tin can, rubber ball, stacking rings) to measure grasp, reflex, and manipulation skills.

TABLE 55.5 STANDARDIZED TESTS OF UPPER LIMB FUNCTION AND FINE MOTOR COORDINATION *Continued*

Dexterity Assessment	Age Range	Description and Features
Melbourne Assessment of Unilateral Upper Limb Function	5–15 years	◆ Measures unilateral upper extremity quality of movement in children from 5 to 15 years of age. It is useful for children who are challenged by any neurological dysfunction.
Pediatric Evaluation of Disability Inventory (PEDI)		◆ Outcome measure that quantifies a child's level of ability and dependence in many functional activities of daily living. PEDI measures task performance in the areas of self-care, mobility, and social functioning.
Arm Motor Ability Test (AMAT)	Adult	◆ Measures ability to perform 13 activities of daily life composed of 1 to 3 component parts. The time taken to complete each task is measured using a stopwatch, and the actions are videotaped and rated on a scale of 1 to 6.
Actual Amount of Use Test (AAUT)	Adults	◆ Measures actual use of the limb on 21 items using a 3-point scale. Patients are videotaped.
Motor Activity Log: Amount of Use Scale (AOU)	Adult	◆ Provides information about actual use of the limb in everyday life situations. Patient reports in a semistructured interview about whether and how well, on a 6 point scale (0–5), 14 daily life activities were performed during a specified period.
Action Research Arm Test (ARA)	1	◆ Three subtests (grasp, grip, and pinch) measure the ability to grasp, move, and release objects of different size, weight, and shape. Scoring is on a 4-point scale (0–3).
Grooved Peg Board Test	5–adult	◆ Measures eye-hand coordination and finger dexterity. ◆ Client places grooved pegs in a 25-hole peg board in various random positions.
Purdue Peg Board Test	5 years +	◆ Measures movements of arms hands, fingers and fingertip dexterity. ◆ Normed for adults and children 5–15 years, 11 months. ◆ Client places pins in a peg board and assembles pins, washers, and collars.
Box and Block Test	7–9 years and adults	◆ Tests manual dexterity ◆ Normed for children 7–9 years, adults and adults with neuromuscular involvement. ◆ Client picks up one black at a time and places it in an attached compartment.
Nine Hole Peg Test of Fine Motor Coordination	Adult	◆ Measures fine dexterity. ◆ Normed for adults >20 years. ◆ Timed score to place nine 1-$\frac{1}{4}$ inch pegs in a 5 × 5 inch board and remove them.
Jebsen-Taylor Hand Function Test	5 years +	◆ Evaluates functional capabilities. ◆ Subtests include writing, card turning, picking up small objects, simulated feeding, stacking checkers, and picking up light and heavy objects.
Minnesota Rate of Manipulation Test	13 years +	◆ Measures dexterity. ◆ Assesses placing, turning, displacing, one-hand turning and placing, and two-hand turning and placing of round blocks.

Some assessments are more comprehensive that evaluate a number of the issues referred to above, whereas several assessments are easily categorized by problems specific to motor function, motor impairment, motor coordination, and motor control.

INTELLECTUAL HERITAGE AND OCCUPATIONAL THERAPY THEORETICAL FRAMES OF REFERENCE GUIDING NEUROMOTOR INTERVENTIONS

The field of motor control draws from a wide range of disciplines and reflects the scholarly and research activities of scientists who are interested in motor behavior. Research findings and theories about motor control and recovery of function have had an ongoing influence on the practice of occupational therapy focused on adults and children with motor control disorders. In the years following World War II, the dominant therapeutic approach that was used in the field of physical disabilities was muscle reeducation. This approach, although useful for polio, was not appropriate for treating people with disorders of the CNS with resultant paresis. Because of the inadequacies of applying muscle reeducation principles to CNS disorders, a few occupational and physical therapy practitioners (e.g., Ayers, 1972; Bobath, 1965; Brunnstrom, 1970; Knott, 1956; Rood, 1952; Voss, Ionata, & Myers, 1965) began to study and hypothesize about how the nervous system controls movement and applied these principles to clinical practice. As a result of their efforts, the development of organized approaches and techniques to restore CNS function emerged in the therapy fields. The period from the mid-1950s through the 1980s was marked by the development and teaching of specialized neurotherapeutic approaches such as proprioceptive neuromuscular facilitation, neurodevelopmental therapy, and Brunnstrom's movement therapy. These approaches were situated in the knowledge of the time focused on specific sensorimotor techniques and assumptions about the CNS and the organization of motor behavior. More recently, these approaches have been less favored, as there are more current theoretical approaches that have better research evidence supporting their use.

The field of motor control and learning tries to explain both the regulation and control of normal movements, as well as the factors and processes that are involved in normal motor learning. Motor learning is commonly defined as the processes associated with permanent changes in motor behavior resulting from practice and experience. The reader is referred to texts that provide in-depth explanations of the motor learning process and the research that supports learning using different practice conditions and the salient factors such as feedback that affects motor learning (e.g., Brooks, 1986: Schmidt & Lee, 2005).

The motor control approaches that are used in occupational therapy reflect an integration of ideas that explain the nature and regulation of movement. There is no one singular motor control theory of occupational therapy; rather, there are several applied motor learning and control approaches and models. These approaches are supported by motor learning and control research drawn from the movement and therapeutic sciences and provide evidence supporting different occupational therapy interventions.

Understanding motor control implies knowledge about what is controlled and how the controlling processes are organized (Horak, 1991). **Motor control** involves the ability to regulate or direct the mechanisms that are essential to movement. Rosenbaum (1991) has proposed that the central issues in motor control revolve around the multiple factors that determine movement selection, movement sequencing, and the coordination of perception and action in goal-directed activities. For instance, a fundamental question for motor control theorists is how stability is maintained and controlled while the individual acts in and on the environment. In the context of occupational performance, this question becomes "How are postural stability and movement regulated and controlled for in an individual engaged in an everyday daily life activity such as dressing while sitting on a stable or unstable surface such as a chair or soft mattress?"

Motor learning is directed more toward understanding how movements are acquired and modified with practice. Schmidt (1988) has defined motor learning as a set of processes associated with practice or experience leading to permanent changes in the capability for skilled acts. Shumway-Cook and Woollacott (2001) have proposed that motor learning develops from a complex set of perceptual, cognitive, and action that are processes developed in response to individual-task-environment interactions.

The field of motor control and learning continues to provide occupational therapy with new ideas for understanding the nature, cause, acquisition, and modification of movement supporting optimal occupational performance. The following section provides a synopsis of the prevailing motor learning and control theories and their implications for occupational therapy treatment. Theories are organized according to whether the control is centralized within the CNS or dispersed throughout the CNS and or other systems.

Motor development is the culmination of a number of underlying subsystems. These underlying subsystems all develop and mature at their own rates relative to other subsystems. Examples of these subsystems include, but are not limited to, the skeletal system, the muscular system, the central and peripheral nervous systems, the endocrine system, and the sensory systems (visual, auditory, gustatory, olfactory, haptic, proprioceptive, and vestibular systems).

Historically, motor development was thought to occur through specific and prescribed stages. Gessell (1928) and others (Gessell & Ames, 1947; McGraw, 1935) developed

ontogenetic stages that depict developmental milestones for children from approximately 6 months to 6 years of age. These developmental milestones include postural and motor abilities that are believed to be stereotypical of various stages of development. The typical development follows certain directions, specifically cephalocaudal (head to tail) and proximodistal (axial to extremities). In other words, developmentally, a child gains control of the head before gaining control of the lower parts of the body (e.g., the ability to walk). In a similar vein, developmental milestones show that proximal stability is required before the affordance of distal mobility. If the trunk is not stable, the ability to successfully reach for an object will be diminished. These directionally dependent constructs require that the CNS organization is largely hierarchical in nature. That is, higher, more complex parts of the brain control or have some dominion over lower centers of the brain. Most primitive reflexes have their neuroanatomical origin in the midbrain, cerebellum, and medulla. As was stated earlier, if damage occurs to a higher area of the brain (e.g., the cerebral cortex), then the reemergence of primitive reflexes is not uncommon. This gave empirical evidence that reaching developmental milestones within the "normal" stereotypical time periods was a good indication of the child's overall development. Further, the evaluation and assessment of primitive reflexes and developmental milestones was believed to be a reliable method for evaluating the potential for success in age appropriate occupations (Capute et al., 1982).

Recently, however, there has been some question as to the veracity of this assumption (Bartlett, 1997). Bartlett evaluated 156 infants who were believed to be developing normally on the Primitive Reflex Profile and the Alberta Infant Motor Scale. Assessments were at 6 weeks and at 3 and 5 months. Bartlett found no statistical correlation between the developmental scale scores and the primitive reflex scores. Thus, Bartlett concluded that there was no relationship between motor development and the presence of primitive reflexes. Along the same lines, Thelen (1986) found that when a 6- to 7-month-old infant was supported over a treadmill, the infant demonstrated a relatively mature bipedal stepping motion. This is particularly interesting because the traditionally held ontogeny of developmental milestones asserted that the stepping motion normally appears as a newborn but then disappears at approximately 2 months only to reappear at approximately 12 months of age (Strauss, 1982). What Thelen has shown was that when the environment was manipulated (e.g., by supporting the child's body weight, thereby reducing the effects of gravity), the child spontaneously demonstrated a precocious bipedal stepping motion. Because it is illogical to think that the CNS matured only while the child was supported, it is clear that the assumed hierarchical organization of the CNS is not the exclusive factor or control mechanism in motor development.

Another line of evidence regarding grip configuration questions the traditionally held belief that there is a stereotypical sequence of hand grasp configurations (J. S. Connolly & Elliott, 1972; K. J. Connolly, 1973; Gessell, 1928). This sequence involves the initial use of a gross grasp/clawlike configuration and ending up with a mature finger-thumb opposition configuration. One group of researchers (Newell, Scully, Tenenbaum, & Hardiman, 1989) developed an interesting experiment in which the participants were asked to grasp blocks of varying sizes from 0.8 cm to 24.2 cm in width. Participants included 26 preschoolers aged 3 years 3 months to 5 years 4 months and 22 adults aged 18 to 46 years. These researchers found that when the ratio of the width of the block to the size of the hand was the same, similar types of grip configurations were elicited regardless of the age of the participant. These results demonstrated that if the child's environmental constraints are manipulated to match the constraints that an adult would face, the child will demonstrate grip configurations similar to those that the adult employed. Subsequent studies have shown similar results (Cesari & Newell, 2000; Newell, McDonald, & Baillargeon, 1993; Newell, Scully, McDonald, & Baillargeon, 1989).

Conceptually, these studies by Thelen, Newell, and others offer a departure from the belief that development is based on hierarchical organization of the CNS. On the basis of theoretical work by Bernstein (1967), these more contemporary theorists believe that the "system" (meaning the various organ, tissue, and bodily systems) is organized in a heterarchical fashion. This means that the method by which a person successfully plans and executes a motion requires the input of many subsystems (e.g., muscle groups, nervous systems), each of which contributes to the movement solution as the task requires. The subsystems are not necessarily under the direct control of the cerebral cortex; that is, the cerebral cortex or consciousness regarding the motor plan does not prescribe the specific details of what each subsystem must do for a successful motor action. Bernstein (1967) argued that although the "executive function" knows the general goal of the task at hand, it does not have the capability of knowing the precise myriad of details required by each of the subsystems. The executive function knows the goal of the task and can direct in a very general manner, but the subsystem is what handles the small details, such as how much range of motion is required at each joint, how much force is required with each muscle, and how many motor neurons to recruit, the sequential timing of the agonist and antagonist muscles.

Bernstein (1967) further argued that the subsystems tend to work together in synergistic patterns. For example, suppose that a person is sitting on a sofa and reaches for a television remote control that is two feet in front of the person on top of a coffee table. Certain muscle groups are recruited, such as the anterior deltoids and the triceps, as the primary muscles to fling the arm forward to the remote. Now suppose that the person is lying on his or her side on

the sofa instead of sitting. The person reaches for the remote as in the previous example, but because the position of the arm in relation to the remote and to gravity is different, a different set of primary muscles is recruited (namely, the medial deltoid to counteract the direct pull of gravity, along with the anterior deltoid and the triceps) to move the arm in the direction of the remote. If one were to compare the electrical activity of the anterior deltoid and triceps between the two conditions, the electromyography would be completely different. An important thing to remember in this example is that although the goal was the same in both situations (i.e., grab the remote), different subsystems were recruited depending on what the situation required. The following section provides more information about some specific models of motor control that take these concepts into account.

DISTRIBUTED AND SYSTEM MODELS OF MOTOR CONTROL

General Description of Distributed Models of Motor Control

In this model, control of movement is not peripheral or central. As scientists examined different motor behaviors along with task and environmental constraints, a concept of distributed control of movement emerged; that is, the internal and external forces acting on this system were considered (Keshner, 1991). Distributed models of motor control are not unidirectional. Rather, they allow for communication within the nervous system to take place in ascending, descending, and lateral arrangements. The control hierarchy is perceived not as a descending chain of command but as an overlapping circular network in which each level influences those above and below it. Various sites within and throughout the system are part of the process underlying and controlling movement. Some models of distributed control, however, minimize the relevance of the nervous system. Others, such as neural network models, continue to rely heavily on processing units that consist of neurons and their extensive system of linked dendrites (Bate, 1997). Control of movement in these models is seen as being distributed throughout many working systems, which can include mechanical and environmental factors as well as nervous system factors. The following subsections contain a brief description of a few of many theories involving distributed control of movement.

General Description of Systems Theory

Bernstein, a Russian scientist, was among the first to look at internal and external forces acting on the body to understand the characteristics of the system being moved. The body was regarded as a mechanical system with mass and subject to external forces, such as gravity, as well as inertial and movement-dependent forces. Bernstein asked

questions related to (1) the function of the system in a continually changing environment, (2) the properties of the initial conditions affecting movement, and (3) the body as a mechanical system influencing the control process (Shumway-Cook & Woollacott, 2001).

Bernstein (1967) was also responsible for identifying what is known as the degrees of freedom problem. In describing the mechanics of the system, Bernstein noted that many degrees of freedom need to be controlled for coordinated movement to occur. For example, there are many joints that can flex, extend, and/or rotate, and these multiple options complicate the control of movement. Control therefore involves converting the body into a "controllable" system (Schmidt, 1988).

Bernstein's solution to this problem was proposing that hierarchical control exists to simplify the body's multiple degrees of freedom. He proposed that (1) groups of muscle are constrained to act together as a unit, and (2) these units are activated at lower levels in the system.

Description of Dynamic Pattern Theory

This is an operational approach to the study of coordinated movement (Keshner, 1991) as used in the movement sciences. The impact of this theory is seen in a variety of research areas, including development (Thelen & Smith, 1994), aging (L. S. Greene & Williams, 1996), rehabilitation (Scholz, 1990), and coordination research (Lee, 1998; Sternad, 1998; Walter, 1998). Dynamic pattern theory incorporates aspects of Bernstein's systems theory and the study of dynamics and synergistics. It is an attempt to define terms and provide behavioral and mathematical predictions for coordinated movement patterns. The following basic concepts are fundamental to many dynamical systems approaches and motor control research.

1. The human system exhibits self-organizing behavior.
2. The human system is a many element system that can be described by a few elements, which are referred to as *collective variables.* Collective variables are the fewest number of variables that completely describe the behavior. For example, Heriza (1991) proposes that for humans, walking is a highly complex behavior that is characterized by a specific movement pattern. The new walker compresses the many degrees of freedom available from the muscles, bones, joints, tendons, neurons, and motor units into a relatively few degrees of freedom that can be observed in walking. In this example, a complex behavior—walking— becomes characterized by a description of the behavior: the specific movement pattern.
3. Collective variables characterize movement patterns and capture the systems that cooperate to produce the movement, as movement is more than just muscles and motor neurons. For example, kicking, stepping, and throwing a ball are examples of coordinated movement patterns. Again, an example by Heriza (1991)

helps to clarify this. In intralimb coordination, as seen within one limb in kicking or stepping, the identified collective variables are the timing of the individual movement phases, such as flexion and extension; phase lags, defined as the time between the onset of movement of one joint and that of another joint; and the relationship of individual joints to each other.

4. The identification of phase transitions is basic to understanding behavior. Control parameters are variables that shift the movement from one form to another movement form. Control parameters act to reorganize the system. In the example of intralimb coordination as well as in interlimb coordination, behavioral states can drive the system. For instance, when an infant is asleep or drowsy, little kicking is noted. If the infant is aroused, the spatial and temporal pattern of kicking is observed. If the infant is in a crying state, a new pattern emerges that is described as a rigid coactivation of all the muscles into stiff mobility. Therefore, control parameters can be defined as components that are essential but nonspecific to the movement behavior. In this example, the control parameters can reside in the individual, such as behavioral state; in the environment, such as gravity; in the social environment, such as the caretaker; or in the goal or in the task. New coordinated patterns emerge because old patterns become unstable and the system is driven to a new state. Changes in the control parameters push the system to a new state. During these shifts in phase or phase transitions, the prevailing movement pattern becomes less stable and more easily perturbed by the control parameter (Heriza, 1991).

5. The study of the stability or instability of behavior during transition periods is essential to understanding pattern change in complex systems. In this approach, movement behavior and control can be aptly described by a set of collective variables and control variables associated with phase transition (Haugen & Mathiowetz, 1995).

IMPLICATIONS. Dynamical systems are systems in which behaviors evolve over time and are marked by their capacity to change states. Systems theories take into account factors other than the nervous system in regulating movement, for example, the physical characteristics such as the mass of the system being moved. These theories have enlarged the understanding of the multiple factors that are responsible for controlled movement. The individual is seen as active within the environment with movement an emergent product of many systems. These theories may be helpful in taking into account the passive components of a patient's biomechanics and factoring these components into explanations for movement stability and instability (Bate, 1997).

LIMITATIONS. The role of the nervous system is minimized in these theories. Transitions in movement patterns are explained in terms of physical causality, mathematical functions, and variables. These theories primarily seek physical explanations contributing to movement characteristics and thus seem more aligned with biomechanical interpretations of movement. However, several recent reviews of motor control theories suggest that dynamical motor control views and alternative information-processing views are not necessarily mutually exclusive (Walter, 1998). Furthermore, Walter contends that the relative role, as well as the strengths and weaknesses, of each theoretical account of motor control needs to be determined.

Parallel Distributed Processing Theory

Computer analysis and simulations are also providing models and theories for motor control. These have been recent efforts to develop models of higher-level processes that are based on an understanding of neural processing and patterns of neural activity provided by imaging studies. These attempts start by asking how the brain might achieve higher-level processing rather than by asking how the brain actually achieves such processing. Modeling starts from a basic understanding of how neurons work and asks: How could higher-level function be achieved by connecting basic elements like neurons together (Anderson, 1995)?

The parallel distributed processing (PDP) theory of motor control describes how the nervous system, as a network, processes information for action. It reflects current knowledge in neuroscience about the serial and parallel processing of the nervous system. Serial processing is the simultaneous processing of information through a single pathway while parallel processing is processing information through many pathways (Kandel, Schwartz, & Jessel, 2000). Parallel distributed processing is unique in its emphasis on explaining neural mechanisms associated with motor control. Neural modeling, that is, computer simulation of nervous system functioning, has correctly predicted aspects of processing in both the perception and action systems. As neural modeling develops, it could provide further knowledge as to how the nervous system solves particular problems.

Implications

Modeling of function and dysfunction can be integrated into clinical practice Shumway-Cook and Woollacott (1995) propose that a PDP model could be used to predict how changes within the nervous system affect function. As an example, the theory predicts that parallel redundant pathways exist in the system and that a loss of a few elements will not necessarily affect function. The loss of additional elements or loss once a certain threshold is attained, however, could affect the capacity of the system to function. This idea—threshold of dysfunction—is demonstrated in many pathological cases, such as in Parkinson's disease.

Limitations

PDP theory is a tool to think about the way in which the nervous system works. Some of the proposed functions are not replicated in nervous system processing, and modeling cannot fully account for what is known about nervous system processing.

Ecological Theory

Ecological theory, which was developed by James Gibson (1966), explores the interaction between the motor (action) system and goal-directed behavior. Gibson's research focused on how we detect environmental information and how we use that information to control our movements. Environmental information was seen as relevant to action in the environment. Perception rather than sensation is important to the individual acting on the environment. From this perspective, determining how the individual detects information in the environment, the form of this environmental information, and how this information is used to modify and control movement are important. In ecological theory, the organization of movement depends on the active exploration of tasks, the environment, and the individual's multiple ways to accomplish a task. Perception guides action and action guides perception. Therefore, movement disorders are not only the consequences of structural changes, but also can be understood as an atypical spatial temporal organization in the perception–action coupling and in movement coordination (Wagennar & van Emmerik, 1996). This approach has broadened our understanding of nervous system function from depending on sensory motor control to that of a more global perception action system that actively explores the environment to satisfy its goals. Likewise, disordered motor control is a disruption in the perception action system and not at the level of the CNS.

Implications

A major contribution of this perspective is seeing the individual as active in the environment and the environment as crucial in determining movements. Active exploration of the environment allows the individual to develop multiple ways to accomplish a task.

Limitations

This approach has enlarged the understanding of the interaction between the organism and environment. Research is at the level of the organism-environment interface. It has contributed less to the knowledge of the organization and function of the nervous system, which is a primary concern of therapists intervening in motor control problems, based on traditional neurotherapeutic approaches.

Task-Oriented Theory

In task-oriented theory, motor control is understood by identifying what problems the CNS has to solve in order to accomplish a motor task. By the term *task,* P. H. Greene (1972) was referring to the fundamental problems, such as the degrees of freedom problem described by Bernstein, that the CNS is required to solve in order to accomplish a motor task. Peter Greene (1972) proposed that this approach could provide the basis for a more coherent picture of the motor system.

Implications

This perspective suggests practicing functional tasks for retraining in therapy. It acknowledges the role of perceptual, cognitive, and action systems to accomplish tasks (P. H. Greene, 1972). It requires an understanding of motor strategies that are used to accomplish a task, as well as an understanding of the perceptual basis for action and the cognitive contributions to actions.

Limitations

There is a lack of agreement as to the fundamental tasks of the CNS. There is also lack of agreement as to the essential elements that are being controlled within a task. For example, in studying postural control, some scientists consider that the essential goal of the postural system is to control head position. Other scientists studying postural control think that controlling center of mass position to attain body stability is the essential goal of postural control (Shumway-Cook & Woollacott, 1995).

Perceptual Motor Workspace

How does the body know how to do something? In other words, how does the body know which subsystems need to be recruited in any given situation? A model proposed by Turvey, Kugler, McDonald, and Newell (Kugler & Turvey, 1987; Newell & McDonald, 1994; Turvey & Kugler, 1984) called the *perceptual motor workspace* has its basis in the dynamical systems theory (Gleick, 1987) as well as the ecological approach to perception and action (Gibson, 1979, 1982). In simple terms, the perceptual motor workspace model states that the motion solution that is employed for any given task is a direct result of how the person perceives (both consciously and unconsciously) the constraints of the task, the environment, and the constraints within himself or herself. Newell (1986) defined constraints as being information that provides boundaries. Further, Newell argues that constraints provide opportunity as well. Constraints give information that allow a person to size up the situation; that is, constraints yield an awareness regarding the unique characteristics of the object or situation. Once the person perceives these constraints, the person's nebulous "system" then calls into action specific subsystems (e.g., portions of the CNS and muscle groups) to interact with each other, a process that culminates in a solution that is uniquely attuned to the specific task and environment at hand.

Implications

Part of this model requires that the person accurately perceive the constraints in the environment. If the person misperceives a constraint, such as the location of the remote control, he or she will either overshoot, undershoot, or otherwise miss the remote control. In another common experience, if a person attempts to lift up a paint can, believing that it is full when in reality it is empty, the person will lift the can up with greater force than necessary, resulting in the can's accelerating in an unanticipated manner. Similarly, if a child does not have a good sense of where his or her body is in space, then he or she might be considered to be clumsy. It is quite possible that once the child is allowed to explore the limits of his or her body, the child will have a better sense of where his or her body is in relation to the surrounding environment. The resulting change will be fewer uncoordinated motions. The idea of misperceiving the environment is not uncommon. One of the authors of this chapter remembers an instance during a summer campout at a state park involving an accompanying niece, who was from a large metropolitan area and had little camping experience. When first arriving at the campsite, the niece saw the fire grate, but she did not recognize it as a fire grate. She perceived the fire grate's height to afford her a nice seat, on which she sat while wearing her white shorts (don't worry—there was no fire). The consequence was that she had a seat of appropriate height, but unfortunately for her, the back side of her shorts gave the illusion of a zebralike pattern. Here the environmental perception of the height of the fire grate was accurate, the task perception of sitting down was accurate (she successfully sat down), but she apparently had no previous experience with fire grates—hence, the "mistake" was made. The author has been informed that this error has not occurred a second time. This brings up an important point: that having memories on which to draw is an important constraint of the person when mapping perception to action.

Limitations

There is no evidence to support this model from a rehabilitation or clinical point of view. Therefore, this model currently has limited applicability to rehabilitation and other types of clinical settings.

MOTOR CONTROL APPROACHES PROPOSED FOR THERAPEUTIC INTERACTION

New approaches to intervening with motor performance deficits that affect occupational performances have evolved. These therapeutic approaches are based on both motor learning principles and on more contemporaneous models and research about the control of movements in both typical populations and populations with movement disorders.

Task-Oriented Model

The task-oriented model (Gordon, 1987; Horak, 1991; Shumway-Cook & Woollacott, 2001) targets both peripheral and central control systems. In line with system models of motor control, the task-oriented model assumes that control of movement is organized around goal-directed functional tasks. Clients are taught to accomplish goals for functional tasks. By practicing a wide variety of movements, the client solves different types of motor problems. The assumptions seen in Table 55.6 guide treatment.

Along with these assumptions and guidelines, Horak (1991) suggests organizing questions around several areas in treating clients with motor performance deficits. These areas are the client's behavioral goals, movement strategies, musculoskeletal constraints, compensatory strategies, and need for adaptations. Examples of questions about these areas are as follows:

1. **Behavioral goals:** Are the therapist's and client's goals the same? This might entail the practitioner incorporating the use of the Canadian Occupational Performance Measure (COPM) and the Assessment of Motor and Process Skills. Using both would allow the practitioner to determine what is important to the client and what are the strengths and weaknesses in the client's motor and process skills.
2. **Movement strategy:** What are the organizing principles of a normal movement strategy?
3. **Musculoskeletal constraints:** How much of the motor deficit in a patient with neurological deficits is due to a deficit in the musculoskeletal system rather than the neural components?
4. **Compensatory strategies:** Has the patient found the most effective strategy?
5. **Adaptation:** How must a movement strategy be adapted to accomplish a task in a new environmental context?

Motor Re-Learning Program

The Motor Re-Learning Program (Carr & Shepherd, 1987) is a synthesis of the prevalent contemporary models of motor control and the motor learning process (Sabari, 1995). It is specific to the rehabilitation of patients following stroke. The program is based on four factors that are thought to be essential for the learning of motor skill and assumed to be essential for the relearning of motor control: (1) elimination of unnecessary muscle activity, (2) feedback, (3) practice, and (4) the interrelationship of postural adjustment and movement. In this program, treatment is directed toward relearning of control rather than to activities incorporating exercise or to facilitation or inhibition techniques.

Treatment is directed toward enhancing motor performance, and the emphasis is on the practice of specific

TABLE 55.6   ASSUMPTIONS GUIDING THE TASK-ORIENTED APPROACH

Assumptions	Treatment Principles
◆ Movement is controlled by the individual's goals. ◆ A wide variety of movement patterns can be accomplished with a task. ◆ Facilitation of normal movements is not necessary. ◆ The nervous system adapts continually to its environment and musculoskeletal constraints. ◆ The nervous system is not a passive recipient of sensory stimuli but actively seeks to control its own perception and actions. ◆ Voluntary and automatic control systems are interrelated. ◆ Multiple system involvement results in movement. ◆ The nervous system is exposed to its own specific environment. ◆ The nervous system seeks to accomplish goals with remaining systems after injury.	◆ The goal of therapy is to teach clients to accomplish goals for functional tasks. ◆ Therapists do not treat or limit therapy to one normal movement pattern. ◆ Therapists try to teach the nervous system how to solve different motor problems by practicing in a wide variety of situations. ◆ The therapist seeks to manipulate these environmental and musculoskeletal systems to allow for efficient, purposeful behavior. ◆ The client needs to practice motor behaviors motivated by the goal of task accomplishment. ◆ Clients are encouraged to assist voluntarily in accomplishing a motor behavior with therapist's encouragement. ◆ The therapist and the environment provide feedback. ◆ The therapist must design interventions in which practice of controlled movements is outside structured sessions. ◆ The therapist helps the patient to identify and use compensatory strategies.

CASE STUDY: *Emily: A Toddler with Problems Walking*

Emily, a 2-year, 1-month-old girl with a recent diagnosis of athetoid cerebral palsy, was referred to a pediatric medical center for a diagnostic workup by an early intervention team that included an occupational therapist. The child's parents were concerned that Emily was not able to walk but that she seemed okay in other areas of development. She appeared playful and responsive and enjoyed playing and moving around the play area. Although she was not pulling to stand and was obviously delayed in her ability to walk, Emily's language, feeding ability, and play patterns seemed near age level.

Team Evaluation

The diagnostic team that gathered to assess Emily decided to use several tools that would provide an overview of her cognitive, sensorimotor, adaptive, and social-emotional developmental functioning and play behaviors. Because Emily appeared typical in her behavioral responses and play interests, the team did not have her parents complete a sensory profile on Emily, as she did not seem overly responsive or underresponsive to sensory stimuli and appeared not to have regulation problems. Mostly, she appeared to be a typical child who was significantly delayed in her ability to walk. However, she was able to come to a sitting position independently, and she negotiated the environment by either rolling or coming into an all-fours position and then collapsing but moving forward. She was able to bear weight on all four extremities when in quadriped, but she was unable to maintain that position for more than a few seconds or to crawl. The team decided to use the Bayley Scales of Infant Development to assess Emily's development in all areas and also decided to observe her in a natural play environment with both her parents present. The team administered the Bayley Scales with several of the team members present. Also, the speech therapist and occupational therapist observed Emily eating a snack to determine whether there were any problems with the task of eating. Emily's performance in all areas was remarkable in that she completed all tasks at her age level other than the movement tasks that seemed to precede walking or coming to a stand. Emily was able to finger-feed and sip from a cup. It was noted that weakness and athetoid movements were interfering more with her use of the lower limbs and only her ability to crawl, pull to stand, or walk.

Continued

CASE STUDY: *Emily: A Toddler with Problems Walking*   *Continued*

She was responsive to coming to all fours and to a stance when manually guided or directed through age-appropriate play activities, but she was limited in her ability to self-initiate or maintain these positions independently. However, when a large rectangular cushion was placed in front of her, Emily pulled up on her knees independently and played for several minutes with the Fisher-Price busy box that was on the cushion in front of her.

The Occupational Therapist's Reasoning

After assessing this child, the occupational therapist had several decisions to make:

1. Was Emily an appropriate candidate for services?
2. Would it be necessary for the occupational therapist to see Emily twice a week, once a week, or not at all?
3. Could the occupational therapist function more as a collaborator/consultant with the family and or other team members?

Even though the parents had expressed concerns only about Emily's walking, the occupational therapy practitioner wondered whether the family might have some other concerns and thought that administering the COPM to them could provide additional insight into their concerns about Emily's performance in different domains. Emily was limited in mobility but overall at age level in other areas, and the occupational therapist thought that she herself could collaborate most effectively with the team and the family on tasks and environmental challenges that might foster Emily's ability to pull up on all fours and to stand.

Occupational Therapy Intervention: Family Education

The occupational therapist decided to speak to the parents further. She emphasized that Emily had many strengths and that her movements appeared to be constrained by her weakness and instability in her lower extremities. How-

ever, the occupational therapist also suggested that Emily's use of her lower extremities could be enhanced by using the natural home environment and play opportunities that challenged her use of her lower body. She reviewed with the parents how to structure the home environment so that Emily had to move in an environment that gave her the opportunities to come up on her knees, pull to stand, and cruise safely. Also, the occupational therapist emphasized that many factors contributed to Emily's difficulty with crawling and standing and that giving her opportunities to move and use her body while also being engaged in play would help Emily to grow and develop in her natural context. The therapist also spoke to the family about more recent research that suggests that motor learning occurs with practice and that having Emily "practice" and try out different movements while engaged in play would help her to develop.

The Six-Month Plan

The therapist with the team recommended that Emily be seen in six months to determine whether her play and development continued on course and whether she had achieved measurable goals in regards to being able to crawl and to stand independently. To monitor progress, the team decided that the physical therapist would see Emily in the home once a week and provide movement opportunities for Emily as well as modeling for her parents ways to challenge Emily so that she would learn to move in a goal-directed way. The occupational therapist planned to meet with the family when Emily was scheduled for follow-up and at that time administer the COPM to determine whether there were other performance concerns that the family has about Emily. Also, the occupational therapist would periodically speak with the treating physical therapist to discuss Emily's progress and provide suggestions in regard to play and challenges to be incorporated into the environment.

---

tasks, the training of controllable muscle action, and control over the movement components of these tasks. The major assumptions about motor control underlying this approach are listed in Box 55.1.

To provide this program, a four-step sequence is followed for skill acquisition. Step 1 is an analysis of the task, including observation. Step 2 is practice of missing components, including goal identification, instruction, practice, and feedback with some manual guidance. Step 3 is practice of the task with the addition of reevaluation and encouraging of task flexibility. Step 4 targets transfer of training (Carr & Shepherd, 1987).

Contemporary Task-Oriented Approach

Description

Haugen and Mathiowetz (1995) have proposed a task-oriented approach based on a systems model of motor control and influenced by contemporary developmental and motor learning theories. This model takes into account the interaction between the personal characteristics or systems of the person such as the sensorimotor system and the performance context. Occupational performance emerges from the interaction between personal characteristics and performance contexts as seen in Table 55.7.

BOX 55.1   **ASSUMPTIONS UNDERLYING THE MOTOR RE-LEARNING APPROACH WITH GUIDELINES FOR EXERCISE AND TRAINING TO OPTIMIZE MOTOR SKILL**

- In regaining motor control, learning is required. This learning follows the same principles and factors as those incurred in normal learning. Therefore, practice, receiving feedback, and understanding the goal are essential for treatment.
- Motor control is exercised in both anticipatory and ongoing modes.
- Sensory input is related to motor output and helps to modulate action.
- Control of a specific task can be effectively regained by practice of that specific motor task in various contexts.
- Conscious practice of tasks builds up awareness of the ability to elicit motor control activity.
- Progression of practice is from conscious awareness to practice at a more automatic level in order to ensure that a skill is learned.
- Cognitive function is emphasized. If the client is to learn, then the environment must encourage the learning process.

- When clients can perform a task effectively and efficiently without thinking about it in a variety of contexts, learning has occurred.
- Contemporary theories of motor control emphasize distributed control rather than a top-down or bottom-up approach. Therefore, in the Motor Re-Learning Program, recovery is directed to relearning control through many systems.
- The client is defined as an active participant in the treatment process. The major goal in rehabilitation is to relearn effective strategies for performing functional activities.
- The role of the therapist is to prevent the use of inefficient strategies by the client.
- The program addresses seven categories of functional daily activities: upper limb function, orofacial function, sitting up over the side of the bed, balanced sitting, standing up and sitting down, balanced standing, and walking.

Source: Carr & Shepherd (1987, 2003).

The Task-Oriented Approach (Mathiowetz, 2004) considers the person's role performance as well as the performance in areas of occupation. In addition, this model espouses that a task analysis be performed to determine the factors (from the person, the environmental context, and the task itself—the same three factors as in the perceptual motor workspace) that either facilitate or restrict performance. The treatment focus of this approach involves any individual or combination of the following:

- Environmental modification
- Manipulating or grading the task
- Remediating skills/abilities that are particularly limiting within the person

Implications

Specific strategies are espoused for the remediation of limiting factors within the person. Many of these strategies are founded in the motor learning body of knowledge. Some of these strategies involve how feedback is given. For instance, it has been shown (particularly with nondisabled populations) that reduced feedback actually results in better retention and transfer of the motor skill being learned (Rice, 2003; Rice & Hernandez, 2006; Winstein & Schmidt, 1990; Wulf, Schmidt, & Deubel, 1993). See Shea and Wulf (2005) for a review. Another motor learning strategy involves presenting tasks to be learned or practiced in a random fashion (e.g., moving from task to task without providing repeated trials on any given task) rather than giving multiple trials of the same task before moving on to another task.

Limitations

Much of the motor learning research has been performed on healthy college students, and the tasks have usually involved simple rote motor skills that do not represent normal occupationally oriented activities. Therefore, the generalization of these strategies to special populations should be done with caution until a greater body of evidence supports their use with special populations.

TABLE 55.7 ASSUMPTIONS GUIDING A CONTEMPORARY TASK-ORIENTED APPROACH	
Assumptions	**Treatment Principles**
◆ Functional tasks help to organize behavior. Recent research suggests that parameters of motor behavior are not performance components but in fact functional goals (Burton & Davis, 1992; Gentile, 1992; Heriza, 1991; Thelen, 1989). ◆ Occupational performance emerges from the interaction of multiple systems that represent the unique characteristics of the person and the performance context. ◆ After CNS damage or other changes in personal or environmental systems, clients' behavioral changes reflect their attempts to compensate and achieve functional goals. ◆ Personal and environmental systems are hetarchically organized. There is no inherent ordering of the personal and environmental systems in terms of their influence on motor behavior. There is also no inherent ordering within the system, even within the CNS. ◆ A person must practice and experiment with varied strategies to find optimal solutions for motor problems and develop skill in performance.	◆ Because the primary purpose of motor behavior is to achieve functional goals, therapists begin and end therapy by focusing on occupational performance. The emphasis on task performance and evaluation is primarily at the disability level, using the World Health (1980) Organization Model of Disablement. ◆ The therapist assesses all systems that are contributing to problems in functional performance or supporting optimal performance, keeping in mind the tasks the person currently does or will be doing in the future. Because the client brings to the situation a unique constellation of characteristics, the therapist makes the client's perspective the focus of assessment. The client determines the important goals and roles necessary for occupational performance. ◆ Movement patterns that are used for compensation and achievement of functional goals must be understood fully. The evaluation of occupational performance must include an examination of the process (actual movement patterns), the outcome, and the stability or instability of observed motor behavior. ◆ Evaluation strategies consider all personal and environmental systems. The ones that interfere the most with performance are evaluated first. ◆ As part of treatment, clients practice, experiment, and problem-solve in order to achieve functional goals. Treatment planning is to develop and implement learning opportunities for clients with problem-solving abilities. When clients are unable to problem solve, the therapist might need to train them to use given routines.

Constraint-Induced Movement Therapy

Description

Constraint-induced movement therapy (CIMT) is a relatively new model of practice that focuses on restoration of the affected limb in individuals with unilateral stroke or brain injury. Many techniques have traditionally employed compensatory strategies for helping a person gain function, for example, teaching one-handed techniques with the unaffected limb to perform functional tasks. CIMT focuses on the function of the affected or paralyzed limb. The basic idea is to constrain (specifically, to splint, sling, or otherwise immobilize) the unaffected limb for a period of time while the affected limb is free to engage in activities, tasks, and occupations unilaterally. Although this idea is radically

different from traditional neurorehabilitation approaches, its efficacy is beginning to be established in the literature (Broeks, Lankhorst, Rumping, & Prevo,1999; Taub, Crago, & Uswatte, 1998; Taub, Miller, et al., 1993; Taub & Morris, 2001; Taub, Uswatte, & Pidikiti, 1999; Taub & Wolf, 1997; Wolf, LeCraw, & Barton, 1989; Wolf, Thompson, et al., 2005). The general procedure involves a two-week period of constraining the unaffected limb during all waking hours. During this period, patients are engaged in what are termed *shaping techniques* with the affected limb for up to six hours per day for five days per week. Shaping involves the selection of tasks and motor skills in an area that a therapist deems to require functional and motor improvement for that individual. Common inclusion criteria for the above-mentioned studies

CASE STUDY: *Aetos: A Man with a Gunshot Wound to the Head*

Aetos is a 22-year-old man who immigrated to the United States from Cyprus. He worked in a convenience store, where he sustained a gunshot wound to his head when someone robbed the store during his shift. He was transported to a local trauma hospital and was stabilized. He was comatose for three weeks, after which he became cognitively responsive. Currently, he is the Ranchos–Los-Amigos cognitive scale level 6 (Confused-Appropriate). He presents with left-upper extremity hemiparesis. Although he has gross grasp abilities in his left hand, his fine motor control is limited. He requires minimum assistance for dressing and self-care. Before his injury, Ryan independently maintained his own apartment and enjoyed hosting parties for his friends. He particularly enjoyed planning and preparing the food for these parties.

Two possible approaches to addressing this case in occupational therapy are focusing on the impairment of the client or using a more client-centered and contextually sensitive approach.

Impairment-Focused Approach

The impairment-focused approach can involve evaluating and assessing the specific client and body factors, such as range of motion, strength, fine motor skill, sensation, visual perception, and cognitive function (specifically, memory, attention, and the ability to concentrate). On the basis of these evaluations, therapy is directed toward improving the patient's performance in these specific areas with the hope that these improvements will translate into functional improvements. The therapeutic milieu involves grading the tasks on the basis of the perceived "just right challenge" for the patient in these separate treatment areas. Throughout the session, the therapist provides feedback to encourage participation in these various domain-specific treatment areas. The majority of occupational

therapy treatment occurs in the rehabilitation gym using domain-specific rehabilitation equipment and supplies. Additionally, a SaeboFlex splint was ordered, and practice sessions occurred using the supplied balls and baskets. Discharge from occupational therapy will be based on accomplishment of measurable goals in these treatment areas (strength, coordination, memory, etc.) as well as predetermined functional independence measure goals.

Client-Centered Approach

The client-centered and contextually sensitive approach is more organized according to the client's stated goals. In this case, it might be a goal related to food preparation for a party. The therapist and the client plan several of the treatment sessions to be organized specifically around preparing vegetables to garnish hamburgers. The majority of the occupational therapy sessions will therefore occur in the rehabilitation clinic's therapeutic kitchen. One of the chosen occupationally embedded tasks is cutting tomato slices. The therapist grades the task by choosing a large enough tomato that the client can safely grasp it with the affected limb while slicing the tomato with the non-affected limb. Grading this task can be accomplished by using tomatoes of various sizes and degrees of ripeness. Additionally, the style and size of the knife can be manipulated to provide the "just right challenge." Safety and cognition can also be addressed, as well as task sequence. Repetition can be based on how many hamburgers have been planned, and variability can be manipulated through the use of multiple tomatoes as well as the inclusion of other vegetable garnishes. Discharge from occupational therapy will be based on the accomplishment of measurable goals regarding the successful and safe food preparation tasks as well as predetermined functional independence measure goals.

---

require that the person have at least 10 degrees of active metacarpal extension and at least 20 degrees of wrist extension. Participants in these studies have, for the most part, demonstrated remarkable improvement in their affected limb's motor function following the two-week period. Furthermore, some of these studies have shown the retainment of motor function at two years after the CIMT treatment (Taub, Miller, et al., 1993). There are several theories as to why success occurs in improving the function of the affected limb. These theories are based on the concepts of learned nonuse (Morris, Crago, DeLuca, Pidikiti, & Taub, 1997; Taub, 1994) and cortical reorganization (i.e., brain plasticity) (Liepert, 2006; Liepert, Bauder, et al., 2000; Liepert, Miltner, et al., 1998).

Implications

CIMT is an excellent example of an evidence-based model of practice. This approach has been exclusively driven by research findings from controlled research studies. For participants who meet the inclusion criteria, there is strong evidence that this treatment approach is effective in facilitating functional return to hemiparetic limbs.

Limitations

The inclusion criteria that are in the research studies mentioned above are relatively narrow. That is, this approach has been documented as effective only for participant who have a minimum of 10 to 20 degrees of extension at their

metacarpals and wrist, respectively. Some critics would argue that individuals with this type of return already are experiencing spontaneous recovery anyway. Additionally, this treatment approach requires a high level of motivation on the part of the patient in order to tolerate what is undoubtedly a frustrating experience with constraining the unaffected limb during all waking hours.

Orthotic Approaches

Description

Some of the most recent approaches to upper limb control and skill learning are based on the use of repetition with functional practice and the principle of activity-dependent plasticity. Specific protocols such as the Functional Tone Management Arm (F.T.M.) Training Program incorporate use of a dynamic orthosis, the SaeboFlex, with specific repetitive practice (Hoffman & Farrell, 2005). The SaeboFlex is a custom dynamic resting hand orthosis that features a spring-loaded finger extension system (Figure 55.7). The extensor spring system assists in opening the fingers following functional grasp. When using the SaeboFlex, the client grasps an object using voluntary flexor control, places the object in a specified location, and then relaxes flexor tone enough to allow the extensor springs to assist in extending the fingers.

Like the CIMT protocol, the F.T.M. protocol was designed to decrease learned nonuse; increase learned use;
reduce spasticity; improve range of motion, strength, and control; improve functional arm use; and improve quality of life for individuals with some shoulder and elbow function but minimal hand movement. To qualify for this protocol, individuals must exhibit active shoulder elevation of 15 degrees, 10 degrees of active shoulder abduction, and active elbow flexion of 15 degrees with full passive range of motion into elbow flexion and be able to flex their digits at least a quarter of their range in a fist position (Hoffman & Farrell, 2005). Also, a minimum of 15 degrees of wrist extension with the fingers fully extended is required for F.T.M. training. The training protocol incorporates evaluating the patient's use of the hand without the orthosis, fitting the individual with the orthosis, and then having the client, with the orthosis, engage in one of four levels of crate activity that incorporates the client repetitively grasping and releasing specified objects. The program focuses on performing high-repetition strengthening exercises involving weak muscle groups. The gross motor items that are used with the protocol are assumed to effectively challenge the individual to achieve the motor function essential to complete the task. Completion of these tasks is assumed to translate into the individual's better functional use of the upper limb. Colorful study equipment used with the protocol includes the Height Adjustable Target (H.A.T.), the Multi-Purpose Exercise Device, the Four Tier Ball Activity, and the Five Ball Peg Activity (Figure 55.8).

Implications

The F.T.M. is an example of the use of an orthosis with a specific activity-oriented program that facilitates constant repetition and practice of grasp, placement, and release. It is proposed as a protocol to be used with clients who present with limited arm and hand function secondary to a stroke or traumatic brain injury. The approach, developed by two occupational therapists, is based on reasoning derived from research evidence about the efficacy of training techniques permitting repetitive selective muscular activation, recruitment of muscular activity versus inhibition and strengthening the arm (Fowler, Ho, Nwigwe, & Dorey, 2001). It may be of benefit to clients who have some use of their arm and are motivated to use their hand with an assisting orthosis both in the clinic setting and at home.

Limitations

Although this approach is based on evidence about the impact of repetition and strengthening on functional upper limb use, the evidence base for the specific protocol is limited. Research using this protocol has been primarily at the lower levels of research evidence using both case studies and single-subject design. However, this approach is one of the newer ways to treat and more than likely will undergo more rigorous research as

FIGURE 55.7 The SaeboFlex splint.
FIGURE 55.8   Saebo protocol.

it evolves and randomized controlled studies can be undertaken.

Robot-Aided Motor Training

Another recent addition to the techniques that are used to foster skill return is the use of robotic manipulators for providing training of arm movements. Robot manipulators have been used primarily in experimental paradigms that are attempting to examine the mechanisms underlying normal motor control and learning as well as attempting to examine the mechanisms underlying disorders of upper limb movements in patients with movement disorders. However, since the 1997 pioneering study of the MIT-Manus robotic manipulator at the Massachusetts Institute of Technology, the number of research groups engaged in this area with patient populations has substantively increased. Also, more devices have been developed for automated training for arm and wrist movements following stroke. The range of robotic possibilities is promising, as robots are precise and tireless and can easily simulate what a therapist can do in assisting movement (Patton, Kovic, & Mussa-Ivaldi, 2006). Also the research in this area has demonstrated that robot-assisted movement training improves movement ability following acute and chronic stroke (Kahn, Lum, Rymer, & Reinkensmeyer, 2006). Training is assumed to follow two interacting

processes: the patient trying to move and the robot applying forces. A fundamental motor learning principle involved in robot-assisted movement is that movement practice improves motor function. Evidence to date with this therapy suggests that active participation is required and that progressive training that is robot assisted and based on measures of movement coordination yields substantively improved outcomes. Recent research suggests that the most appropriate focus for robotic therapy might be movement coordination rather than muscle activation (Hogan et al., 2006).

Implications

There is limited evidence that robot-assisted movement affects change in both the acute and chronic stages of stroke recovery. Also, use of this technology has been helpful in examining the processes that are involved in learning and movement recovery.

Limitations

If movement practice is the primary stimulus for movement recovery, robotic devices that incorporate practice with the application of forces might be both unnecessary and expensive. Indeed, nonrobotic technology, including hand cycles, low-cost movement monitors, virtual reality systems, and passive antigravity devices such as the tradi-

COMMENTARY ON THE EVIDENCE

Therapeutic Approaches to Improve Motor Control in Daily Life

Practitioners often apply scientific principles and thinking to practice. As part of the assessment and evaluation process, the client-centered practitioner frames the patient's occupational therapy performance problems with the patient and considers alternative intervention strategies that may be of help. Likewise, practitioners engage in hypothesizing how they can most effectively help the client learn or recover habits and skills that support their full participation in everyday life activities.

However, in the past 20 years, the evolving sciences of movement science and neuroscience have challenged the practitioner's understanding of movement control and learning, and how the practitioner can apply current scientific thinking to skill learning (Bate, 1997; Shumway-Cook & Woollacott, 2007). Our basic understanding of the principles guiding movement organization and recovery has shifted, and this shift has influenced the research as well as the more current approaches to intervention that are being proposed for occupation-based skill learning and recovery. Also, the evidence to support the influence of neuromotor techniques guiding occupation-based practice and recovery of function is limited, while evidence has accumulated supporting the importance of using context, repetition, and variability in the practice context to foster skill learning and control (Giuffrida, Shea & Fairbrother, 2002; Wolf et al., 2005). In this section, we highlight the surprising but ongoing influence of the neurofacilitation techniques on the practice of therapy and the increasing evidence for current strategies and approaches that promote skill learning and control.

Although occupational therapy was still a relatively young discipline during the early 1960s, the neurofacilitation and neurodevelopment therapeutic approaches based on the movement science of the time were developed (Mathiowetz, 1995; Woollacott & Shumway-Cook, 2007). These approaches resulted in a dramatic change in clinical interventions targeting those with neurological impairments. Prior to the development of the neurofacilitation approaches, therapy for those with neurological impairments was directed toward changing function at the level of the muscle. Current approaches were focused on muscle re-education, were more suited to the patient with movement disorders resulting from polio, and had less impact on altering movement patterns for those with upper motor neuron lesions such as stroke or cerebral palsy (Horak, 1991). The neurofacilitation techniques developed both in response to a clinician's dissatisfaction with seemingly non-impactful muscle re-education techniques and a desire to develop approaches that were more useful for those with movement problems secondary to a neurological dysfunction.

Neurofacilitation approaches include the Bobath approach developed by Karl and Berta Bobath (1965), the Road approach developed by Margaret Rood (Stockmeyer, 1967), Brunnstrom's approach developed by Signe Brunnstrom (1966), proprioceptive neuromuscular facilitation (PNF) developed by Voss (Voss et al., 1985), and the sensory integration theory developed by Jean Ayres (1972). These approaches were based largely on assumptions drawn from the then prevailing theories of motor control, the reflex and hierarchical models of motor control.

These approaches focused on retaining motor control and modifying the CNS through techniques designed to facilitate or inhibit movement patterns. As these approaches were associated with both the reflex and hierarchical theories of motor control, clinical practices were developed based on the importance of reflexes and hierarchical control in normal and abnormal motor control and the recovery of function (Mathiowetz, 1995; Montgomery, 1991). In these approaches, several key assumptions prevailed : (1) functional skills will return if abnormal movement patterns are inhibited and normal movement patterns are facilitated; (2) repetition of the normal movement pattern will result in the transfer to functional skills (Shumway-Cook & Woollacott 2007). Along with these assumptions, practice was guided by the prevailing thoughts about the importance of reflexes and hierarchical control in movement control (Bartlett, 1997; Easton, 1972; Gordon, 1987). Therefore, in these approaches, there is a focus on identifying the presence or absence of normal and abnormal reflexes controlling movements. Intervention is

COMMENTARY ON THE EVIDENCE   *Continued*

directed toward modifying the reflexes controlling movement and sensory input is used to direct and influence motor output. Use of a hierarchical theory suggests that a goal of therapy is to regain control of movement by higher centers of the CNS. Thus, the patient gains movement control and also recovers functionally, as patterns of movement are basic to function and development.

Although the evidence to support reflex and hierarchical motor control approaches to intervention is limited, these approaches still influence the way practitioners assess and intervene with patients with neuromotor problems (Shumway-Cook & Woollacott, 2007). However, many of the approaches have changed their approach to practice to incorporate more current scientific thinking about the nature and cause of movement. Within the neurofacilitation approaches today, there is more of an emphasis on training for functional recovery and less emphasis on inhibiting reflexes and facilitating normal patterns of movement (Howle, 2002). Also, there is more incorporation of motor learning principles into treatment interventions. Explanations and assumptions guiding the use of these neuromotor approaches have shifted to in-

corporate more of the current understanding of motor control, organization, and learning. However, rigorous scientific evidence supporting the use of these interventions is limited, while an increasing body of evidence supports CIMT interventions focused on the intensity and duration of functional treatments, repetition in practice as demonstrated in robotic training and the Sabo protocol, and the importance of the interaction of the person with the task and the environment, as evident in the task-oriented and systems approaches (Hoffman & Farrell, 2005; Morris et al., 1997; Sabari, 1995; Taub, Uswatte & Pidikiti, 1999). The more recent studies based on current motor control and learning science support more the tenets of occupation-based practice and the multiple, reciprocal, and distributed personal, task, and environmental influences that support the person's functional recovery, allowing fuller participation in all aspects of life. This evidence, as well as the paradigmatic shift in scientific thinking that has occurred regarding movement control and learning, highlights for the practitioner the importance of being current with the scientific thinking of the time if science and evidence is to continue to guide occupational therapy practice.

---

tional mobile arm supports and overhead slings, could provide the advantages of movement practice at a much lower cost than robotic technology.

CONCLUSION

To foster motor skills in clients, the practitioner must understand the interaction of motor development, control, and learning and the contextual factors that influence skill acquisition and reacquisition. The evolving science of movement science and research on neuroplasticity have dramatically altered our understanding of movement organization, control, and learning and how we as practitioners can foster skill recovery. Practitioners need to be aware that as scientific knowledge about movement evolves, new models of practice may emerge. Practitioners need to keep up to date on motor control and learning research so that they can provide clients with the most effective treatment

possible for motor deficits. Likewise, practitioners need to keep current on the amount and quality of the levels of research evidence supporting all motor interventions. With the client's input, therapists can select among evidence-based approaches or combination of approaches that are best suited to assisting the client to maintain and or recover everyday routines and skills.

Psychobiological Factors

BARBARA PRUDHOMME WHITE

Learning Objectives

After reading this chapter, you will be able to:

1. Describe a number of psychobiological factors that arise from the autonomic nervous system (ANS), including prominent signs of stress.
2. Describe some of the relationships between ANS and central nervous system (CNS) processes.
3. Describe some of the physical and psychological reasons for ANS disturbance.
4. Describe strategies that therapists can employ to support ANS stability during intervention.
5. Define and describe several examples of human biomarkers that are of interest to occupational science and therapy research.

INTRODUCTION

Imagine your typical day. Did you have to hurry to get to a class on time? Did you get enough sleep that you felt rested? Did you have a paper due or an exam to take? Are you worried about someone? Did you think about someone special? Are you angry with a friend? Are you excited about going on a vacation? Each of these questions should evoke some sort of response from you—either a neutral "No, that's not me" or a quickening heart rate, increased breathing, and tension as you recognized something relevant about which you are concerned. Possibly, one of these questions made you feel a sensation of love, all warm and fuzzy inside with an increased heart rate. This chapter addresses the internal responses that humans have in relation to real-world events, memories, or imagined possibilities. The human body is in continual dialogue with both the outside and inside environments. How we respond is shaped by both how we are constructed in our mother's womb, including our genetic potentials from our parents and our fetal experiences and nutrition, and how we are, moment by moment, influenced by our experiences from our birth forward. The dynamics of what is happening to our bodies in transactions with the environment are intimately linked with each other and not easily teased apart. However, as occupational therapists, we have an interest in this dialogue between the body and the internal and external environments because it influences why

people do what they do (engage in activities and occupations) and how successfully they do them.

Psychobiological factors refer to the body function level in the OT Practice Framework (American Occupational Therapy Association, 2007) and pertain to the anatomical and physiological interconnections among brain and body structures as they transact with the environment. Environments are defined as both external (the world) and internal (what we perceive, think, or feel). Psychobiological factors in an individual describe physical responses as our bodies interact with both our internal and external environments and can be broken down into biological and psychological components. *Body functions* in the OT Practice Framework include sensory, cardiovascular, respiratory, pain, visual, auditory, vestibular, olfactory, oral, cognitive, and endocrine (e.g., hormone) functions.

Biological responses (e.g., our internal biophysiology) arise from the body's interaction with the external environment moment by moment in terms of nervous system arousal, engagement, brain response, neurotransmitters and hormone response, and so on. For example, a person who exercises regularly increases demands to the heart muscle and vascular system, and the body becomes stronger and accustomed to this demand. These changes are both immediate (an increase in heart rate to deal with the exercise) and long-term (repeated exercise influences the cardiovascular system's response over time by increasing the size and amount of heart and leg muscle cells as well as blood-pumping efficiency). However, the system remains adaptive; for instance, if the person goes to a higher altitude, the cardiovascular system has to adapt again; less oxygen in higher altitudes means that the heart has to pump faster. In addition, the person experiences accommodations in blood chemistry so that more oxygen-carrying hemoglobin is available. Thus, contextual demands induce physical adaptation in heart rate and internal blood chemistry so that the individual can function effectively in different environments.

Psychological influences to biological responses are those linked with cognition, perception, and emotion instead of, or in addition to, environmental demands. The term implies a certain degree of higher-order "thinking" and its subsequent reaction throughout the body, but this is not necessarily so. For example, we sometimes have emotional reactions to smells and touch sensations for which we are not always aware of the reason. Indeed, neuroanatomical connections exist among structures in the brain that process emotion, which suggests that being aware of the environment is not always necessary to establish an emotional response. Furthermore, relationships with other beings often trigger emotional responses that influence our bodies. Love or feelings of affiliation are associated with high amounts of the hormone oxytocin in the limbic portion of the brain, which cause physical reactions in our body, including increased heart rate and facial flushing. Sometimes, our perceptions influence our responses. For example, when you see a cat, your physical responses (e.g., heart rate, epinephrine release) are mediated by whether you learned to be fearful of cats or are fond of them. Sometimes we can increase our physical reactions by merely thinking about a task (a midterm exam!) that we have to do, often in the middle of the night when there is no external environmental reason to have a racing heart rate.

REGULATION OF BODY SYSTEMS AND BEHAVIOR

Simply put, *regulation* refers to a dynamic balance between systems that are on "go" and those that are on "rest" (Figure 56.1). For example, when a person is exposed to bacteria, the immune system needs to be on "go" to capture and destroy the invading cells. Once the threat is over, the immune system needs to replenish itself and "rest" in wait for the next attack. These states are defined medically as *allostasis* ("go") and *homeostasis* ("rest"), the balance of which is generally managed unconsciously through the autonomic nervous system (ANS). This is a good thing; otherwise, in addition to remembering to do your laundry and study for an upcoming exam, you would have to add, among a thousand other tasks, "monitor body temperature," "mend radial bone crack," "make more white blood cells, killer-T variety," and "check those cortisol levels in the bloodstream" to your already busy day.

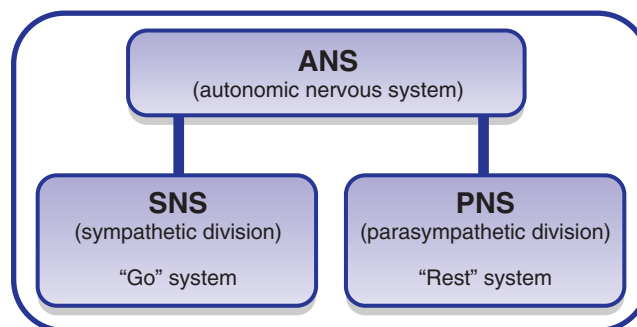
The ANS has two major branches that coregulate each other through homeostatic and allostatic processes: the sympathetic branch (SNS) (also referred to as the sympathetic-adrenomedullary system [SAM]) and the parasympathetic branch (PNS) (Kandel, Schwartz, & Jessell, 2000). Each system serves purposes that are antagonistic to or the opposite of each other; therefore, at any time, one system takes precedence over the other. However, at the same time, the SNS and PNS branches work together to support physiological, emotional, and


FIGURE 56.1   Autonomic nervous system with sympathetic ("go") and parasympathetic divisions ("rest/chill").

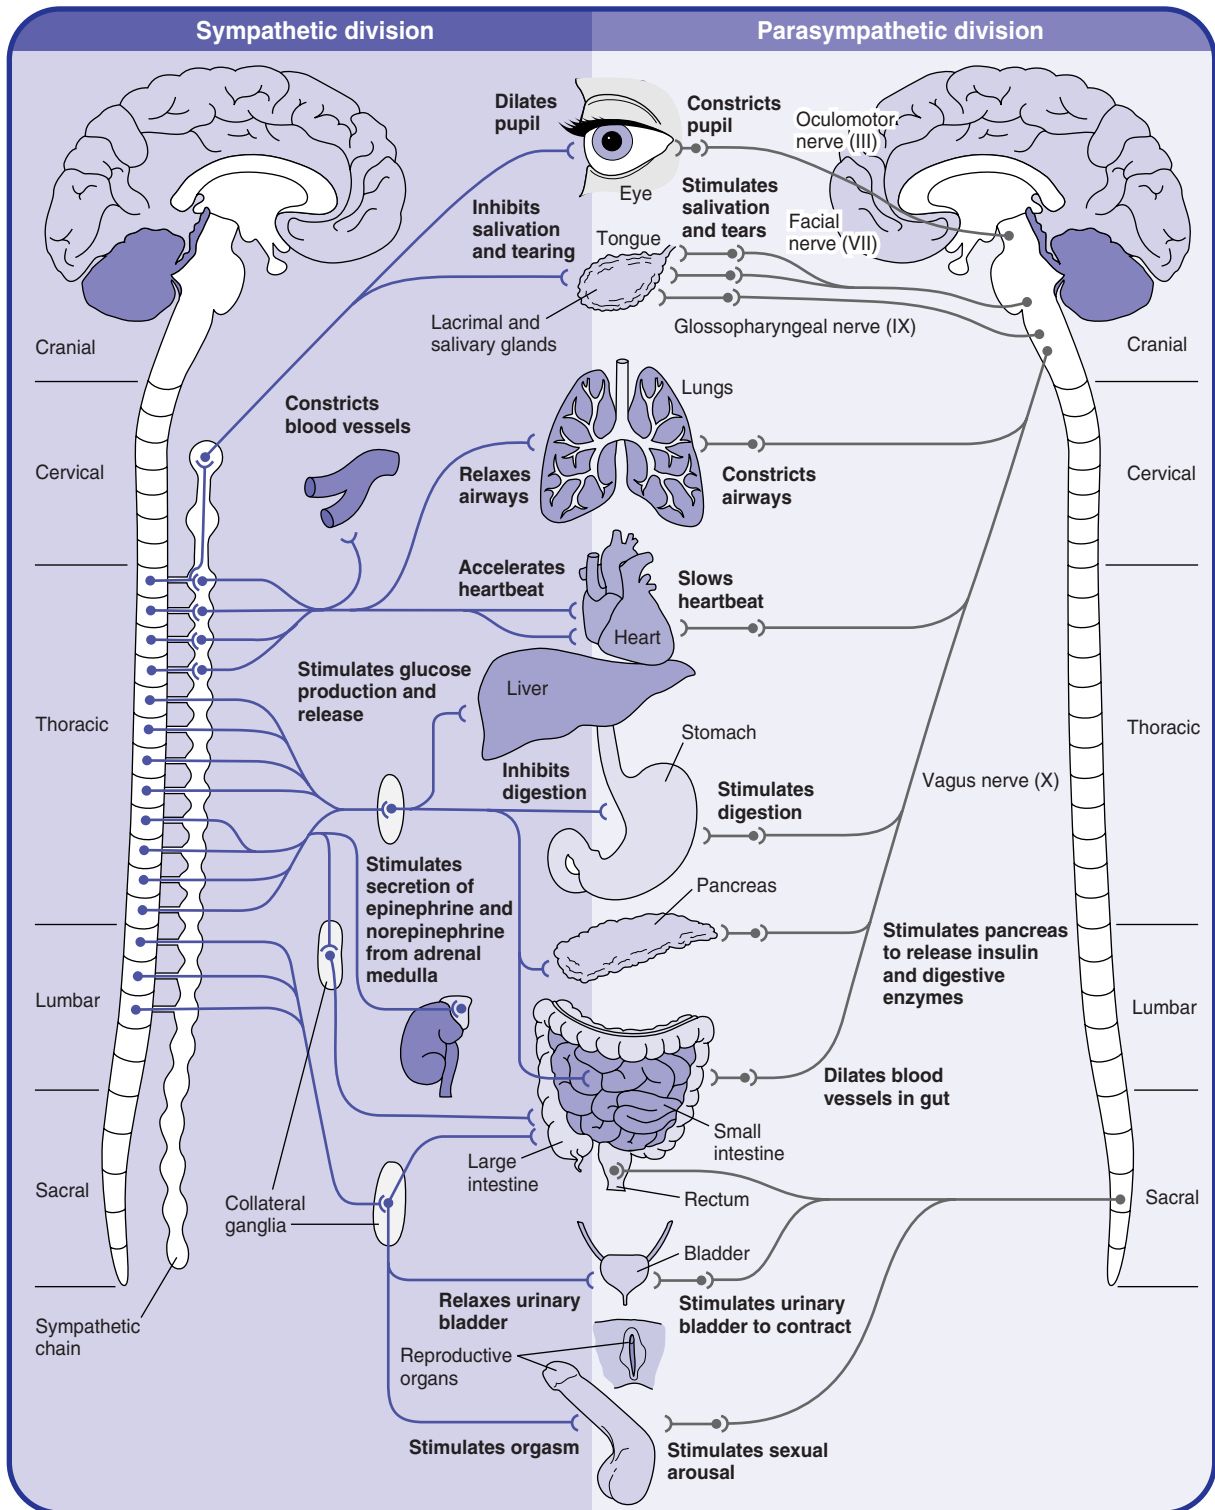
behavioral functioning. In synergistic fashion, both systems adjust and fine-tune what happens in our bodies while we are awake and when sleeping to ensure our capacity to adapt and survive in our environment (Figure 56.2). The SNS drives the fear, flight, or fight responses with increased respiration, cardiac activity, and metabolic activity, among others. Connections between the SNS and the adrenal glands produce the primary stress hormones, epinephrine (also known as adrenalin) and norepinephrine (also known as noradrenalin). Conversely, the PNS branch is concerned


FIGURE 56.2   The autonomic nervous system and its primary functions.

with generalized *homeostasis,* or the state in which primary goals are the conservation and restoration of energy, the digestion and absorption of nutrients, body repair and healing, sexual reproduction, and excretion of waste. Often, the limbic system is included in the structural description of what supports stress responses (see Figure 56.3). The limbic system comprises a number of brain structures that are responsible for emotion formation and emotional behavior as well as complex cognitive thought processing (e.g., memory). The limbic system wraps around the brain stem and is beneath the cerebral cortex. Parts of the limbic system include the cingulate gyrus, the parahippocampal gyrus, the dentate gyrus, the hippocampus, and the amygdala. The parts of the limbic system are highly interconnected with other structures in the brain, including the cerebral cortex, hypothalamus, thalamus, and basal ganglia (Kandel, Schwartz, & Jessell, 2000).

Most regulatory activities of allostasis and homeostasis via the ANS are out of our control; however, regulation gets messy when we consider the interconnections with consciousness, or CNS activity. We often refer to the regulation of emotions and behaviors as *self-regulation.* However, there are components of emotional and physical behavior that are both controllable and not necessarily controllable. For example, when angry, we can control whether we yell or storm out of a room, but we might not be able to control our racing heart rate and flushed face. For most people, controlling ANS responses such as body temperature and heart rate is not a common skill; however, some people can do it naturally, and many people can learn to do it. Indeed, controlling some aspects of the ANS is what underlies biofeedback as a technique for managing a degree of control over body systems. Biofeedback is used successfully with a variety of regulatory behaviors, including stress management (via body temperature and heart rate regulation), fear and anxiety (via cognitive appraisal and stress response system regulation), and attending behavior (via regulation of brain wave states that promote focused attention).
FIGURE 56.3   The limbic system.

Self-Regulation and Psychobiological Systems

Most psychobiological factors tap into systems that support self-regulation in each environmental context in which an individual finds himself or herself. Self-regulation is critical in supporting functional, adaptive behaviors in occupations and occupational tasks. Thus, understanding more about the body structures and physiology that support self-regulation is in the interest of occupational science and occupational therapists. Self-regulation is defined in this chapter within three primary domains, although in reality, these domains function in tandem (Barkley, 1998; Rothbart, 1981; Rubia et al., 2001). Self-regulation of behavior is the ability to adjust one's activity level to contextual demands of the environment. Sitting relatively still and quietly as the teacher speaks in front of the class is an example of adaptive self-regulation of behavior in a classroom. The child who gets up and walks around the room or fidgets so much that she falls out of her chair represents less well-adapted behavioral regulation. Cognitive self-regulation is the ability to generate or maintain attention skills that meet the needs of the environment, for example, maintaining enough attention to the teacher in the front of the classroom so that one hears and retains the content delivered by the teacher. Emotional self-regulation involves generating and maintaining suitable affect or emotional expression that is appropriate to the demands of the social environment. An example of this is the ability to know when, where, and at what intensity to show happiness or sadness. In a classroom environment, it is not suitable or socially adaptive to burst out laughing because someone tripped and hurt himself. Structures and systems that support self-regulation skills are often the target of psychobiological measures. Self-regulation skills that blend physical, cognitive, and emotional influences support successful occupational engagement in environmental contexts (see Box 56.1).

Stress

The concept of stress is a complicated one. A simple description of stress is as a condition in which either regulatory systems, self-regulatory capacities, or both are out of balance. Most of us use the word *stress* to denote a negative state, as in "I am so stressed I can't think straight." However, in its true definition, stress comes in all forms, many of which are positive. When you are falling in love, for example, you experience a form of stress. Exercise is also a good form of stress; exercise initially takes a toll on the body, but after exercise, we experience a rebound effect in the PNS that is responsible for homeostasis. In other words, after working out, our bodies are replenished with all sorts of hormonal benefits that make us feel good (e.g., endorphins) as well as strengthening and repairing body structures and restoring needed glu-

Many children have difficulty regulating their behavior, emotions, and cognitive state in varying contexts. Self-regulation emerges over time, drawing on the development of frontal areas in the brain; young children are not yet very good at it, while older children and adults are expected to have quite a bit of skill in self-regulation. Sometimes, otherwise typically developing children have trouble regulating emotions, attention, and behavior, leading many parents and professionals to describe them as having an attention disorder. In reality, an attention disorder reflects problems regulating more than just attention; behavior, emotions, and cognitive arousal states are frequently clustered together and observed as impaired self-regulation skills. Self-regulation skills can be developed and/or improved through intervention; indeed, the ability to adapt self-regulation skills provides the rationale for an intervention strategy developed by occupational therapists called "How Does Your Engine Run?" This intervention approach, developed for children, provides an understandable structure to help clients recognize their internal arousal states and learn to manage them more effectively in specific environments. (Shellenberger & Williams, 2007).

---

cose and other nutrients in our blood and cells. Moreover, exercise has the added benefit of helping us to use up unnecessary fat stores. Stress responses support action and, in just the right amount, make us effectively productive. Too much stress, however, takes its toll on functional performance and can degrade the body through excessive wear and tear. There are two stress response systems that are engaged when we encounter a stressor. A primary one is the sympathetic-adrenomedullary branch of the ANS (SAM axis), described previously, which produces epinephrine and norepinephrine. This response is designed to be a fast (within milliseconds) mobilizer of the body for fight, fright, flight, and sex—known with affection as the 4-Fs of the stress system. The SAM axis is designed to be short-lived and highly responsive. Another system, the hypothalamic-pituitary-adrenal (HPA) axis (Figure 56.4), is designed for more sustained body mobilization and is engaged minutes or more after a stressor is encountered or imagined, primarily by releasing cortisol, the major corticosteroid in the human body. Cortisol raises blood sugar by triggering the release of stored fats, as well as by breaking down stored body tissue proteins and triggering the liver to covert them into blood glucose. Cortisol also suppresses the immune system and places most homeostatic functions on hold, including digestion and cell replenishment and repair. The effects of cortisol on the body and brain are extensive and, when long lasting, eventually cause excessive wear and tear on most body structures and systems.

Imagine chronic stress, or allostatic load, as an extended activation of the longer-lasting stress response system, a "go" state in which little if any time is spent on replenishment, growth, and repair. Because of its many functions, it is easy to appreciate why chronic stress has a systemic effect on the body. However, as was previously noted, certain amounts of stress are positive and normal. Optimal stress has been described by a U-shaped curve, borrowed from a description of how much optimal strength of a stimulus is necessary for learning to occur. Referred to as the Yerkes-Dodson principle (Figure 56.5), it also applies nicely to the characteristic of stress, such that increasing amounts of it support and enhance functional behavior until it reaches a peak. After the peak, increased amounts of stress and stress hormones begin to degrade performance and function, leading to imbalances in physiology that also affect health. Chronic increases in stress and cortisol, for example, are linked with immune system dysfunction, cardiac disease, metabolic syndromes including diabetes, and cancer and autoimmune disorders (McEwen, 2002; Sapolsky, 2004).

Stress is also a function of the balance between the type of stressor and the environment paired with the individual's coping resources, attitude, and mood (Figure 56.6). Thus, when faced with a situation, a person weighs environmental information, the nature of the stressor, and his or her own capacities in order to behave adaptively. Often, this appraisal process occurs on an unconscious level. As you can imagine when you think of individuals who thrive in high-stress jobs, one person's stress is another person's delight. Conversely, what may overwhelm one individual might seem like a mere irritant or not even be noticeable to another. A large part of this complexity comes from the capacities and attitudes with which we engage the world around us.

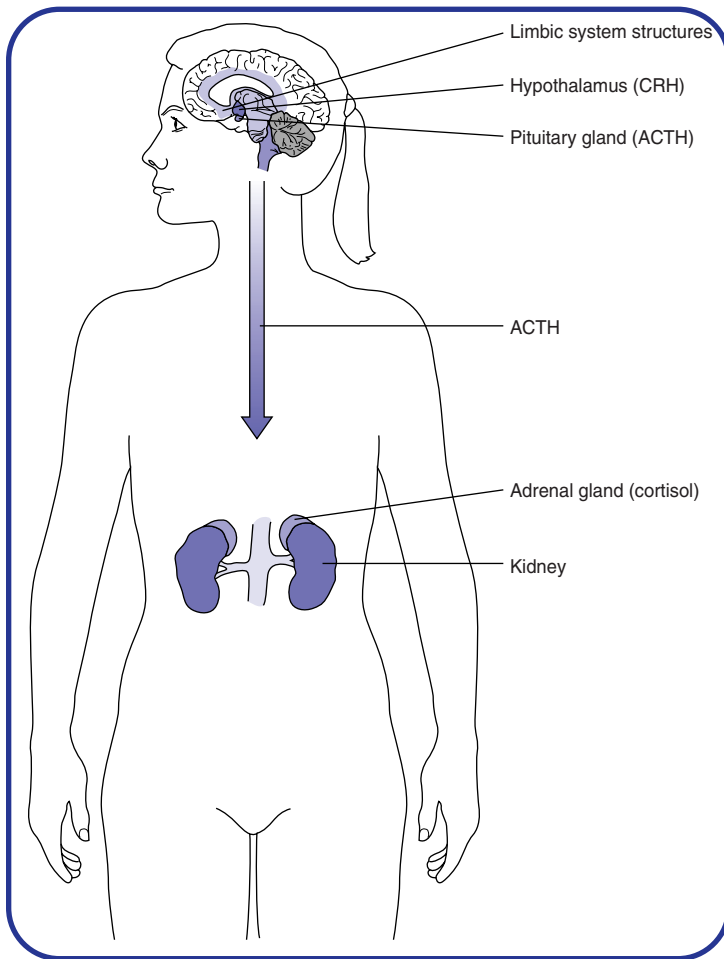
Imagine this scenario: You are taking a course in neurology; you feel fully skilled in your study habits, have put in the time necessary to do all of the readings, and have attended all of the lectures; you feel respected by the instructor; you eat well and get enough sleep; and you


FIGURE 56.4   The hypothalamus-pituitary-adrenal (HPA) axis.
FIGURE 56.5   The Yerkes-Dodson principle of optimal arousal is linked to performance and health. (Source: Adapted from Yerkes, R. M., & Dodson, J. D. (1908). The relation of strength of stimulus to rapidity of habit-formation. *Journal of Comparative Neurology and Psychology, 18,* 459–482.)

have a good idea of what will be expected of you on an upcoming exam. You appear to have the "just right" resources in place to do well, and in this situation, you probably feel energized by taking an exam in the course. However, any variations of this scenario might place you in a less-prepared situation, and as a result, you might feel heightened stress at the prospect of taking an exam.

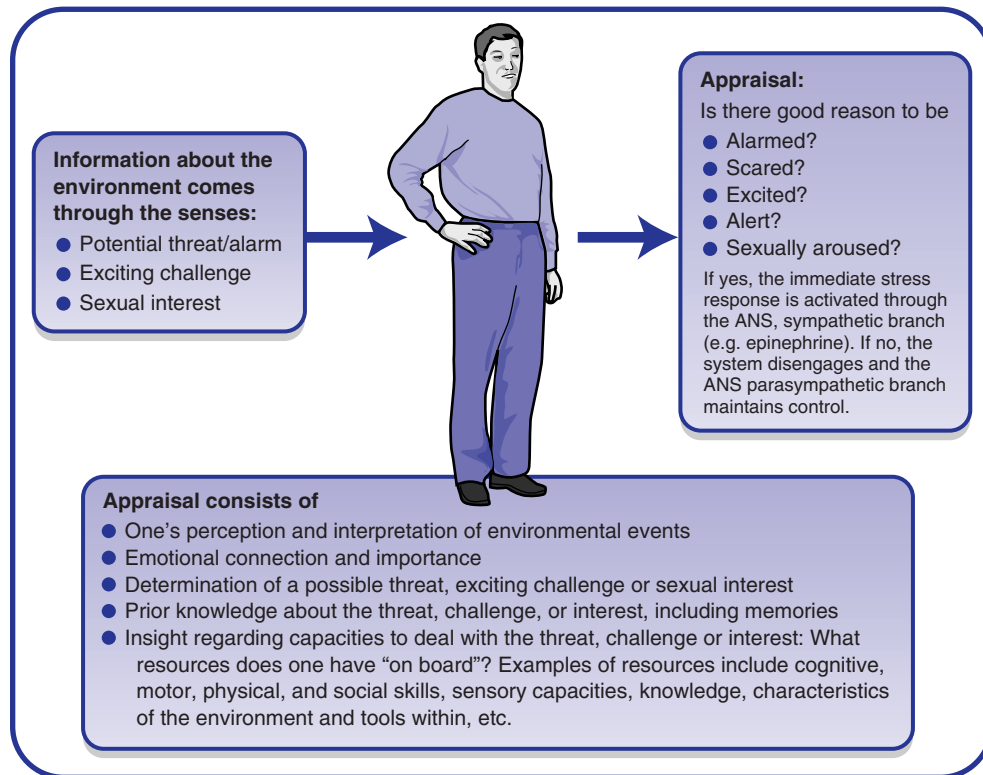
Personal capacities and resources vary from intellect and social skills to environmental characteristics. Essentially, anything that contributes in a positive way to an individual's ability to adapt to environmental demands can be thought of as a resource and can lead to resilience in the face of threats or challenges. Conversely, characteristics of a person or environment that overwhelm the person may be risks or liabilities. Balancing personal resources with "just right" challenges leads to effective and meaningful engagement in activities and occupations. Being aware of weaker capacities can lead to targeted skill development, improved self-regulation, and accommodations that may lessen the possibility of chronic stress experiences.


FIGURE 56.6   The physical, emotional, and cognitive factors that are related to stress.

Occupational therapy practitioners are most concerned with *occupational engagement,* or the "doing" of occupations in real contexts. We are most interested in the dynamics between the person; motivation to participate; functional, adaptive behavior; and the environment. Thus, the technologies that allow us to evaluate questions that address real-time participation and engagement in relevant occupations are ones that are likely to be most attractive for us in clinical practice and research. In practical terms, occupational therapy practitioners, as well as occupational scientists, are keen observers of purposeful human behavior. However, this chapter presents information about "internal" and sometimes "hidden" processes that also support functional behavior. These internal states of operation are managed by either the ANS or the CNS and ANS together and are important clues to how well a person's body, emotions, and behavior are both regulated and self-regulated to the context and task demands at hand. The extent to which an occupational therapy practitioner is aware of and can adapt for these internal working states can determine how successfully an individual client will engage in activities and occupations. The next section presents common signs and symptoms of ANS and CNS dysregulation in the clinic or home setting and offers a variety of appropriate response options that can support an individual's engagement in intervention.

POSSIBLE PSYCHOBIOLOGICAL FACTORS THAT ADDRESS THE CONCERNS OF OCCUPATIONAL THERAPISTS

This section describes two sets of psychobiological factors that influence occupational behavior. While these are not intended to be exhaustive lists, the factors that are described are ones that are most commonly identified by clinicians and researchers. OT practitioners should note that any psychobiological factor might be influenced by medication. Therefore, an assessment of medications and their possible influences on heart rate, respiration, temperature, sweating, and emotional expression, among others, is a critical part of understanding psychobiological factors. *Clinically relevant psychobiological factors* are the factors that can be observed in the clinic or community setting without special equipment; these are critical for practitioners to be aware of when working with clients. A second set of *research relevant psychobiological factors,* also referred to as *biomarkers,* are ones that are often used in medical and psychological research, including occupational science and therapy research, to learn how body systems work and adapt meaningfully in response to contextual demands. These biomarkers can also be used in shaping intervention practices by conducting research that

suggests to us how and why different intervention strategies are effective in producing meaningful and functional behavior.

Clinically Relevant Psychobiological Factors

Heart Rate and Blood Pressure

Most of us are aware of our resting heart rates and can detect changes as we move around, exert ourselves, or are suddenly emotionally aroused by someone we care about or with whom we have had an argument. Heart rate is adaptive and changes continuously in response to internal or environmental demands. A cardiologist is interested in heart rate and blood pressure as a person increases his or her demand on the cardiovascular system. For example, how hard does the heart have to pump when this person climbs a set of stairs? This is a basic example of the external environment (stairs) influencing the body (increased heart rate). The technology that is available to measure what is happening in the heart includes electrocardiography (abbreviated ECG or EKG), blood pressure measurement, and ultrasound. However, we might also think about another way in which the heart is influenced: by whether the person is angry or frightened— a psychological influence. Thus, changes in heart rate can be triggered by an external event (climbing stairs), by an internal event (having a fear of spiders and thinking of them or seeing them), or both (climbing the stairs to escape the spiders). ECG, blood pressure, or ultrasound does not easily measure only psychological influences; rather, as described above, these measures are based on detecting functional changes because of psychological influences or environmental demands. How might we measure the psychological influences on the heart and tap into an individual's perception of meaning and context? Later in the chapter, a sophisticated method (i.e., vagal tone or respiratory sinus arrhythmia [RSA]) is described that measures the relative contribution of psychological processes to heart rate variability. How might this knowledge inform what a clinician observes in clients within a community or therapeutic context? For one thing, therapists can appreciate that heart rate changes have psychological influences as well as physical ones. For example, if a person who is in cardiac rehabilitation following bypass surgery begins to have racing heart symptoms, it might be caused by the person being nervous or frightened to challenge his or her fragile heart as well as by the physical condition of the heart. A great example of this phenomenon is portrayed in the movie *Something's Got to Give,* in which Jack Nicholson plays an older man recovering from a heart attack who falls in love for the first time with a woman his own age, played by Diane Keaton. During the period in which they are broken up, he has multiple heart "events" that he perceives to be other heart attacks, which in reality they are not. In fact, he is in love and reacts to his emotions with a racing heart and sweaty palms when he sees the woman.

However, increases or decreases in heart rate can be signs of ANS dysregulation and physical stress. For example, in individuals with spinal cord injury, a decreased heart rate may be a sign of autonomic dysreflexia (AD), also known as hyperreflexia, a condition that is unique to individuals with spinal cord injury at C5–C6 or above. AD is a life-threatening condition in which the ANS responds to a physical stressor, often a blocked urinary catheter, a skin lesion, or extremely cold or hot ambient temperatures. Other symptoms of AD include pale skin color below the level of spinal cord injury and flushed skin above, disorientation and/or fainting, headache, increased blood pressure, and sweating above the injury level. This physical stress condition is serious and requires immediate medical assistance.

An increase in heart rate or blood pressure is observed by an accompanied increased breathing rate, reddened skin color changes, nonverbal grimacing or grunting, skin temperature changes, sweating, and complaints of a racing heart and/or a pounding headache. Therapists should quickly determine whether the person's life is threatened by accessing appropriate medical personnel and emergency services. Once an individual has been cleared medically, meaning that the symptoms are not the result of a physical life-threatening cause (e.g., heart attack, extreme high blood pressure), then careful assessment should be used to gather information about any possible psychological influences. In collaboration with the client and other clinicians, the occupational therapist should attend to the clinical symptom through close communication, paving the way for therapeutic intervention to proceed effectively. See Tables 56.1 and 56.2 for information on how to monitor cardiac function.

Sweating

Only the sympathetic branch of the ANS innervates human sweat glands in the skin. This means that only under "stress" do we sweat. However, stress to the body takes many different forms, not all of which are psychological. Body temperature outside of the optimal range (e.g., 98.6°F core temperature) is a form of stress. Therefore, in overheated environments, the body sweats to regulate body temperature by causing sweat on the skin to evaporate, thus cooling the skin and body in the process. Illness is a state of physical stress to the body, as is also the immune system's response to any pathogen that makes us ill. As the immune system triggers a fever to kill off invading pathogens, the body responds by sweating to reduce the increased body temperature. The same mechanism is triggered when the body is heated from exercise. Exercise is also a form of physical stress, albeit a good one. Research shows that individuals who are in good physical condition typically have highly responsive sweating capacity,

TABLE 56.1 CARDIAC INDICATORS

How to Measure Heart Rate via Pulse	Normal Heart Rate by Age	Maximum Heart Rate	Target Heart Rate	Normal Blood Pressure (18 years of age and older)
Carotid pulse (neck): Place your first two fingers horizontally beneath the chin, near the ear. Radial pulse (wrist): Place your first two fingers across the wrist, with finger pads under the thumb. Measure for 10 seconds and multiply by 6 for beats per minute.	Newborn: 120–160 0–5 months: 90–140 6–12 months: 80–140 1–3 years: 80–130 3–5 years: 80–120 6–10 years: 70–110 11–14 years: 60–105 14+ years: 60–100	Maximum heart rate (MHR) is the highest rate that a person should achieve during physical exertion. It is linked to both age and physical fitness. A rough estimate of maximum heart rate is to subtract one's age from 220. However, other factors, including weight and fitness, also need to be considered. 220 − age = MHR Refer to Table 56-2 for maximum heart rate per age.	Target heart rate (THR) is a percentage of an individual's maximum heart rate. It is used for fitness training purposes. Depending on a person's age and overall baseline fitness level, THR will fall somewhere within 50–85% of maximum heart rate. Refer to Table 56-2 for target heart rate per age.	Systolic pressure < 120 Diastolic pressure < 80

TABLE 56.2 TARGET HEART RATE AND AVERAGE MAXIMUM HEART RATE PER AGE GROUP

Age	Average Maximum Heart Rate (100%)	Approximate Target Heart Rate Zone (50–85%)
20 years	200 beats per minute	100–170 beats per minute
25 years	195 beats per minute	98–166 beats per minute
30 years	190 beats per minute	95–162 beats per minute
35 years	185 beats per minute	93–157 beats per minute
40 years	180 beats per minute	90–153 beats per minute
45 years	175 beats per minute	88–149 beats per minute
50 years	170 beats per minute	85–145 beats per minute
55 years	165 beats per minute	83–140 beats per minute
60 years	160 beats per minute	80–136 beats per minute
65 years	155 beats per minute	78–132 beats per minute
70 years	150 beats per minute	75–128 beats per minute

CASE STUDY: *Callie: Exercise and Activity After a Bilateral Knee Replacement*

Callie, age 62, was diagnosed with severe osteoarthritis in both knees. Because she was in so much pain and her mobility was significantly compromised, Callie was referred for bilateral knee replacements. She had both knees replaced without complications and recovered quickly, moving into outpatient rehabilitation about a week after surgery. There, Callie received both physical and occupational therapy, with a focus on personal activities of daily living (ADLs) and functional mobility around her home. Callie's physician determined that Callie was stable enough to participate four times per week in rigorous exercise and occupational engagement. Callie attended a local rehab clinic and participated in 30 minutes of cycling and upper extremity weight lifting as well as walking with supervision for 30 minutes followed by a gardening activity in which she weeded the clinic's vegetable and flower garden. During gardening, her occupational therapist noted that Callie began to sweat visibly, become flushed, and increase her breathing rate. Even though Callie said that she felt "just fine, thank you" when asked, her occupational therapist was concerned, observing Callie carefully. What might be a possible reason(s) for Callie's apparent discomfort? Is it possible that Callie's activity level is too much for her at this time? What are possible steps you would take next, assuming that Callie's color was not typical and her breathing rate continued to be too fast?

making them more likely to sweat a lot during exercise. However, it is also true that there is a lot of variability in the amount that individuals sweat during exercise.

People sweat during psychological stress as well. Think about what happens to most of us when we have to stand in front of a group of people and speak. Individuals might also sweat when anxious about their performance in activities or occupations, especially during assessments. For reasons that are not fully understood, women going through menopause also tend to become overheated periodically and may increase the amount that they sweat during hot flashes.

Sweat happens, and in most instances, it is the natural response to a warm environment, physical exercise, illness, or some degree of typical psychological stress. However, is important to recognize that sweat is also an easily observed sign of stress and anxiety due to extraordinary psychological disturbance. If an individual sweats in the presence of an occupational therapy practitioner, the practitioner should determine the reasons for sweating. If the sweating does not appear to be due to warmth, exertion, menopause, or any other identified cause, then the therapist might consider it to be possibly due to psychological stress. Observed examples of sweating and generalized anxiety due to nervousness from being in a hospital or clinical setting are fairly common among the elderly, people who come from rural areas, and those who come from impoverished backgrounds. Even for people who are familiar with modern health care facilities and personnel, there may be personal reasons for anxiety in these places. It is easy to become comfortable in health care settings when you work there and you understand the people and the culture. However, for many people, hospitals, rehabilitations centers, and outpatient clinics are sources of unknown expectations and loss of control. An astute practitioner never loses his or her perspective that clients and patients may be highly stressed and anxious about being in a health care facility and will consider this in his or her assessment and intervention approaches with the client and the client's family.

Skin Color: Pale or Flushed

Skin color is largely due to how much pigment is present in the dermis, or uppermost layer of the skin. However, baseline skin color can redden or pale perceptively by alterations in blood flow within the skin in response to physical stress or emotions. Although changes may be easier to detect in individuals with lighter pigmentation (e.g., Asian or Caucasian), all people have subtle skin color changes, especially in the face, which are possible to see with careful observation. Some diagnoses—Raynaud's syndrome, for example—can cause skin color changes that are seen typically as blanching in the hands and feet, especially in colder environments. Individuals with Raynaud's syndrome sometimes respond to biofeedback intervention in which they learn to exert some degree of control over their ANS by engaging PNS influences to relax capillaries in their extremities. Skin color and texture changes are also common in individuals with complex regional pain syndrome, a poorly understood condition that affects mostly women in their middle to senior years. In the absence of a known medical condition for atypical skin color changes, most changes can be assumed to be the result of ANS stimulation. Blood vessels in the skin generally constrict when the SNS is engaged, for shunting blood to larger muscles and organs in the body. This effectively supplies blood where it is most needed for physical action. Conversely, blood vessels relax and open under parasympathetic control, allowing for nourishment of all body cells and structures. However, physical stressors such as exercise or fever can cause facial reddening, as can disturbances in cardiac or respiratory activity. Sudden paling may also be a sign of internal physical stress, such as acute

or severe pain. Certain emotions, such as love and anger, can cause sudden reddening of the skin or blushing. At the same time, other emotions, such as fear or anxiety, can pale the skin. It is important that occupational therapy clinicians attend to skin color changes and determine reasons for the changes. Color change may be the first indicator, for example, that an individual client is experiencing pain during movement or activity. In addition, it can be possible that an individual is angry or embarrassed and will not otherwise express the emotion. Furthermore, some individuals might ignore physical symptoms of cardiac or respiratory distress and attempt to push through the warning signals. A clinician who pays close attention to skin color, as well as other psychobiological factors discussed in this chapter, can be instrumental in identifying underlying barriers to successful occupational performance.

Breathing

Respiratory rate is linked with environmental conditions and oxygen levels, physical fitness, cardiac strength and condition, health state of the lungs, and amount of red blood cells and iron available, as well as other health and environmental factors. For example, problems with respiration may be indicative of chronic obstructive pulmonary disease (COPD), which is a term that refers to both chronic bronchitis and chronic emphysema. COPD is caused by obstruction to airflow that interferes with normal breathing. Asthma, another airflow obstructive disease, can also affect respiration rate and is common in children and many adults.

The respiratory rate can also be affected by stress and anxiety; links with cardiac changes make this inevitable. However, respiration is also affected by direct connections from both sympathetic and parasympathetic branches of the ANS. The SNS innervates the lung to open up airways for deep breathing, anticipating hard work in the form of exercise, and either escaping or fighting the threat at hand. In contrast, the PNS constricts airways for more energy-efficient breathing associated with calmer states.

Individuals experiencing psychological stress and anxiety have a similar stress response, just as if they were exercising; they experience faster, deeper breathing to accompany their increased heart rate and in response to sympathetic inputs. Occupational therapy practitioners should ascertain the nature of increased breathing and follow the same clinical reasoning as described for cardiac signs and symptoms. Once physical threats to respiratory stability have been ruled out, the symptom may be determined psychological in nature and indicative of an emotional response (e.g., anger, fear, stress, or anxiety). Respiratory rate is also used in research along with skin conductance and heart rate, as part of what is commonly known as a lie detector test. Respiratory rate is rarely used alone; its meaning is more thoroughly understood in the context of cardiac, skin color, and skin resistance changes.

Skin Temperature: Hot or Cold, Wet/Clammy or Dry

Body and skin temperature is regulated by neurons in the brain stem and the hypothalamus, with connections to other structures within the ANS. Temperature regulation happens in concert with autonomic, endocrine, and motor systems. Temperature feedback sensors are located throughout the body, many of them in the skin as well as in the hypothalamus. Thus, there is constant feedback from the body to the brain regarding temperature, and adjustments are made accordingly. This feedback happens neurochemically, as well as through direct nervous connections. For example, cold temperatures cause the hypothalamus to make thyroxin, a thyroid hormone that increases metabolic rates. Other hormones also affect body and skin temperature; as a result, body temperatures, including subsequent sweating, can vary in women during their menstrual cycles as well as during perimenopause. Shivering is an involuntary response that is driven by the ANS to muscles to increase body temperature, although shivering can also be caused by generalized body temperature disturbance, as in the case

CASE STUDY: *Anxiety in a Woman with an Eating Disorder*

Maggie is a 20-year-old woman with an anorexia-type eating disorder. She was hospitalized recently for severe weight loss and has been silent regarding her feelings about her eating disorder. At the hospital, Maggie attends occupational therapy regularly. One of her goals is to develop her skills in painting, and she and her therapist, Janna, recently went shopping for art materials and had lunch at a local art gallery. Another occupational therapist, Michael, also began working with Maggie. At first, Maggie seemed enthusiastic working with Michael. However, Michael noticed that each time he entered a room where Maggie was, her behavior changed. He observed that Maggie appeared agitated and that her color flushed when he was close by. When asked about it, Maggie admitted that she felt funny, had racing heartbeats, could not breathe well, and became cold and sweaty when Michael came nearby. He encouraged Maggie to discuss her reactions with her counselor, and as a result, Maggie was able to recount a history of sexual abuse by a male family member that she had not previously acknowledged to her caregivers. Maggie said that she felt embarrassed talking about it and thought initially that it had nothing to do with her eating disorder.

Even though Maggie had insisted at first that nothing was wrong when Michael was present, careful attention to her stress signals revealed that she was more upset than she revealed; her body was unable to hide her feelings, and an observant occupational therapist was able to uncover key information that was critical to Maggie's recovery. Can you think of other situations in which subtle signals of distress in another person betrayed feelings and emotions that were otherwise not acknowledged? What are some of the typical signals you might look for in someone who is angry or scared?

An intervention approach that Michael suggested to Maggie was biofeedback training. Michael instructed Maggie in deep breathing exercises and meditation to help manage her racing heart and her shallow breathing. He attached a biofeedback thermometer to her index finger and asked her to mindfully increase the temperature of her fingers. Since warm hands are associated with high PNS influence and increased blood flow, an increase in her distal finger temperature would be a good indicator that Maggie was able to influence her body into a relaxation response. The use of a biofeedback thermometer allowed Maggie to see her success at raising her own finger temperature through purposeful thinking. Once she mastered the technique, Maggie was able to use the technique in other situations in which she felt anxious, allowing her a degree of control over her emotional reaction.

---

of fever-induced shivering. The immune system also influences body and skin temperature by producing substances that cause fever. Fever is indicated by hot, dry skin and feelings of malaise as the body attempts to kill off invading pathogens by increasing body temperature. The typical baseline temperature for humans is 98.6°F, although body temperature drops lower naturally during nighttime sleep.

Cold hands and feet can happen for a variety of reasons, including personal baseline temperature variation and conditions such as Raynaud's syndrome. Other medical conditions that affect blood perfusion in the extremities, including diabetes, can also affect skin temperature in the extremities. However, SNS engagement during stress or anxiety can also cause cold hands and feet. Indeed, acute stress can be accompanied by feeling cold all over. The SNS constricts blood vessels, especially in the extremities, in response to stress. If a client complains of being cold, especially in the hands and feet, or if shivering is observed, the occupational therapy practitioner needs to determine what could be a physical cause. For instance, is the person thin and susceptible to cold? Is the person ill and feverish? Once physical causes have been eliminated, the clinician may reason that cold extremities could be indicative of a stress reaction.

Tears, Salivation, and Digestion

Only the parasympathetic branch of ANS produces tears and saliva. As you recall, the PNS and SNS override each other such that only one system can be "in control" at any one time. Thus, crying with tears does not happen during acute stress. The same is true for salivation and digestion; in fact, the SNS inhibits salivation in the mouth, blood flow to the stomach, and stomach acid production, thus inhibiting digestion during acute stress. This explains why we often experience a dry mouth and indigestion when we feel highly stressed. Only after acute stress, when parasympathetic input is restored, do we experience normal digestion, elimination, and crying with tears. The astute reader might be thinking that people cry during chronic stress and depression, however. This is true, and it brings up a good point about differences between chronic and acute stress. The acute stress response system through the SNS is designed for short-term engagement only. The longer-lasting stress response that is mediated through the HPA system (see Figure 56.4) is designed for more sustained arousal. However, it cannot possibly be on "go" the entire time a person perceives stress. Humans would literally burn themselves out by depleting all nutrients and running internal body systems in high gear. Therefore, chronic stress is riddled periodically by parasympathetic

CASE STUDY: *A Healthy Stress Response*

Torrance is a 35-year-old Iraq war veteran who is currently in outpatient rehab to learn how to use his new upper extremity prostheses. One of Torrance's goals in therapy is to reestablish a busy lifestyle with his children, including his favorite leisure occupation, skiing. His occupational therapist, Selena, along with Torrance's family, planned a ski trip to a local mountain ski resort that specializes in adaptive sports. At the top of the mountain, before his first run, Torrance began unexplainably to cry, sweat, and complain that his heart was racing. Selena noted that this was an expected reaction and began to talk Torrance through the challenge at hand. In addition, she gave him a deep breathing exercise and asked him to focus on his prior skills in skiing. Once Torrance seemed relatively in control, Selena asked him to head down the fall line of the mountain. Was Torrance's life at risk in any way, or was he having a healthy stress response? In pointing out Torrance's capacities, which included an expert level of skiing prior to his injury, what was Selena trying to do? Why did she explain to Torrance that his reactions were normal and expected? How can you prepare for situations like this?

rebounds that allow some degree of restoration to support survival. It is during these intermittent periods that the chronically stressed person is likely to cry tears. Indeed, some researchers suggest that crying is one way in which the PNS mobilizes a return to homeostasis; in other words, crying is a self-regulatory action that produces hormones to make us feel less upset after a stressful situation. This makes sense in light of the old saying "You'll feel better after a good cry." Indeed, most of the time, we do.

Humans are the only animals that cry with tears. Obviously, crying has strong links with emotional experiences. Sometimes we cry when we are happy, and often we cry when we are sad, but there is always a strong emotional experience. Researchers have noted that the chemical constitution of tears changes depending on the reasons for crying, such that happy tears are different from sad ones, which are also different from the tears we produce when cutting an onion. Though the reason for tears has perplexed researchers, and a number of theories have been produced, most researchers agree that tears serve as a communication signal to others. Researchers who are interested in why behaviors develop from an evolutionary perspective believe that tears are a social signal to others that sends a message about true emotional expression. Indeed, crying is hard, if not impossible, to fake unless you "call up" emotional memories to make yourself sad. Therefore, we assume that people who cry tears are expressing their emotions in an honest manner, and we are compelled to act supportively.

Knowing this information about tears, salivation, and digestion should make the occupational therapy practitioner more aware of what subtle behaviors can be observed clinically or in community settings. For example, a dry mouth accompanied by indigestion could be a number of things; for example, medications often have these symptoms as side effects. However, it might also be a signal that an individual is experiencing high amounts of stress and is not expressing this verbally or through other behavioral means. In a similar fashion, crying with tears can be a sign of emotional distress, or it may be the result of emotional lability resulting from neurological damage to limbic system structures and/or the right hemisphere in the brain (i.e., primary locations for emotional regulation). Occupational therapy practitioners need to be aware of the reasons for the emotional expression and address intervention accordingly.

Vision

Any number of things, including age, medications, and disease, can cause changes in visual acuity. However, there are also visual implications related to mood and stress. The SNS dilates the pupil in the eye to support long-distance vision and vigilant behavior. This makes sense because in challenging or stressful situations, an individual needs to be "on guard" for what is happening in the environment. In addition to vision, all senses are heightened so that the person is ready to react. As a result, a highly stressed individual might be less able to focus visually on nearby items and might be unable to attend well or concentrate adaptively to various task demands. In fact, the person might seem agitated and flighty. Conversely, the PNS constricts the pupil and allows for more focused vision, supporting close-up work and social interaction. A calm person is also one who can visually attend for longer periods.

Pain: Grimace and Other Nonverbal (or Verbal) Expressions of Pain

The 2001 Joint Commission on Accreditation of Health Care Organizations report recommended that pain be considered a fifth vital sign, along with pulse, respiration, blood pressure, and temperature, in the physical assessment of patients. Pain is commonly defined as an unpleasant sensory and/or emotional experience that is often associated with damage to body tissues (Figure 56.7). However, many definitions separate pain *sensation* from pain *perception*
FIGURE 56.7 Wong-Baker FACES Pain Rating Scale. Many health care providers assess pain through scales, especially because pain is difficult to describe and explain in terms of magnitude. Some scales use a numbering system (0 = no pain to 10 = intolerable pain); others use words (low to excruciating). This example provides a visual scale for pain assessment that is used effectively with clients from age 3 years through adulthood. (Source: Hockenberry, M. J., Wilson, D. & Winkelstein, M. L. (2005). *Wong's Essentials of Pediatric Nursing,* ed. 7, p. 1259. Copyright, Mosby: St. Louis. Used with permission.) Done

because pain is an experience that is open to interpretation by other sensations, feelings, and thoughts that coincide with the pain. In other words, the perception of pain changes with environmental context, mood, and stress levels, among other things.

For example, imagine this scenario: You stub your big toe on the way to class and experience sudden, intense pain. However, you are late and shrug off the pain sensation in order to run to class on time. In fact, you hardly feel your bruised big toe at all over the next 30 minutes as you hurry to class. Once you settle in your seat, greet your friends, gather your materials, and begin listening to your professor, your body quiets. Slowly, or perhaps abruptly, you become aware of a throbbing pain in your big toe. What changed? The nerve impulses carrying pain sensations from your big toe did not change since you stubbed it; the nerves continued to respond to the slight swelling and development of a bruise indicating mild damage to the tissues of the big toe. What changed was your perception of the pain in the quieter classroom context with fewer competing sensory perceptions, along with a quieter state of mind and body in which you were more receptive to the pain sensations. Indeed, we are often unaware of slight bumps, bruises, and cuts until we go to bed, where the quiet environment and stillness of our bodies allow pain sensations to jump to the forefront of our awareness. The characteristics of pain that make it adaptable to mood and context along with individual interpretations of perception make pain, especially chronic pain, difficult to assess, understand and manage.

Acute pain is short-term (e.g., minutes, hours, days) and is typically related to injury, disease, or surgery. Acute pain functions as a signal to stop whatever you are doing and rest the damaged body area so that it may heal (Britt, 2006). In this way, pain is a useful messenger. However, chronic pain provides more of a challenge. By definition, chronic pain lasts beyond body damage and repair; furthermore, it is often associated with psychosocial disorders and

might not always connect to an actual physiological event (Britt, 2006). Phantom limb pain, for example, exists long after the wound from an amputation has healed. Identifying the source or reason for back pain is often a mystery for health practitioners. It is clear, however, that psychological stress, depression, anxiety, and negative mood affect pain perception. Occupational therapy practitioners need to pay attention to a person's overall mood and perceived stress level in order to understand the nature and magnitude of the person's pain. To help individuals manage pain, especially during ADLs and other daily occupations, clinicians should be mindful of addressing the individual's stress and anxiety level, mood orientation, and social network (including supports and nonsupports) in addition to the physical aspects of pain management.

Short-term physical stress, including exercise, blunts pain perception through the release of beta-endorphins. These substances, released by the pituitary gland and throughout the body, are internally produced pain relievers, also known as endogenous opiates. Thus, during periods of acute stress, beta-endorphins provide a degree of short-lasting pain relief. Chronic stress, on the other hand, is associated with increased cortisol levels in the body, which appear to make many people hypersensitive to pain perception. As a result, pain thresholds, or the amount of tolerable pain an individual can handle without functional impairment, are lower in the presence of chronic stress.

Intervention Responses to Psychobiological Factors

Stress management, relaxation, and self-regulatory interventions should always be guided by client choice.

Psychobiological Changes Related to Physical Stress

Examples of psychological changes related to physical stress include changes in breathing (too fast or too slow),

CASE STUDY: *Pain in a Woman with Carpal Tunnel Syndrome*

Truth was referred to your clinic for evaluation and possible therapy for bilateral carpal tunnel syndrome. Truth is a 40-year-old woman who works as an administrative assistant to several attorneys in a busy law firm. She has held this position for 12 years and stated that she loves her job; however, she was worried that she would not be able to continue in her position if her condition progressed. She confessed that she was highly anxious about her future job security. Truth had also recently divorced and was sharing custody of two young children with her husband. She was the provider of health benefits for her children. Truth was compliant with her exercises and splinting routine and, as a result, began to show modest improvements in her wrist pain. However, she reported that she did nothing but work, giving up her normal exercise routine as well as cooking for her family because she was fearful that if she used her wrists and hands too much, the pain would increase and she would be unable to work. As a result, Truth appeared worried most of the time. During therapy, her occupational therapist noticed that Truth became dry-mouthed, unable to pronounce words clearly, and asked for water. Truth also was unable to sit still, seemed distracted in therapy, and appeared on edge. At one point during a therapy session, Truth stated that she felt faint and that her heart was racing.

What might be happening? How might Truth's psychological state be affecting her recovery? What are some strategies that her occupational therapist could use with Truth to address her anxiety? What are the possible physical implications for healing if Truth remains anxious and possibly depressed?

cardiac changes (heart rate too fast or slow, blood pressure too low or high), temperature, sweating, skin color changes, vision changes, emotional lability, indigestion, and complaints of pain.

Intervention Suggestions

- Ascertain whether the client is in any immediate life-threatening danger. If so, access medical help.
- Instruct the individual on how to self-monitor his or her activity level within the range specified by his or her care providers (e.g., know and measure target heart rate).
- Instruct the client on energy conservation techniques for basic and instrumental ADLs.
- Instruct the client in various techniques for stress management, including breathing exercises, relaxation response training, and biofeedback training as appropriate.
- Instruct the client in time management to ensure adequate time spent in leisure occupations and social activities.
- Suggest a pet or other social companion.
- Instruct the client in cognitive-behavioral techniques to promote optimistic mood orientations and prosocial attitudes.
- Instruct the client in reframing techniques to develop better self-control.
- Instruct the client on the importance of sleep, nutrition, and exercise.
- Assist the client in incorporating the suggestions of other professionals (e.g., dietician, nursing, physician, social worker, physical therapist, psychologist) into daily routines, activities and occupations.
- Explore the possible use of complementary alternative medicine approaches such as acupuncture and massage.

Psychobiological Changes Related to Psychological Stress or Problems in Self-Regulation

Examples of psychobiological changes related to psychological stress or problems in self-regulation include changes in breathing (too fast or too slow), cardiac changes (heart rate too fast or slow, blood pressure too low or high), temperature, sweating, skin color changes, vision changes, complaints of pain, mood changes, emotional lability, crying, distractibility, and hyperactivity.

Intervention Suggestions

- Instruct the client to self-monitor internal physical and psychological states.
- Teach the client techniques to modify internal states as appropriate to environmental contexts.
- Instruct the client in various techniques for stress management, including breathing exercises, relaxation response training, and biofeedback training as appropriate.
- Instruct the client in time management to ensure adequate time spent in leisure occupations and social activities.
- Instruct the client on the importance of sleep, nutrition, and exercise.
- Assist the client in incorporating the suggestions of other professionals (e.g., dietician, nursing, physician, social worker, physical therapist, psychologist) into daily routines, activities, and occupations.
- Suggest a pet or other social companion.
- Explore the possible use of complementary alternative medicine approaches such as acupuncture and massage.
- Instruct the client in cognitive-behavioral techniques to promote optimistic mood orientations and prosocial attitudes.
- Instruct the client in reframing techniques to develop better self-control.

◆ Assist the client in broadening his or her activity and occupational repertoire.

◆ Assist the client in managing drug and alcohol abuse by helping him or her to incorporate necessary life changes into daily routines and healthy habits.

RESEARCH RELEVANT PSYCHOBIOLOGICAL FACTORS: BIOMARKERS

Occupational science and occupational therapy research, from a psychobiological perspective, concerns itself primarily with structures and processes that support occupational behavior. Essentially, the questions that drive research are ones about what is going on inside a person's body or brain that supports or drives the behaviors we see. Technological advances give us tremendous insight into body structures, but we are still limited in measuring internal processes as people *do* something. As a result, some psychobiological-based measures lend themselves more easily to addressing this interest in *understanding the doing* than perhaps do others. Some measures are technically difficult to obtain or measure things that might not be relevant specifically to occupational therapy. For example, a computed tomography (CT) scan gives a detailed picture of body structures that are essential in identifying normal versus atypical growth and development. However, a CT scan does not give information regarding how they the body structures work in context (a question that is relevant to occupational therapy). Similarly, a functional magnetic resonance image (fMRI) assesses body structure and function, but does not address contextual functional performance in the way occupational therapists define *function*. Though a great tool for investigating functional skills that can be performed in an MRI bed and tube, with only finger movement for pointing, the fMRI limits the sort of questions that might be asked of people who are performing meaningful tasks within typical environments. Can you imagine trying to measure a person's brain function with an fMRI scanner under the task demand of making a peanut butter sandwich?

Some measures are too intrusive for occupational therapists to obtain regularly. For example, unless an occupational therapy practitioner or researcher works in an acute care setting and has direct access to blood and urine samples, these measures would not be feasible to collect. Saliva samples, on the other hand, as well as cardiac measures, lend themselves to greater possibilities for use as measures in occupational therapy research. Thus, the extent to which occupational scientists and occupational therapy practitioners can measure psychobiological factors is influenced by available technology, as well as by our interest in certain behaviors. This next section describes a selection of psychobiological measures that can give us a window into internal processes. When measures are based on psychobiological processes, we label them *biomarkers.* Some biomarkers are direct and "up close" to what is the target for measurement. For example, a test of the number and type of blood cells in the body (or complete blood count, or CBC) measures red and white blood cells in a sample of blood; this is pretty straightforward as biomarkers go. On the other hand, some biomarkers are more "distal" in nature, meaning that they measure something that is one or more steps removed (distal) from the actual process of interest. Cortisol is an example of a distal biomarker. Often measured in saliva as an unobtrusive biomarker, salivary cortisol is an estimate of the cortisol in blood that is related to the amount of the precursor hormone adrenocorticotropin hormone (ACTH) in the body. ACTH is sent to the adrenals from the pituitary gland because of how much of the precursor corticotropin-releasing hormone (CRH) is sent from the hypothalamus. CRH was released because of messages sent to the hypothalamus from the ANS to sustain a heightened stress state. This might seem complicated, but you get the point. In a perfect situation, we would rather assess the amount of CRH that is sent from the hypothalamus to the pituitary in response to a stressor, because this would be a more direct measure of a stress response. However, we cannot ethically tap into people's brains to measure these processes in healthy adults. Therefore, we need to rely on biomarkers that are more distal. Distal biomarkers are still relevant, but they can be tricky to understand because they are not the immediate measure of a response but rather are a measure of something that happened a few steps back. However, research ethics preclude the type of research that measure biomarkers within brain structures and other organs; this is one of the reasons why animal research can be so valuable.

The following sections discuss selected examples of psychobiological measures that are used in research.

Electrodermal Response

Because sweat glands are innervated by the SNS (the "go" system) and thus affect the tension of the skin, many researchers have been interested in using skin resistance via sweat glands as a stress response biomarker. Electrodermal response (EDR), also known as galvanic skin response (GSR), refers to a measurement of the electrical conductance of skin, specifically related to the sweat glands. The preferred term is *EDR* or *electrodermal activity.* Sweat glands respond to ANS activity by fluctuations in salt and water concentrations that lead to either sweaty or dry skin. The concept that supports EDR is that emotional arousal and subsequent ANS activity from the SNS causes changes in skin conductance. Some evidence suggests that brain circuitry originating in the prefrontal cortex and limbic structures mediates the electrodermal response through the SNS (Critchley, 2002). Higher SNS stimula-

CASE STUDY: *Depression in Individuals with Acquired Brain Injury*

Liz works as an occupational therapist in a rehabilitation facility. Her primary caseload is with individuals who have acquired brain injury, either from trauma or from a stroke. Within this setting, her team is noticing that a large number of individuals are depressed following the injury, and they suspect that it is more than just depression due to ability and lifestyle changes. The rehabilitation team has followed recent research regarding depression and links to dysregulation in the stress response system. They would like to include a psychobiological measure, or biomarker, in a research study, and the local university is willing to assist them. What are possible psychobiological measures that would address stress physiology and possibly depression? What ones are more feasible for use, on the basis of Liz's need to be as nonintrusive as possible? What other measures would be appropriate to include?

tion (e.g., arousal or stress) is associated with skin sweating, a lowered skin electrical resistance, and therefore increased electrical conductance. A relaxation state or higher PNS is associated with drier skin and higher electrical skin resistance, resulting in decreased electrical skin conductance. Unfortunately, a number of emotions (e.g., sexual desire, anger, fear) produce the same response (e.g., SNS arousal), making an interpretation of the results difficult. For example, an individual's response could be based on fear, happiness, or the need to go to the bathroom, which are all SNS-arousing events but for very different reasons. The most common application of EDR is as part of a polygraph assessment, or lie detector test. The polygraph uses cardiac and respiratory information as well as EDR. However, the polygraph is considered a controversial assessment for legal use because of its unreliability in discerning the source of an individual's response. In a novel application of this biomarker, a recent study (Marci & Riess, 2005) used EDR to objectively measure the degree of connectedness in developing therapeutic rapport between a therapist and a client.

EKG/ECG and Vagal Tone

Previously, we asked, "How might therapists measure the psychological influences on the heart that tap into an individual's perception of meaning and context?" This question has driven a number of researchers, including some occupational therapists, to learn measurement strategies that assess the unique contribution of cognitive and emotional appraisal to heart rate variation. This psychobiological measure, called *vagal tone,* is a derived estimate of heart rate variability that is due not to physical reasons, but rather to psychological ones. Thus, vagal tone is an example of a biomarker that estimates psychological influences (e.g., cognition and emotions) on a body system (e.g., heart rate).

EKG/ECG does not easily measure psychological influences on heart rate; rather, as was described previously, it is based primarily on measuring functional changes in heart rate in response to immediate environmental demands (e.g., blood oxygen levels, climbing stairs). The vagus nerve (tenth cranial) provides a direct nervous system connec-

tion to the heart, and is primarily influenced by the PNS. While both branches of the ANS influence the heart, the SNS contributions increase heart rate and blood pressure, while the PNS slows down the heart and thus influences the resting heart rate. Heart rate variability is measured in periods, also referred to as R-R intervals or interbeat intervals. In a simple example, if a person experiences an environmental threat, the SNS takes precedent and increases heart rate; in contrast, when a person is relaxed, the PNS is predominant and slows the heart rate.

Porges (1992) as well as other researchers have developed algorithms that calculate a measure of RSA or vagal tone. These require EKG/ECG readings that are then further analyzed to factor out heart rate variability contributions that can be attributed to vagal nerve inputs. An overall measure of RSA is then computed. In general, lower measures of heart rate variability are associated with less adaptable behaviors and poorer developmental capacities. Highly competent parasympathetic reactions appear to be faster and more flexible and are thus reflected in higher values of heart rate variability. Another technique for quantifying heart rate variability uses spectral analysis of cardiac electrical frequencies (Zhuravlev, Rassi, Mishin, & Emery, 2002). The parasympathetic and sympathetic branches of the ANS oscillate at different frequencies and can be captured by using EKG/ECG heart rate monitors and computerized analysis. The results are displayed as power spectrums of low- and high-frequency bandwidths that disentangle the sympathetic and parasympathetic components. While this biomarker is useful for research purposes, it cannot be used clinically because it requires specialized computers, ECG/EKG connections, and technical expertise.

Cortisol

Cortisol is a glucocorticoid hormone (i.e., steroid) that is released by the adrenal glands that sit on top of each kidney. The hormone is released as part of a complex system called the hypothalamic-pituitary-adrenal axis (see Figure 56.4). The purpose of this hormone is to sustain metabolic activity, increased vigilance, and increased blood pressure, among other things, such that the individual can

COMMENTARY ON THE EVIDENCE

Examples of Relevant Research Using RSA (Vagal Tone)

Schuetze (2006) examined RSA in young infants (4–8 weeks) with and without prenatal cocaine exposure and found that differences existed in RSA between both groups, depending on the extent of cocaine exposure. In general, infants with greater cocaine exposure displayed lower RSA variability when compared to typical children and to those with lower amounts of cocaine exposure (Schuetze & Eiden, 2006). The same researchers also found that 2- to 4-week-old infants who were exposed to prenatal maternal smoking as well as environmental smoke after birth had lower RSA values when compared to nonexposed infants. In addition, although both boys and girls appeared affected by smoke exposure, they found a greater effect for boys, suggesting greater vulnerability. Smith (2003) found that very low-birth-weight premature infants also had lower vagal tone, suggesting potential risks for developmental outcomes.

In one study of typical 2-year-old children, researchers found that vagal tone differed as a result of maternal interaction style (Calkins, Smith, Gill, & Johnson, 1998). Children's behavioral and emotional regulation was linked to lower vagal tone in children whose mothers were more negative in their interactions. This study highlights a potentially important variable of parenting style in the development of self-regulation skills and opens discussion for abilities such as self-regulation to be adaptive to environmental influences. Other researchers have noted the influence of parents and social environments in the development of self-regulation abilities, especially in relation to attention and behavioral regulation (Quas, Bauer, & Boyce, 2004).

DeGangi, Porges, Sickel, and Greenspan (1993) used a measure of vagal tone with infants who had been determined to have some degree of regulation disorder at 8–11 months. Regulation problems included disturbances in sleeping, self-calming, and state-transition control, as well as early signs of sensory processing problems. The infants were untreated and were assessed again at 4 years of age and compared to typical peers. Their results suggested that low vagal tone assessed earlier in infancy was associated with poorer developmental outcomes and behavior regulation skills at 4 years of age in comparison to typical children. These data, though based on a small sample, suggest that vagal tone might be a reasonable biomarker for potential developmental difficulties, as related to behavior regulation. Schaaf, Miller, Seawell, and O'Keefe (2003) used vagal tone measures in children with problems in sensory processing. Although it was a small pilot study, they also found lower vagal tone in children with sensory processing problems when compared to children without problems, and documented the need for further research in this area.

---

deal with environmental challenges. Cortisol is released in pulses or surges throughout the day and night as part of a circadian cycle as well as in response to both internal and external events, such as feelings of excitement or worry or a police siren and lights pulling up behind you on the freeway.

Salivary α-Amylase

Salivary α-amylase has recently been studied as a marker of SNS activation or stress system responding. Generally, catecholamines provide a reliable marker for SNS activity in research by measuring epinephrine and norepinephrine in urine or blood. However, collection of blood and urine is either too invasive and/or impractical for many human research endeavors. α-Amylase is a protein-based digestive enzyme that is produced by the salivary glands (e.g., the parotid glands) in response to SNS activity, thereby increasing the amounts of α-amylase in saliva for the purpose of breaking down sugars in the digestive tract so that energy is released to support "fight-or-flight" behavior. In contrast, parasympathetic activation of the salivary glands increases the saliva flow rate and thus reduces the amount of α-amylase in saliva (Rohleder, Nader, Wolf, Ehlert, & Kirschbaum, 2004). Salivary α-amylase appears sensitive to both physical (e.g., exercise) and social stressors in studies of typical individuals (Granger et al., 2006; Rohleder et al., 2004; Wetherell et al., 2006). Normal secretions of α-amylase appear to follow a reliable daily release pattern in typical adult individuals (Granger et al.,

COMMENTARY ON THE EVIDENCE

Relevant Research Using Salivary Cortisol

There is converging evidence from multiple well-conducted research efforts that suggest that HPA dysregulation is real in people with stress-related and other health conditions and that it links well with what is known from animal studies (Gunnar & Vazquez, 2006; Schneider, Moore, Kraemer, Roberts, & DeJesus, 2002). Furthermore, we can use this research to help shape interventions. For example, in individuals who are recovering from cancer, depression is linked with rates of recovery and survival (Jehn et al., 2006). One of the emerging biomarkers for depression in cancer patients is cortisol along with an immune system biomarker, interleukin-6 (Jehn et al., 2006). Researchers have proposed that these biomarkers can be used to identify people with cancer who are at risk for depression and then intervene proactively. Although further research is needed to better understand whether HPA dysregulation is the cause or a symptom of health disorders, researchers seem to agree that it is a mixture of both.

Another relevant use of cortisol in research might be as a psychobiological measure to mark, among many occupational therapy interventions, the potential effects of social participation and occupational engagement. HPA reactivity appears to be sensitive to environmental influence and interventions. Gitau, Modi, Gianakoulopoulos, Bond, and Glover (2002) demonstrated that cortisol levels were modifiable in preterm infants through skin-to-skin contact with mothers. In children, the social environment appears to influence responses to stress (Braarud & Stormark, 2006; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; Young, Vazquez, Jiang, & Pfeiffer, 2006) through both supportive (e.g., sensitive) and nonsupportive (e.g., parental depression) caregiving patterns. In adults, the HPA appears to be sensitive to social mediators as well, in the form of supportive friendships (Heinrichs, Baumgartner, Kirschbaum, & Ehlert, 2003). In other words, in the presence of supportive relationships, people appear to be able to lower their overall stress state, at least as measured by their stress-related hormones.

CASE STUDY: *Sensory Modulation Disorder in a 5-Year-Old Girl*

Gillian is a 5-year-old girl with some peculiar behaviors. Her parents are not quite sure how to understand her and think that at times she acts strangely for attention. However, they recently inquired about the possibility that Gillian has a sensory modulation disorder. As they describe her behavior to her pediatrician, it becomes clear that Gillian's behavior crosses a line into a functional impairment. For example, Gillian refuses to wear any clothes but two outfits, and she prefers that they be unwashed. She refuses all socks on her feet, stating that they "hurt." She protests if her mother attempts to wash her bedsheets, and she cannot tolerate having any windows open in the house. In addition, certain lights "hurt her ears," especially in grocery stores, and she is fearful of public places and anywhere there is the possibility of loud noises. To her parents' dismay, she does not like to be hugged or cuddled, and her diet is restricted to solid, firm foods such as apples, bread, and cheese. Her parents have also noticed that she seems to be developing anxiety around leaving the house. For example, she is now complaining about headaches and stomachaches, and she seems to become anxious and jittery for no apparent reason.

What are some psychobiological indicators that are possibly associated with Gillian's behavior? How would you determine whether she is experiencing stress responses related to otherwise non-threatening things in her environment? How might you incorporate stress management interventions to help Gillian with her sensory disturbances? Can you think of ways to use any psychobiological factor as an indicator of possible effectiveness of sensory integration intervention?

CASE STUDY: *Weight Loss and Obesity Prevention*

Jay is an occupational therapist working in a community-based outreach program for individuals with low incomes. Jay is interested in using a number of outcome measures that would demonstrate the effectiveness of an intervention program that he directs along with a dietitian, a nurse, and a social worker. The program's key purposes are to promote weight loss in low-income single mothers, to prevent obesity in children through participation in exercise that is embedded in daily routines, and to teach healthier eating habits. For example, participants learn to take the stairs when possible and to avoid elevators unless they need to go above five floors in a building. In addition, Jay teaches participants how to shop for healthy foods on a budget as well as low-fat meal preparation. The intervention group also works with the mothers on time management skills and on other forms of exercise. Many of the women and children in the program report high stress and anxiety levels that affect them daily. The team, in consultation with community physicians and university researchers, would like to include psychobiological measures as a part of their research approach, in addition to a number of other measures, including weight loss. Many of the mothers have elevated blood fats and are showing signs of developing type 2 diabetes.

- What questions could you ask about psychobiological factors in these women and children that are related in some way to their occupations and activities?
- What would you hope to see change if this program is effective?
- Are any psychobiological measures presented here that could address your questions?
- Where might you look for further information on psychobiological factors and obesity?
- How could occupational therapy practitioners complement research that is being done in other science areas?

2006). This pattern appears to run opposite to that of salivary cortisol; whereas cortisol peaks in the morning and gradually declines throughout the day, typical α-amylase patterns appear to demonstrate lower levels in the morning and higher levels in the afternoon and evening (Rohleder et al., 2004). To date, studies using α-amylase levels in typical children are just emerging (Granger et al., 2006), and nothing has been published regarding atypically developing children. There is also preliminary research using salivary α-amylase in pregnant women. The use of α-amylase as a biomarker appears promising, but there are obvious needs for future research in multiple samples across the life course.

Functional MRI

Functional MRI (fMRI) measures increased blood flow and oxygen use in different parts of the brain under stimulus-response conditions. This increased blood flow that supports the neural activity is accompanied by a characteristic decrease in a substance called deoxyhemoglobin, a normal by-product that is produced when cells extract oxygen from hemoglobin in the blood. Deoxyhemoglobin has weak magnetic properties that provide the source of the signal for the fMRI. The process is different from regular MRI in that no radioisotopes are injected into blood circulation. To collect fMRI data, an individual lies flat in an MRI scanner (Figure 56.8). A variety of auditory, visual, and touch stimuli (depending on the purpose of the fMRI) are introduced to the individual while he or she lies still in the apparatus. The individual then generates a response either by moving fingers (e.g., touching a clicker to respond "yes" to a question) or by saying something aloud (Figure 56.9).

Electroencephalography, Magnetoencephalography, and Event-Related Potential

An electroencephalograph (EEG) provides a noninvasive method of looking at brain activity. The EEG records the brain's natural electrical activity through electrodes that are strategically placed on an individual's scalp. EEG research has documented characteristic electrical signals or patterns for various states such as awake and sleep such that individual EEG signals can be compared to typical expectations. EEG is useful in displaying how long it takes and, broadly, what regions are important in processing various kinds of information in the brain. However, EEG does not show specific structures or which specific regions of the brain do specific tasks.

Magnetoencephalography (MEG) is a new technology that measures natural magnetic signals that are emit-
FIGURE 56.8 Magnetic resonance imaging (MRI) scanner.

COMMENTARY ON THE EVIDENCE

Relevant Research Using MRI or fMRI

Functional MRI (fMRI) is being used in a number of research studies related to human behavior. Recently, Aron, Gluck, and Poldrack (2005) noted that fMRI can be a stable measure over time in individuals, suggesting that it can be a reliable marker of brain development as well as neurodegeneration over time. Thus, fMRI might be a suitable biomarker for outcome-based research on the efficacy of occupational therapy interventions. For example, Talati, Valero-Cuevas, and Hirsch (2005) investigated brain function in normal individuals performing an in-hand manipulation of a spring that required calibration of force and fine motor accuracy. The researchers altered trials such that the participants performed the tasks sometimes under visual guidance and sometimes under tactile-only conditions. The findings noted that the neural networks to produce accurate fine motor performance required a highly distributed and integrated neural complex that included multiple structures in the brain, which sometimes differed depending on whether the participants used vision to guide their motor actions. This suggests that fine motor dexterity is interdependent on sensory input and that the processing of sensory input takes place in multiple areas. From a therapeutic standpoint, we might use this information to support using rich sensory experiences when helping others acquire or relearn fine motor skills. Erickson

and colleagues demonstrated, using fMRI as a psychobiological measure, that skills training in older individuals lessened cognitive decline, which is often associated with aging (Erickson, Colcombe, Elavsky, et al., 2007; Kramer, Colcombe, McAuley, Scalf, & Erickson, 2005). The results suggested that fMRI could detect beneficial changes in prefrontal areas in the brain as a result of training, as well as demonstrating that the aging brain was still capable of plasticity, or adaptive changes in response to the environment (Erickson, Colcombe, Wadhwa, et al., 2007).

Researchers who investigated specific brain regions associated with social interactions (Walter et al., 2004) provided another interesting example of fMRI use in behavioral studies. Their findings suggested that social interaction appraisal (e.g., understanding other people's intentions in social interactions) is supported by specific brain regions in the prefrontal cortex (e.g., the paracingulate gyrus area in the brain). Social intention understanding is important for a theory of mind (e.g., understanding that what others might be thinking may be different from your own thoughts) and is one of the significant deficits identified in individuals with autism spectrum disorders. A clearer understanding of the brain areas that may be impaired in diagnoses such as autism will help with diagnosis as well as contributing to new treatments and interventions.
FIGURE 56.9   MRI image of an individual's brain.

ted from brain activity. Although MEG produces a highly accurate record of brain cell activity, only a few machines are currently available worldwide because of cost (millions of dollars), size (eight tons or more), and advanced technology (a specialized quantum physics apparatus is needed). As with other machines that measure brain activity, MEG is impractical for investigating brain function under contextual demands such as meal preparation, self-care activities, and other occupations. However, it might prove useful for limited questions of functional performance similar to those posed in fMRIs.

The event-related potential (ERP) is similar to EEG in that it is a measure of electrical activity in the brain. However, the ERP is a neural signal that reflects the coordinated pattern of activity in groups of neurons as they respond to a meaningful event. Meaningful events for ERP analyses are usually noises or visual stimuli, but they can

---

CASE STUDY: *Constraint-Induced Techniques*

Tim works with adult stroke patients in an outpatient rehabilitation facility. He has recently learned how to use constraint-induced techniques with his patients and believes that he is seeing improvement of function. However, there is little information in the research literature that links this intervention approach to behavioral changes as well as the possible neural plastic changes that would support improved motor behavior. Tim contacts Rowan, a researcher in the area who is interested in the similar issues, and they decide to work as a team. Rowan and Tim decide to write a grant together and develop a research plan. What specific questions can you develop for their research topic that might use a psychobiological measure? How would you use this measure(s)? What are some of the behavioral measures that you would use in addition to your biomarkers?

---

also reflect emotional states or other internally generated "events." A type of ERP is the auditory evoked potential, which measures specifically brain activity to sounds. This is a powerful tool in determining the potential for hearing in people who otherwise cannot state whether they can hear (e.g., infants, nonverbal adults). One strength of ERP is the ability to see cortical networks as they engage and disengage depending on the events or the tasks that the person is doing. However, during assessment, an individual is connected with an elaborate head covering in which the electrodes are strategically placed, limiting the questions that can be posed of brain function while the person is engaged in occupational "doing."

Oxytocin

Oxytocin is a mammalian peptide composed of amino acids that is produced by the pituitary gland. It is a potent hormone in the body and neurohormone in the brain, responsible for sexual reproduction and supporting caregiving behavior, including stimulating milk production for breastfeeding. In both males and females, orgasm releases large of amounts of oxytocin. Moreover, if you have ever experienced the feeling of "love," you have experienced a rush of oxytocin in the emotional centers of your brain. Oxytocin is similar to vasopressin, another pituitary hormone/neurohormone that is responsible for salt and fluid regulation in the body as well as blood pressure. One of the effects of oxytocin in the brain is to suppress the HPA axis, thereby reducing levels of cortisol (Detillion, Craft, Glasper, Prendergast, & De Vries, 2004; Heinrichs et al., 2003) as well as blood pressure. Because oxytocin is associated with social behavior, it is an attractive psychobiological measure for studying human behavior in social contexts. The research is somewhat limited at the current time only because it is not an easy measure to collect. However, in concept, oxytocin would be an excellent biomarker for studies investigating the effects of social participation and occupational engagement in individuals with a variety of disorders that especially influence social abilities, including autism spectrum disorder, obsessive-compulsive disorder, and schizophrenia. More-

over, it would be an effective biomarker for documenting the effects of stress management interventions, since studies document that oxytocin acts as a buffer for the stress hormone cortisol (Heinrichs et al., 2003; Kiecolt-Glaser et al., 2005), especially when individuals have companionship.

Oxytocin can only be measured in blood or cerebral spinal fluid at this time, and levels of oxytocin appear to change within seconds and/or within a few minutes in response to an environmental stimulus, making its use as a psychobiological measure somewhat limited in human studies.

SUMMARY

Sophisticated and adaptive mind-body connections in humans allow for the richest and most complex behaviors on the planet. Indeed, we are such elaborate thinkers and doers that we risk underappreciating and perhaps even missing the more subtle aspects of our behavior. Moreover, we can sometimes use our language skills to either dismiss or cover up our "true" feelings in certain situations. This chapter presented information about the subtle signs and "hidden" indicators linked with human behavior that offer us a peek into how internal body processes support interest, motivation, and engagement in activities and occupations. Sometimes individuals are not aware of the influences that, for example, a health condition might be having on their performance. Some people might not be aware of psychological reasons that can influence participation and fulfillment. Others might mask their true feelings for a variety of reasons, and unless voiced, these feelings can impede daily functioning. Moreover, some individuals certainly attempt to dull or bury unmanaged stress, anxiety, worry, or pain by abusing alcohol or drugs, by overeating or undereating, or by participating in other risky activities that can impair their health and well-being. We might not care so much about these subtle psychobiological factors if they did not have so much influence on our participation in daily life activities and occupations and on our overall health. Indeed, many of

these psychobiological factors, as we discussed in this chapter, are related to either physical or psychological stress that can greatly affect our health and well-being. The extent to which occupational therapy practitioners are aware of subtle psychobiological factors will influence and shape their practice. It is important that practitioners appreciate the ways in which psychobiological factors may be observed and understand the potential messages that they can impart about their clients' wellness, health, and participation in life activities and occupations. Furthermore, practitioners should know a wide variety of stress management techniques and be prepared to use them along with other practice skills in any area of occupational therapy practice. Finally, an enhanced appreciation of psychobiological factors and their potential in research will help to define the next generation of occupational science scholars and therapy practitioners by giving us a better understanding of mind-body relations in human functional performance as well as by adding to objective documentation of the effectiveness of therapy intervention.

Evaluation and Intervention for Cognitive Perceptual Impairments

57

JOAN PASCALE TOGLIA,
KATHLEEN M. GOLISZ, AND
YAEL GOVEROVER

Learning Objectives

After reading this chapter, you will be able to:

1. Define cognition and describe its association with activity limitation and participation.
2. Discuss the role of occupational therapy practitioners in cognitive rehabilitation.
3. Describe the key characteristics of three evaluation approaches that can be used in cognitive rehabilitation.
4. Discuss the difference among the main three intervention approaches: remedial, functional, and multicontext.
5. Discuss the factors that need to be considered when choosing evaluation and intervention approaches.
6. Define specific cognitive and perceptual skills, identify possible assessments to evaluate these skills, and discuss the different approaches for therapy that are described for each cognitive and perceptual skill.

"Thinking, remembering, reasoning, and making sense of the world around us are fundamental to carrying out everyday living activities" (Unsworth, 1999, p. 3). **Cognition** consists of interrelated processes including the ability to perceive, organize, assimilate, and manipulate information to enable the person to process information, learn, and **generalize** (Abreu & Toglia, 1987). Because so much of rehabilitation in general requires learning

and generalization, the principles of intervention that are discussed in this chapter are important to consider with a wide spectrum of clients and are not limited to those who are typically identified with cognitive impairments. Cognitive impairments may be seen as a result of developmental or learning problems, brain injury or disease, psychiatric dysfunction, or sociocultural conditions (American Occupational Therapy Association, 1999). Cognitive impairments can result in significant activity limitations and participation restrictions in all aspects of the client's life, potentially compromising safety, health, and well-being. For example, decreased abilities to recognize potential hazards, anticipate consequences of actions and behaviors, follow safety precautions, and respond to emergencies are often major factors that interfere with independence. Cognitive limitations can also diminish one's sense of competence, self-efficacy, and self–esteem, further compounding difficulties in adapting to the demands of everyday living. The influence of cognitive symptoms can be observed across all aspects of the domain of occupational therapy practice. The aim of occupational therapy intervention for people with cognitive-perceptual impairments is to decrease activity limitations, enhance participation in everyday activities, and assist individuals to gain the abilities they need to take control over their lives and develop healthy and satisfying ways of living. Although the ultimate goal of intervention with this population is clear, there are different perspectives and rehabilitation approaches to accomplish the goal. These approaches are discussed in detail in this chapter.

OCCUPATIONAL THERAPY ROLE WITHIN A MULTIDISCIPLINARY TEAM

Currently, there is no single discipline that is responsible for the evaluation and intervention of cognitive-perceptual impairments. Multiple team members have the potential to make valuable contributions to understanding the client who has a cognitive-perceptual impairment. A strong interdisciplinary approach is needed to address the complex of issues that arise from cognitive-perceptual problems. Team goals should be identified, as well as specific discipline goals. The family and client are also members of the team and should be involved in team discussions and provide input into the overall intervention plan.

Occupational therapists provide a unique contribution to the evaluation and rehabilitation of cognitive perceptual process skills because of their educational background, knowledge of occupation, training in activity analysis, and ability to analyze how cognitive-perceptual symptoms are affected by changes in activity demands and context. The role of the occupational therapist in evaluating cognition and perception is to provide clear, comprehensive information on the effect of cognitive-perceptual impairments on activities of daily living (ADLs), instrumental activities of daily living (IADLs), education, work, play and leisure, and social participation. The work environment in which the therapist practices may determine the depth of the occupational therapist's involvement because of the nature of the practice setting and the client's length of stay.

An interdisciplinary intervention program should emphasize the same major goals during intervention rather than working on separate skills. For example, the speech-language pathologist might address **attention** problems within the context of language material, such as listening to tapes or conversations; the neuropsychologist might use remedial attentional exercises; the physical therapist might reinforce attention through motor tasks; and the occupational therapy practitioner might address attentional strategies within the context of self-care, leisure, community, or work activities. An integrated approach that assists the person in seeing patterns of behaviors across different activities is strongly advocated, rather than one that reinforces the fragmentation that the client already perceives.

The occupational therapy assistant works in cooperation with the occupational therapist to contribute to the evaluation process and implement aspects of the occupational therapy intervention plan (AOTA, 1999). If state licensure permits and service competency has been demonstrated, an occupational therapy assistant can administer selected portions of cognitive assessments as directed by the occupational therapist, provide clinical observations, and complete behavioral checklists. Once the targeted behaviors for intervention have been clearly identified, the occupational therapy assistant and occupational therapist collaborate to choose a variety of different activities that can be used to reinforce the desired behaviors.

THE PROCESS OF COGNITIVE REHABILITATION

Evaluation

This section provides detailed information about cognitive evaluation issues that are necessary for practitioners to understand before choosing and performing appropriate evaluations and assessments. We present the importance of the evaluation process, its goals, and important considerations in choosing an assessment.

The evaluation process begins with an occupational profile that considers the client's typical routines and occupations (AOTA, 2002). The client is usually asked to identify everyday activities that he or she is most concerned about or would like to be able to do with greater ease. However, people with cognitive impairments often have limited awareness of their impairments and limited understanding of the implications of these impairments (Goverover, Chiaravalloti, & DeLuca, 2005); therefore, a close relative or friend should participate in identifying concerns and priorities for intervention. It should be kept in mind that in inpatient settings, clients and their relatives might be unaware of the presence of mild cognitive impairments. Subtle cognitive symptoms tend to be apparent only

in higher-level activities such as driving, social participation, shopping, or using public transportation. A client in an acute or rehabilitation inpatient setting has not yet had the opportunity to resume these higher-level activities.

Comprehensive cognitive evaluations are needed for two primary reasons. First, evaluations provide evidence and information about the presence of impairments and competencies. Such information can be used to establish baselines, to plan discharge, and to measure intervention effectiveness (e.g., rehabilitation outcomes). Second, evaluations are needed to gather information for intervention planning. Models for cognitive intervention in occupational therapy often guide the focus of evaluation. For example, the cognitive disability model (Allen, 1985) and the neurofunctional model (Giles, 2005) focus on occupational performance and are not concerned with identifying specific cognitive impairments. The cognitive disability approach (Allen, 1985) describes hierarchical levels of cognitive function. Evaluation focuses on identifying the cognitive level at which the person is functioning. The neurofunctional approach (Giles, 2005) emphasizes training functional skills and habits within naturalistic settings; therefore, evaluation emphasizes observation of real-life functioning. The quadrophonic approach (Abreu & Peloquin, 2005) and the cognitive retraining model (Averbuch & Katz, 2005) are concerned with identifying and understanding the cognitive impairments that are influencing occupational performance. Measures of cognitive impairment are examined in combination with broader measures of occupation to guide intervention. The multicontext approach (Toglia, 2005) is concerned with facilitating transfer of learning, so evaluation emphasizes evaluation of learning potential or dynamic assessment. Each of these perspectives is described in greater detail later in the chapter.

Approaches to Evaluation of Cognitive Impairments

Traditional Approaches to the Evaluation Process

Standardized cognitive assessments have specific administration guidelines and compare the client's performance to normative data. They are static in nature, evaluating "here and now" performance. Standardized assessments can help the occupational therapist to determine whether a cognitive impairment exists and to quantify the severity of such impairments. These types of assessments are also useful as baselines against which changes in condition or ability can be measured over time. Examples of standardized assessments are summarized in Table 57.1.

Cognitive-screening assessments are a type of standardized assessment designed to identify problems that need special or further attention. They typically comprise subtests that are divided into specific cognitive subskills such as attention, visual processing, **memory**, and **executive functions**. These assessments are either general in nature, addressing all cognitive subskills, such as the Lowenstein Occupational Therapy Cognitive Assessment,

(Katz, Itzkovich, Averbuch, & Elazar, 1990), or more focused evaluations of a particular subskill, such as the Motor Free Visual Perception Test (Colarusso & Hammill, 2002). Impaired performance on a specific task or subtest is typically used to define the impairment. For example, difficulty differentiating foreground objects or figures from background objects (e.g., picking up a white sock off a white sheet) would be identified as a figure-ground impairment (Zoltan, 1996).

Many cognitive-screening assessments were designed to be used with specific populations, such as clients with strokes (Hajek, Rutman, & Scher, 1989), multiple sclerosis (Rao, Leo, Bernardin, & Unverzagt, 1991), dementia (Mattis, 1976), or traumatic brain injury (Ansell & Keenan, 1989) or elderly clients (Golding, 1989). These assessments have subtests that focus on areas of impairment that are typically seen within the diagnostic population.

Mental status exams, such as the popular Mini-Mental State Exam (Folstein, Folstein, & McHugh, 1975) and cognitive screening assessments have some disadvantages, as they rely heavily on verbal skills, can be culturally biased (owing to comparison to normative populations), and have substantial false-negative rates (i.e., missing possible cognitive impairments). The deficits of clients with focal lesions, particularly right-hemisphere lesions, or mild diffuse cognitive disorders are often missed (Nelson, Fogel, & Faust, 1986). Cognitive-screening assessments usually miss more subtle impairments that are displayed by higher-level, clients as the breadth and depth of item content are limited (Doninger, Bode, Heinemann, & Ambrose, 2000).

Direct Observation of Function

Direct observation of function is an alternative method that is used to identify cognitive-perceptual impairments. A variety of standardized functional assessments (presented in Table 57.1) use a numerical or descriptive scale to rate performance and the amount of cognitive cueing and/or physical assistance required to complete a particular task. Some functional assessments are designed to identify the cognitive and perceptual impairments that interfere with successful performance on such tasks. For example, in the OT-ADL Neurobehavioral Evaluation (A-ONE) (Arnadottir, 1990), a client is observed performing a basic ADL activity (e.g., putting on a shirt) for possible cognitive impairments such as spatial relation difficulties, unilateral spatial or body neglect, and the like. The Executive Function Performance Test (Baum, Edwards, Morrison, & Hahn, 2003; Goverover et al., 2005) is another functional performance test that analyzes cognitive impairments such as initiation, organization, and safety by observing client performance on IADL activities such as making a phone call.

Functional tasks require the integration of a variety of skills, so it can be difficult to isolate the specific cognitive problems interfering with performance. Some functional assessments try to identify broad areas of cognitive and

Test of Oral and Limb Apraxia [TOLA] (Helm-Estabrooks, 1992)

---

perceptual strengths and weaknesses by identifying the underlying processes that contribute to difficulty in performing functional tasks. Therefore, subtle cognitive impairments might not be readily apparent in familiar activities. Functional assessments that simulate performance in a treatment setting might not be predictive of performance in natural **contexts** in which the person has to set goals, plan, initiate, problem-solve, and deal with subtle and complex environmental cues.

Situations that require higher-level cognitive-perceptual skills are difficult to capture in structured treatment environments. In addition, contextual factors can increase or decrease cognitive demands of performance, so it important to consider the context in which an activity is performed. Hamera and Brown (2000) developed the Test of Grocery Shopping Skills as a real-world measure of community function for people with chronic schizophrenia. Clients are asked to shop for a list of 10 grocery items in a natural context. In hospital-based treatment settings, the occupational therapist might not be able to create a close enough approximation of a real-world environment. The contextual influence on performance needs to be kept in mind, and if feasible, performance should be observed across real-world contexts.

Other tools that involve direct observation of performance have been developed to measure the cognitive levels associated with the cognitive disability model. For example, the Allen Cognitive Level Screen (ACLS) (Allen, 1985) uses a leather-lacing task to provide a quick measure of learning and an initial estimate of cognitive function. The ACLS screen is then validated by further observations of performance in craft activities or ADL/IADL activities using additional tools such as the Routine Task Inventory (RTI), Allen Diagnostic Module craft projects, or the Cognitive Performance Test (Allen, 1993; Allen, Earhart, & Blue, 1992).

These tools are interpreted within Allen's conceptual framework and focus on broadly identifying the person's cognitive level or general information-processing capacities. In contrast to functional assessments that are concerned with rating specific cognitive skills or the degree of assistance that is required on specific functional tasks, assessment of the person's cognitive level involves global functional abilities and is meant to explain and predict ability to function in various activities and contexts (Levy & Burns, 2005).

See Table 57.1 for detailed information about performance-based ADL evaluations.

Dynamic Assessment

Dynamic assessment is a nontraditional approach to evaluation that uses cues, mediation, feedback, or alterations of activity demands during assessment to examine changes in performance. Unlike standardized assessments, the focus is not on the outcome of performance but on the

processes of learning and change. Dynamic assessment has also been referred to as assessment of learning potential or cerebral plasticity.

Dynamic assessment investigates a person's ability to learn certain tasks and identifies the conditions that facilitate such learning. The objective is to discover what the person is capable of doing with assistance, or under favorable conditions to determine the full range of performance potential. Because dynamic assessment is interested in *how* performance can be facilitated, it is naturally linked to intervention. During an evaluation, the therapist intervenes to change, guide, or improve the person's performance by demonstrating strategies, providing cues, or modifying the activity (Tzuriel, 2000). This information directly relates to intervention planning. For example, if performance cannot be modified through dynamic procedures, then an intervention approach that seeks to change the environment or train caregivers might be more appropriate than an approach that focuses on changing a person's abilities or behaviors. Dynamic assessment methods have been applied to a wide range of ages and people with cognitive disabilities, including those with developmental disabilities (Hessels-Schlatter, 2002), schizophrenia (Rempfer, Hamera, Brown, & Bothwell, 2006; Wiedl, 2003), stroke, brain injury (Haywood & Miller 2003; Toglia, 2005), and Alzheimer's disease (Fernandez-Ballesteros, Zamarron, & Tarraga, 2005). However, research applications and specific tools are limited. Toglia (2005) describes the use of a dynamic assessment approach for people with brain injury within the framework of a dynamic model of cognition. Dynamic assessment and intervention within this model involve investigating self-perceptions of abilities before and after activity experiences, facilitating change in performance if a person has difficulty, and investigation and analysis of strategy use. The Contextual Memory Test (Toglia, 1993b) and Toglia Category Assessment (Toglia, 1994) are two examples of dynamic assessments (Table 57.1). Other resources by Toglia (2005) provide information on how to apply the dynamic assessment process in practice.

Proponents of dynamic assessment claim that conventional static assessments are incomplete in describing the range of performance potential. There is a considerable difference between identifying and quantifying deficits and making specific recommendations for intervention. A more comprehensive picture of the person's ability, including responsiveness to learning situations, is needed to provide guidance for intervention (Kolakowsky, 1998; Lidz, 1991; Tzuriel, 2001). Dynamic assessments therefore do not replace standardized tests but supplement the information that is obtained and provide direct guidance for intervention planning.

Choosing the Most Appropriate Type of Assessment

In selecting the most appropriate type of assessment, an occupational therapist must first decide what questions need to be answered. The therapist can then select the assessment that will most effectively address such questions. Some factors to consider before choosing an assessment include questions such as the following:

1. *Does the therapist need to clarify the presence of cognitive impairments?* To answer this type of question, a traditional evaluation approach can provide the therapist with a normative comparison. The extent to which the person's scores deviates from expected performance within the person's age group identifies the presence and severity of cognitive impairments.

2. *Does the therapist need to understand the effect of cognitive-perceptual impairments on occupational performance (i.e., the activity limitation and participation restrictions from the International Classification of Function (ICF) (World Health Organization, 2001)?* This question could be answered by through direct observation of function. This top-down approach to evaluation permits the evaluator to determine how cognitive impairment affects functional performance or activity participation (Goverover, 2004; Goverover et al., 2005).

3. *Does the therapist need information to guide intervention?* The model of cognitive intervention that the therapist is using, often guides the selection of evaluation tools. Dynamic assessments emphasize the processes that are involved in learning and change (Grigorenko & Sternberg, 1998) and may provide information that is needed to plan and guide intervention that focuses on changing skills or behaviors.

4. *Does the therapist need to establish a baseline as a measurement of change or outcome of intervention?* To answer this question, the therapist needs to take into consideration short-term and long-term intervention goals. In documenting outcomes, it is important to take into consideration the three levels of disability described by the ICF: impairment, activity limitation, and participation restriction. Therefore, a cognitive perceptual evaluation that includes these three components will provide a more comprehensive view of the person's functioning.

OVERVIEW OF INTERVENTION APPROACHES

Interventions for people with cognitive dysfunction differ in the areas that are targeted for intervention and in the underlying assumptions about individuals' abilities to learn and generalize information. The characteristics and underlying assumptions of the different intervention approaches are explored in this section. Factors that are critical in the selection of these intervention approaches as well as methods for systematically integrating them are also discussed. As you read this section, review the case study on cognition and performance context.

CASE STUDY: *Cognition and Performance Contexts*

Scenario 1

Mr. James is a 24-year-old man with a 10-year history of attention and memory problems related to a head trauma that he sustained at age 14. He has difficulty recalling conversations and events that occurred just hours before. During performance of a task, he easily loses track of the steps and repeats some steps twice while omitting other steps altogether. Mr. James denies any difficulty with his concentration or memory and would like to return to school. He currently lives with his parents, who care for him.

Scenario 2

Mr. Cornwall is a 64-year-old man with attention and memory problems related to a head trauma that he sustained three weeks ago. He has difficulty recalling conversations and events that occurred just hours before. During performance of a task, he easily loses track of the steps and repeats some steps twice while omitting other steps altogether. Mr. Cornwall is well aware of his difficulties and is depressed by them. For example, he states, "I can't even remember what I ate for breakfast. What good am I? If I have to give up my business, my life is over." Mr. Cornwall was recently widowed and lived alone before his accident.

Questions

The two scenarios describe the same clinical symptoms, but the performance contexts are different.
1. How do the differences in context influence the emphasis in intervention that you would use?
2. What influenced your selection?

Discussion

There are no absolute right or wrong answers to these questions. In scenario 1, Mr. James is 10 years postinjury, so the potential for change in the underlying cognitive skills is assumed to be minimal. A remedial approach that focuses on improving memory and attention skills would not be warranted unless there was some evidence of potential for further improvement. Compensatory strategies, such as use of a memory notebook or a checklist, could be considered. However, Mr. James denies any difficulty in memory or attention. This lack of self-awareness will present a major obstacle to independent initiation and use of compensatory strategies.

Caregiver training, task and environmental adaptation, and the possibility of functional skill training to increase performance on a specified task appear to be the most appropriate areas for intervention. Techniques to increase awareness may be attempted as a prerequisite for using compensatory aids. External memory aids, such as memory notebook training, may be introduced by using task-specific training methods in combination with maximum prompts and external cues for their use; however, success likely depends on Mr. James's ability to gain some awareness and acceptance of his disability.

In scenario 2, Mr. Cornwall is only three weeks post-injury, so that the potential for change in the underlying skills is presumably present. In addition, Mr. Cornwall is well aware of his problems. This would appear to make him a prime candidate for remedial techniques. However, he is also depressed by his difficulties. He might not be able to cope emotionally with an approach that focuses on the underlying client factors.

An approach that will provide greater opportunities for success and control over his environment could be the initial intervention emphasis. For example, adaptive techniques in which the caregiver or practitioner presents directions one step at a time might make it easier for Mr. Cornwall to follow task instructions. Training in the use of compensatory strategies, such as use of a memory notebook to keep track of daily events and conversations and in use of a checklist to assist in keeping track of task steps that have already been completed, might enhance task performance. As Mr. Cornwall gains self-confidence and control, remedial tasks that focus on improving attention may be gradually introduced if he is able to tolerate them.

Capitalizing on the Assets: The Functional Approach

The functional approach capitalizes on the person's assets to improve occupational performance. The emphasis is on reducing activity limitations and participation restrictions rather than on remediating or restoring impaired skills (Figure 57.1). The functional approach can be subdivided into three intervention techniques: adaptation of the activity or context, functional task training, and compensation. The Cognitive Disability Model (Allen, 1985) emphasizes use of adaptation, while the Neuro-functional Approach (Giles, 2005) focuses on functional task training.

Adaptation of the Activity or Context

Adaptation involves changing, altering, or structuring the activity demands or context to prevent disruptive behaviors or accidents, minimize cognitive or perceptual demands of a task, minimize caregiver burden, and maintain the client's level of functioning (Erikson, Karlsson, Soderstrom, Tham, 2004; Radomski, Dougherty, Fine, & Baum, 1993). Rather than providing direct intervention to the client, the focus

FIGURE 57.1   A pill box organizer can be an important contextual cue to help those with memory impairments safely self-administer medications.

is on providing support, education, and training to the caregiver, family, or employer (Sohlberg, Glang, & Todis, 1998). Adaptations should directly address the problems and needs that have been identified by the client or significant other and be designed in collaboration with them (Campbell, Duffy, & Salloway, 1994) Adaptations might be fixed (e.g., installing an alarm on a door to prevent wandering), or they might require ongoing implementation and monitoring (e.g., preselecting clothes from the closet on a daily basis). In the latter case, implementation depends on the ability, consistency, and reliability of another person.

In some cases, a significant other can be trained to alter or structure the activity demands or context to maintain the person's performance capabilities. For instance, the person might not be able to attend to the task of preparing a meal but might be able to perform individual components, such as mixing the salad or folding napkins in half for the table setting. Engagement in such meaningful activity components can help to maintain the client's performance capabilities and prevent disruptive behaviors (Levy & Burns, 2005). Although adaptations can produce rapid changes in function, the effects are limited to the activity or environment that is adapted, and success often depends on the extent to which other people are able to consistently follow through with the adaptations.

Adaptation: The Cognitive Disability Approach

Allen (1985, 1993) designed a cognitive disability approach that provides guidelines for matching and adapting the individual's cognitive level with activity demands. This approach for evaluation and intervention was designed initially for people with psychiatric disorders and chronic cognitive disabilities (e.g., dementia) and later was expanded

for individuals with different central nervous system problems resulting in cognitive impairments (e.g., stroke).

In this model, function is organized into six ordinal levels of global function ranging from normal (level 6) to profoundly disabled (level 1). Modes of performance within each level further qualify behavior variations and allow for more sensitive measurement of the person's capacity. To get an elaborated description of the Allen Cognitive Level, refer to Allen (1985) and Levy and Burns (2005). Each of Allen's cognitive levels has three components: attention, motor control, and verbal performance. The person's cognitive progress can be seen as a continuum along two dimensions, motor and verbal performance, which are linked by attention.

The six cognitive levels are used to describe functional profiles of capacities and limitations that help to clarify and direct interventions and care. Allen's model provides clinicians with intervention guidelines for different levels of cognitive function. For example, the cognitive levels identify the required assistance needed, as well as what the person is still able to do safely. This information is used to educate and train caregivers and to make recommendations for assistance and environmental adaptations to optimize function and safety. It is also used to select activities that match the person's cognitive level and maximize participation in meaningful occupations (Allen, 1985; Allen et al., 1992; Levy & Burns, 2005).

Functional Task Training: The Neurofunctional Approach

Giles (2005) describes a neurofunctional approach that emphasizes the use of task-specific training or rote repetition of a specific task or routine within natural contexts to develop habits or functional behavioral routines. Emphasis is on the mastery of functional task performance through practice rather than on the underlying skills that are needed to perform the task. Giles (2006) states that development of new functional habits and routines can occur in clients who have decision-making deficits and only minimal awareness of their impairments. Behavioral techniques, including reinforcement and chaining, are incorporated into practice sessions. Intervention involves breaking down a functional task into small subcomponents (Giles, 2005; Glisky, Schacter, & Butters, 1994). Techniques such as errorless learning or the method of vanishing cues may be used. In errorless learning, the person is prevented from making incorrect or inappropriate responses during the learning process. The vanishing cue method involves systematically reducing or fading the cues that are required to perform a task. There is evidence that errorless learning techniques are more effective than the vanishing cue method in people with severe memory impairment (Evans, Levine, & Bateman, 2004; Kessels & de Haan, 2003; Page, Wilson, Sheil, Carter, & Norris, 2006).

Functional task training capitalizes on procedural or implicit memory. Case studies have demonstrated that

functional task training can produce significant changes in activities of daily living and work tasks in people with severe impairments (Giles, 2005; Giles, Rideley, Dill, & Frye, 1997; Giles & Shore, 1989; Glisky et al., 1994, Hallgren & Kottorp, 2005; Kottorp, Hallgren, Bernspang, & Fisher, 2003). However, intervention addresses only one task or routine at a time, and extensive training, time, and effort may be required to achieve success within one task sequence and environment. The person might have difficulty in dealing with minor changes in the task stimuli or the environment. Proponents of this method argue that people with cognitive impairment should be treated in the natural context in which they will function, because people with brain injury have difficulty generalizing learning (Giles, 2005; Glisky et al., 1994).

Compensation

Compensation teaches the person to bypass or minimize the effects of the impairment by modifying the method that is used to perform an activity. The client is expected to initiate and implement the use of an external aid or strategy to enhance occupational performance in a variety of different situations (AOTA, 1999). The complexity of the task and the compensatory strategy may require awareness and acceptance to be generalized and independently applied to a variety of situations (Birnboim & Miller, 2004; Toglia, 1993a). For example, a memory notebook could be used to compensate for memory loss. Independent use requires that the person recognize that he or she is having difficulty with memory and perceive the need to write things down to aid in remembering. It also requires initiation of use of the book in multiple situations. Clients with more severe cognitive impairments can be trained, through rote repetition and errorless learning, to use simplistic compensatory strategies and modifications with minimal awareness of why the strategy is needed (Giles, 2006; Hallgren & Kottorp, 2005; Kottorp et al., 2003). In these clients, the compensatory strategy becomes automatic and integrated into the person's habits or functional routines.

Addressing the Cognitive Perceptual Impairment

The Remedial Approach

Remedial approaches place an emphasis on restoring impaired cognitive-perceptual skills (Unsworth, 2007). The emphasis is on changing the person's underlying skills rather than on manipulating the activity demands or context (Neistadt, 1990; Zoltan, 1996).

In traditional cognitive-perceptual remedial approaches, cognitive skills are conceptualized in terms of higher cortical skills, which are divided into a hierarchy of discrete subskills such as attention, discrimination, memory, sequencing, categorization, concept formation, and problem solving. The lower-level skills provide the foundation for more complex skills and behaviors (Toglia, 1998). For example, attention skills are addressed before higher-level cognitive skills such as problem solving. Intervention emphasizes practice of the specific cognitive or perceptual skills that are deficient, using worksheets, computerized exercises, and electronic scanning devices. One example of a remedial training program is the Attention Process Training Program (Sohlberg & Mateer, 1989a, 2001). This program includes graded worksheets and audiotapes that are systematically graded to place increasing demands on different aspects of attention.

It is assumed that improvement in underlying cognitive perceptual skills will have a greater influence on behavior than will direct training of functional task training because learning will spontaneously generalize to a wider range of activities. For example, if block design construction improves during remedial treatment, it is assumed that there will also be improvement on a wide range of other tasks involving constructional skills, such as dressing or making a sandwich. Remedial training has also been referred to as the transfer training approach (Toglia, 1998).

Improving underlying cognitive or perceptual deficits is thought to promote recovery or reorganization of the impaired skill. Information on functional reorganization and adult brain plasticity supports this view. For example, it has been postulated that some parts of the brain may assume new functions or work together in different ways as a result of environmental experiences (Luria, 1973). Functional magnetic resonance imaging that show changes after cognitive rehabilitation provides preliminary support for this premise (Laatsch, Little, & Thulborn, 2004; Laatsch, Thulborn, Krisky, Shobat, & Sweeney, 2004; Wykes et al., 2002). However, Neisdadt (1994) observed that "because both remedial and adaptive intervention approaches stimulate clients to learn new behaviors, neither approach can claim to take advantage of adult brain plasticity more than the other" (p. 426). Dirette, Hinojosa, and Carnevale (1999) compared remedial and compensatory training and found no significant difference between the two approaches. It was observed that participants in the remedial group began to use compensatory strategies, thus confounding results. Remedial activities focus on the area of impairment and provide structured tasks that accentuate the problem areas; therefore, awareness and insight into one's impairments may improve as a secondary effect. The emergence of awareness could allow some individuals to initiate use of compensatory strategies.

There is some evidence that supports the effectiveness of remedial intervention for specific cognitive skills, such as attention and visual scanning. However, intervention has been found to be more effective when it incorporates use of self-monitoring techniques and strategy training across a variety of activities (Cicerone et al., 2005). Studies have not supported the isolated use of repetitive graded memory drills, computerized memory games, logic games, or other cognitive remedial activities.

Recently, occupational therapists have described several models that utilize a combination of approaches. These include the cognitive retraining model, the quadraphonic approach, and the multicontext approach.

The Cognitive Retraining Model

Averbuch and Katz (2005) describe a comprehensive occupational therapy cognitive retraining model for adolescents and adults with neurological disabilities that integrates cognitive remedial training with strategy use and awareness of abilities to broaden the capacity for learning. The model draws on neurophysiological, neurobiological, and neuropsychological theories to provide a framework for cognitive learning. Training is directed at initially improving impaired cognitive functioning and may involve systematic and structured training in visual scanning, categorization or classification, sequencing, planning or thinking operations. Cognitive training gradually increases the amount and complexity of information presented but, at the same time, teaches new strategies to improve impaired functioning. Once clients learn to use strategies within a variety of activities within the clinic, they practice these strategies in real-life situations. The authors use a combination of paper-and-pencil exercises, tabletop and computer activities, and functional activities. If the client is incapable of using specific remedial-based strategies, procedural strategies that focus on training the components parts of a task are used to promote the ability to perform activities of daily living (Katz & Hartman-Maeir, 2005).

The Quadraphonic Approach

The quadraphonic approach incorporates a micro perspective that provides guidelines for addressing cognitive impairments as well as a macro perspective that provides a holistic perspective. The micro perspective integrates information from information-processing, teaching-learning, neurodevelopmental, and biomechanical theories to provide guidelines for evaluation and treatment of cognitive perceptual skills (e.g., attention, memory, problem solving, and motor planning) and postural control dysfunction. The macro perspective embraces an individualized, client/learner-centered model of therapy within a holistic occupational framework. There is a focus on the client-therapist relationship, occupational engagement, and health adaptation or wellness. The macro perspective examines the person's satisfaction, subjective well-being, meaningful occupations, and lifestyle through the use of interviews, storytelling, storymaking, and narrative analysis. The model conceptualizes a fluid, dynamic movement back and forth between the micro and macro perspectives and argues that performance skills and whole-person engagement in occupation need to be considered together (Abreu & Peloquin, 2005).

The Multicontext Approach

The multicontext approach is based on the dynamic interactional model of cognition (Toglia, 2005). This model draws heavily from cognitive and educational psychology. It emphasizes the dynamic nature of cognition and explains how cognitive symptoms and occupational performance change depending on a combination of person factors (unique characteristics of the person such as lifestyle, personality, beliefs, and values; information-processing capacity, self-awareness, and strategy use) as well as activity demands and environmental factors. Intervention based on this model may emphasize the person, task, or environment or a combination of all three. The multicontext approach is based on this model but is narrower in focus and provides specific guidelines for facilitating awareness and strategy use within activities or environments that might need to be modified so that they are at a "just right" challenge level (i.e., activities that are not too difficult but also not too easy) for the client. This approach emphasizes facilitating transfer of learning.

For example, in the multicontext approach, the person practices application of a targeted strategy such as use of a checklist, mental rehearsal, or self cues across purposeful and occupation-based activities that systematically differ in appearance yet remain at a similar level of difficulty. This places gradual demands on the ability to transfer learning because the more two situations or activities are physically similar, the easier it is to transfer strategies learned in one situation to another (Davidson & Sternberg, 1998; Toglia, 1991b). Table 57.2 shows an example of intervention activities presented along the transfer continuum. Activity demands are not graded in difficulty until evidence of spontaneous strategy use along the entire transfer continuum is observed. The use of awareness training techniques to facilitate self-monitoring skills and self-evaluation is deeply embedded throughout intervention.

The multicontext approach has been used with adults with brain injury (Toglia, 2005) and schizophrenia (Josman, 2005) as well as with children and adolescents (Cermak, 2005; Josman, 2005). It has also been utilized to guide individual as well as group treatment programs (Harrison et al., 2005; Landa-Gonzalez, 2001; Toglia, 2005).

SELECTING INTERVENTION APPROACHES

In planning intervention, the clinician considers the following questions: How much change is expected from the person? How much learning and generalization are expected? How much do the activity demands or context need to be changed or altered to meet the person's capabilities? Is the person responsive to cues? Is the person

TABLE 57.2 THE TRANSFER CONTINUUM							
Strategy emphasized in all activities: Use a checklist to gather and keep track of items to:							
Very Similar		**Somewhat Similar**		**Different**		**Very Different**	
Make vegetable salad (6–8 items)	Make fruit salad (6–8 items)	Set a table for dinner (For 6–8)	Pack 6–8 items in a lunch-box	Pack 6–8 items in a bag for an over-night stay	Put a list of 6–8 appoint-ments in a calendar	Use a list to complete 6–8 party invitations	Use a list to complete 6–8 errands

aware of his or her difficulties? If the person is completely unaware of his or her difficulties, is unresponsive to cues, or does not show potential for change within the intervention time frame, a treatment approach that targets change in strategy use such as the multicontext approach or cognitive retraining approach might not be appropriate. It might be more appropriate to use the cognitive disability model or an approach that changes the environment or activity rather than the person. The neurofunctional approach, which uses repetitive practice to change performance on a specific task, might also be indicated. Assumptions regarding awareness and learning within intervention models need to be carefully considered in planning intervention (Toglia, 2005). This is reflected in Case Study 57-1.

COGNITIVE IMPAIRMENTS: DEFINITIONS, EVALUATIONS, AND INTERVENTIONS

In this section, the main constructs involved in cognition will be discussed in terms of their definitions, evaluation, and treatment. Self-awareness will be discussed first because lack of awareness can affect the motivation, effort, and sustained participation that are needed for intervention.

Following discussion of self-awareness, the areas of **orientation**, attention, memory, executive functions, **motor planning**, **unilateral neglect**, and visual processing will be reviewed. Some of these concepts are also described and summarized in Table 57.3. Although these areas are discussed separately for the purposes of description, it should be kept in mind that cognitive problems are interrelated and rarely occur in isolation.

Evidence-based reviews in cognitive rehabilitation have found that training in strategies, and self-monitoring or self-regulatory skills are key characteristics of studies demonstrating the effectiveness of cognitive rehabilitation (Cicerone et al., 2000, 2005). These interventions will therefore be emphasized. It should be kept in mind that the context of the person's life needs to be considered in plan-

ning and choosing intervention activities (Johnston, Goverover, & Dijkers, 2005). This includes the person's occupations, personality, interests, premorbid level of functioning, culture, values, external supports, and resources. Interventions that address cognitive impairments need to be blended with those that address interpersonal skills, social participation, and everyday activities, routines, and roles (Abreu & Peloquin, 2005).

Self-Awareness

Impaired self-awareness associated with neurological dysfunction includes lack of knowledge about one own physical or cognitive-perceptual impairments and/or their functional implications as well as inability to anticipate difficulties, recognize errors, or monitor performance within the context of an activity (Toglia & Kirk, 2000). Impaired self-awareness presents obstacles to adjustment, collaborative goal setting, and active participation in intervention. Decreased awareness results in poor motivation and compliance, lack of sustained effort, unrealistic expectations, incongruence between goals of the client and family, impaired judgment and safety, and inability to adopt use of compensatory strategies (Hartman-Maeir, Soroker, Oman, & Katz, 2003; Sherer, Oden, Bergloff, Levin, & High, 1998; Toglia & Kirk, 2000). A number of studies support the association between awareness and functional outcome (Fischer, Gauggel, & Trexler, 2004; Goverover, 2004; Hoofien, Gilboa, Vakil, & Barak, 2004; Noe et al., 2005; Tham, Ginsberg, Fisher, & Tegner, 2001). Unawareness may be related to psychological or neurological sources. Denial is a psychological defense mechanism that is related to premorbid personality traits and is characterized by overrationalization, hostility, resistance to feedback, and an unwillingness to confront problems (Prigatano, 1999). A person who has a history of denying inadequacies and resisting help from others and a strong desire to be "in control" is more likely to use denial as a coping strategy. Impaired self-awareness resulting from neurological lesions, represents a lack of access to information

TABLE 57.3 COGNITION: CLINICAL SIGNS AND FUNCTIONAL OBSERVATIONS

Area of Cognitive Impairment	Clinical Signs/Observations	Sample Strategies	Sample Adaptations
Orientation: the ability to understand the self and the relationship between the self and the past and present environment.	Client might think he/she is home in own house rather than a hospital. May confuse the hospital staff with relatives and may believe each time he/she wakes up from a short nap that it is a new day. Client might not initiate basic ADLs because of confusion about time.	Teaching person to look for key cues in the environment when he/she feels confused or has difficulty recalling information.	A talking watch or alarm clock that automatically announces the date and time on an hourly basis; a large, brightly colored sign with the day and date can placed in a key location; large clock. Orientation poster with key personal data listed (e.g., photos of family members, friends).
Attention: multidimensional capacity that involves several components: alertness (detection and reaction), selective attention, sustained attention, shifting of attention, and mental tracking.	Perseveration or difficulty switching between tasks during grooming activities such as shifting from brushing teeth to washing one's face. Difficulty selectively attending and sustaining attention to a task such as a work activity while ignoring music playing or people talking. Simultaneously performing two tasks and mentally tracking one's performance in both (e.g., holding a conversation while driving and looking for a street sign).	Taking time-outs from a task when concentration begins to fade. Remembering to get a sense of the whole situation before attending to the parts. Saying each step of a task aloud to focus attention on the task and inhibit distractions.	Reducing the number of items or choices presented to the client at any one time. Preselecting relevant objects needed for tasks, and task segmentation or presenting only one component or step of a task at a time.
Neglect: failure to orient to, respond to, or report stimuli presented on the side contralateral to the cerebral lesion in clients who do not have primary sensory or motor impairments.	Clients may display asymmetry in functional activities, such as difficulty locating items on the left side of the food tray; shaving only the right side of the face and combing only the right side of the head. May display difficulty scanning left to right while going down grocery store isle; must turn at end of isle and scan for items previously on left (now on right).	Teaching client to find the edges of a page or periphery of stimuli before beginning a task; marking it with an anchor such as colored tape, a colored highlighter, a bright object, or placement of his or her arm.	Placing a vibrating or auditory beeper on the left side (Seron, Deloche, & Coyette, 1989). Using a large colored tape on the edges of tables, corners Lennon (1994).

Memory: gives us the ability to draw upon past experiences and learn new information.	Client may display rapid forgetting of conversations, information read, TV shows watched, or recently met people. May confabulate information. May have difficulty learning new information and remembering to take medications, show up for scheduled appointments, where items are placed, or how to get to particular locations.	Chunking or grouping similar items together; the story method or linking a series of facts or events into a story; rehearsal or repeating information over and over to oneself; rhymes or recalling a fact by changing the fact into a rhyme; and visual imagery.	Cue cards or signs in key places, devices with preprogrammed alarms or alarm messages, electronic devices such as pagers, mobile phones, PDAs, computers, pill box organizers, lists, daily planners, and notebooks.
Visual processing: involves the reception, organization, and assimilation of visual information.	Difficulty locating objects on bathroom sink despite being able to name the item being sought. Difficulty detecting gross differences in size, position, direction, angles, and rotations. Difficulty finding items on a crowded refrigerator shelf, closet, or supermarket shelf. Difficulty identifying objects partially hidden or overlapping on a counter or in a drawer.	Getting a sense of the whole before looking at the parts, teaching the person to partition space before localizing details; using one's finger to trace visual stimuli; covering or blocking out visual stimuli when too much information is presented at once; verbalizing salient visual features or subtle differences and mentally visualizing a particular item prior to looking for it.	Colored tape on buttons to operate appliances; salient color cues on objects to make them easier to locate and discriminate (e.g., bright pink tape on a medication bottle); increased spaces between lines; using a felt-tip pen instead of a pencil to provide greater contrast. Visual stimuli, arranged in an organized manner, with large spaces between items, are easier to perceive.
Executive function: broad band of performance skills that allow a person to engage in independent, purposeful, self-directed behavior (i.e., volition, planning, purposeful action, and self-awareness and self-monitoring).	Difficulty planning and initiating activities that the client needs or wants to complete. Difficulty anticipating consequences, weighing and making choices, conceiving of alternatives, sustaining attention, and sequencing the activity. May appear very passive, may rarely initiate conversation, may appear to have lost his/her sense of humor, is disorganized and unable to get things done once cued to start tasks.	Verbal mediation, self-instruction.	Preorganize an activity or activity materials; audiotape instructions that cue the person to initiate an activity and perform each step at a time in its proper sequence; predictable and structured daily routine.

TABLE 57.3	COGNITION: CLINICAL SIGNS AND FUNCTIONAL OBSERVATIONS *Continued*		
Area of Cognitive Impairment	**Clinical Signs/Observations**	**Sample Strategies**	**Sample Adaptations**
Motor planning: ability to figure out how to get one's body to do what one wants it to do.	May position limb awkwardly in relation to object (e.g., reach with right hand to the left side of the glass) or perseverate on a movement (production errors). May use a body part for the object (e.g., use finger as a toothbrush) when asked to pantomime. Shows spatiotemporal errors during sequencing of a series of actions (e.g., pouring coffee into a cup, adding sugar and milk, stirring, and drinking it). May display conceptual errors when using objects (using a knife as a spoon), have difficulty matching demonstrated gesture to picture or object, or missequence functional tasks such as brushing one's teeth, donning clothes, shaving face, or applying makeup.	Mental practice strategy: before performing an activity, the client imagines him or herself performing the activity in a smooth, accurate, and coordinated manner or imagines how his/her hand will grasp an object. Associate the movement pattern with a rhyme, rhythm, musical tune, visual image, or word. Guide the movement with self-verbalizations.	Colored tape on the handle of a drawer, utensil, or faucet or other salient feature of an object. Adaptations such as elastic-waist trousers, elastic buttons, Velcro fasteners, wash mitts, slip-on shoes, or elastic shoelaces that simplify the task.
Awareness: the degree of understanding one has regarding one's own physical or cognitive-perceptual impairments.	Clients with poor awareness might independently attempt to transfer themselves to the toilet despite dense hemiplegia and the need for physical assistance from a health care worker. Clients might not initiate use of compensatory strategies during home and community activities, thus causing safety risks.	Self-prediction of performance before and after specific tasks. Self-rating of performance for specific tasks. Self-reflection of videotaped performance.	A posted list of self-evaluation questions (e.g., Have I attended to all the necessary information?; Did I check over my work?)

regarding one's cognitive state, and is characterized by surprise, indifference, or perplexity in response to feedback (Prigatano, 1999). In many cases, the neurological and psychological sources of unawareness coexist and cannot be easily differentiated. If denial is the predominant source of unawareness, methods of awareness training might not be effective (Lucas & Fleming, 2005).

Crosson and coauthors (1989) described a hierarchical pyramid model of awareness that distinguishes between three aspects of awareness that are important to consider in evaluation and intervention: intellectual awareness, emergent awareness, and anticipatory awareness. *Intellectual awareness* is knowledge that a particular function is impaired. It is reflected in the ability to verbally describe limitations in functioning. Intellectual awareness is a foundation for emergent and anticipatory awareness. *Emergent awareness* is the ability to recognize a problem only when it is actually happening. It is thought that a minimum level of emergent awareness must be present to be able to recognize the need for compensatory strategies (Bruce, 1993). *Anticipatory awareness* is the ability to anticipate that a problem will likely occur as the result of an impairment before performing a given activity (Crosson et al., 1989). This involves the ability to judge task difficulty in relationship to one's abilities. The hierarchical nature of this model has not been empirically demonstrated, and there is some indication that the interrelationship between these concepts is complex and nonhierarchical (Abreu et al., 2001).

Toglia and Kirk (2000) proposed a dynamic model of awareness that includes self-knowledge or beliefs about knowledge and abilities that exists prior to an activity (i.e., intellectual awareness) and "online" awareness that includes self-monitoring and self-regulatory processes that are activated within the context of an activity. This view of awareness is nonhierarchical and proposes that levels of awareness vary across different tasks and contexts within the same domain. It implies that awareness needs to be assessed both outside and inside the context of an activity (Toglia & Kirk, 2000).

Interview and rating scales for awareness (see Table 57.1) generally evaluate awareness of limitations and strengths, the ability to generalize the impact of limitations on functional tasks, and concerns regarding disability judgment (intellectual awareness). Typically, the person's self ratings are compared to those of a relative or clinician (Bogod, Mateer, & MacDonald, 2003). For example, a client might be asked to rate how much of a problem he or she has in preparing meals, doing laundry, or remembering names. Discrepancy between the client's self ratings and the ratings of others is considered to be an indicator of an awareness deficit, greater discrepancies indicating more severe deficits in awareness. Alternatively, some scales, such as the Self Awareness Deficits Interview (Fleming, Strong, & Ashton, 1996), use a semi-structured interview in which the clinician directly rates

the person's level of awareness, depending on the response to questions. Both of these methods of assessing awareness examine intellectual awareness outside the context of an activity.

Although interviews and rating scales are the most common method of assessing awareness, it can also be assessed within the context of an activity by asking the client to estimate his or her performance before (i.e., anticipatory awareness) and immediately after (i.e., emergent awareness) performing a task. Differences between estimated performance and actual performance are compared. Task estimation, including normative comparison, is used within the Contextual Memory Test (Toglia, 1993b) and the Assessment of Awareness of Disability (Tham, Bernspang, & Fisher, 1999). Changes in awareness that may occur during the experience of an activity can be examined by comparing responses to awareness questions before, during, and immediately after performance.

A comprehensive evaluation of awareness plays a key role in guiding and selecting methods of intervention. In some cases, potential for changes in awareness may be limited, particularly within the intervention time frame. In these situations, intervention methods that do not require awareness, such as functional skill training, errorless learning, or adaptation of the environment, might be most appropriate in facilitating occupational performance. If a lack of understanding of his or her own strengths and limitations prevents a person from choosing goals that are realistic and attainable, the therapist should assist the client in focusing on skills or tasks that are needed for the "here and now."

Awareness training involves helping a person with neurological impairment to learn about the changes that have occurred. It involves helping clients to get to know themselves again. Intervention should be directed toward helping people with cognitive-perceptual deficits to discover their own errors. This is most likely to occur in tasks that are familiar so that the person has a basis for comparison of performance (Tham et al., 2001; Toglia & Kirk, 2000). In addition, the therapist should select activities at a "just right challenge" level so that the person is able to integrate and assimilate the experience. As awareness emerges, the client gradually assumes greater responsibility in the goal-setting and intervention-planning process.

Directly pointing out errors or telling clients that they have problems is least effective in increasing awareness. Direct confrontation tends to elicit defensive reactions (Toglia & Kirk, 2000). There might be times when a person rationalizes his or her mistakes and is difficult to engage in treatment. Impairments should be introduced slowly and indirectly within structured experiences while simultaneously emphasizing strategies to control and monitor the emergence of cognitive symptoms.

Systematic investigation of the effectiveness of awareness training is limited. Initial studies indicate that direct intervention for awareness can be effective in some groups

of clients (Cicerone & Giacino, 1992; Fleming, Lucas, & Lightbody, 2006; Fleming, Shum, Strong, & Lightbody, 2005; Schlund, 1999; Tham & Tegner, 1997; Tham et al., 2001). Following are descriptions of some of the techniques that can be used in a wide range of activities to enhance awareness. These techniques are often used in combination with one other.

Self-Prediction

Self-prediction involves asking the person to anticipate difficulties or predict his or her performance on a task. The client might be asked to indicate on a rating scale whether the activity will be easy or hard or to predict specific parameters of performance. For example, the accuracy of performance, the time required to complete the task, the number of verbal cues required, or the type of difficulties that one might encounter can be estimated and discussed before actually performance of an activity.

Immediately following performance, the actual results are compared with predicted results, and any discrepancies are discussed (Toglia, 1991a, Toglia, 2005). Case studies using self-prediction have been reported in people with executive dysfunction, memory deficits, and unilateral neglect (Cicerone & Giacino, 1992; Rebmann & Hannon, 1995; Schlund, 1999; Sohlberg & Mateer, 2001; Tham et al., 2001).

Specific Goal Ratings

Daily or weekly self-ratings of clearly defined behaviors or targeted strategies can be used to help a person focus on what he or she can do in the present. Goal attainment scales offer a concrete, individualized focus that can increase self-awareness and realistic goal orientation (Malec, Smigielski, DePompolo, 1991; Rockwood, Joyce, & Stolee, 1997). Client self-ratings of goal attainment can be compared to the ratings of the therapist or of a significant other, and any discrepancies can be discussed. For example, suppose a client with moderate memory deficits continually relies on others to remember events and does not use a memory notebook. If the targeted behavior is to rely less on others for information, the client might be asked to rate himself or herself weekly on a scale of 1 (relies on others all the time or does not use the book) to 5 (does not rely on others for information or consistently uses the book). The client's rating can be compared to the rating of a significant other, and any discrepancies can be discussed. Self-ratings can be charted or graphed over time and tracked to improve awareness (Sohlberg & Mateer, 2001).

Videotape Feedback

A videotape of a client that illustrates problems in performing and activity may be used to enhance awareness. Videotape feedback is concrete, and it allows clients to reexperience their performance and evaluate their diffi-

culties as they are occurring rather then simply discussing them after the fact. Videotape feedback has been used successfully in treating people with stroke and brain injury (Liu, Chan, Lee, Li, & Hui-Chan, 2002; Tham & Tegner, 1997).

Self-Evaluation

The practitioner provides a structured system such as a set of questions, a checklist, or a rating system that the client uses as a guide to evaluate his or her own performance (Toglia, 1991a, 1998). Sample self-evaluation questions might include "Have I attended to all the necessary information?" and "Did I check over my work?"

Self-Questioning

Questions that are designed to cue the client to monitor his or her behavior may be written on an index card or memorized. At specific time intervals during the task, the client is expected to stop and answer the same two or three questions, such as "Am I sure that I am looking all the way to the left?," "Am I paying attention to the details?," and "Am I going too quickly?" (Fertherlin & Kurland, 1989).

Journaling

The client keeps a journal in which he or she records activity experiences and performance results. The client is encouraged to reflect on and interpret activity experiences, think about what he or she has learned about himself or herself, and summarize strengths and weaknesses (Tham et al., 2001; Ylvisaker & Feeney, 1998).

Awareness training techniques can be blended with strategy training and incorporated into all treatment sessions. The multicontext approach provides additional guidelines for simultaneously addressing awareness and strategy use (Toglia, 2005).

Orientation

Orientation is the ability to understand the self and the relationship between the self and the past and present environment. Orientation depends on the integration of several mental activities that are represented in different areas of the brain. Disorientation is indicative of significant impairments in attention and memory (Lezak, Howieson, & Loring, 2004). For example, disoriented clients might think they are home rather than in a hospital, might confuse the hospital staff with relatives, or might believe it that is a new day each time they wake up from a short nap.

Evaluation

Evaluation of orientation traditionally includes the client's orientation to person, place, and time. Orientation to person involves both the self and others. Is the client able to report personal facts and events and describe his or her pre-

vious lifestyle? Does the client recognize people and associate them with their role and name? Orientation to place is demonstrated by the client's ability to understand the type of place he or she is in (e.g., a hospital), to report the name and location of the place, and to appreciate distance and direction. Orientation to time requires an ability to report the current point in time (e.g., day, month, and year), to show understanding of the continuity and sequence of time (i.e., estimation), and to associate events with time.

Topographical orientation, often considered a component of orientation to place, is the ability to follow a familiar route or a new route once given an opportunity to become familiar with it. Functionally, the person might not be able to find his or her way from the therapy area to his or her room or describe and draw the layout of a familiar room or route (Unsworth, 2007). Difficulties with the visual-spatial and memory aspects of topographical orientation need to be distinguished during evaluation (Brunsdon, Nickels, & Coltheart, 2007; Unsworth, 2007).

Orientation assessments are traditionally covered in **mental status examinations**. Table 57.1 provides a list of standardized screening tools for orientation. However, occupational therapists frequently use nonstandardized measures of orientation, such as interviews with open-ended questions asked in a conversational or informal manner. Most practitioners use cues to determine the severity of the disorientation. If the client is unable to answer the questions independently, the practitioner might offer a multiple-choice array or verbal cues. Cues usually move from general or abstract to more concrete, as determined by the severity of disorientation (e.g., "Today is the beginning of the work week" versus "Today is the day after Sunday"). The number and type of cues offer a method for scoring and monitoring progress. Fluctuations in orientation during the day should be noted, as clients might experience **sundowning**, in which they become confused in the evening because of fatigue.

Intervention

Strategy Training and/or Adaptations of Task or Environment. Strategy training for disorientation involves teaching the person to look for external cues when he or she is feeling confused or is having difficulty recalling orientation information. For example, an information poster that contains orientation facts can be placed on a wall, in a closet, or eventually inside a notebook. When the client is asked orientation information, he or she is expected to locate the information poster to verify responses or to find the correct answers. A memory book, containing pictures and names of familiar people or important life events, can also be placed in a key location within the room. As an alternative, an audiotape or videotape can be created by a family member to review orientation information at set times during the day or used whenever the person feels confused. An alarm that is pre-

programmed to ring several times a day can be used to cue the person to read his or her orientation fact book or listen to the audiotape. Orientation questions with use of cueing strategies can also be incorporated into a bean bag toss game, a board game, or a "Family Feud" style game within a group format (Toglia & Golisz, 1990).

A calendar posted on the wall or closet may be helpful in orienting the person to time. If the client has poor selective attention, a single piece of paper with the day and date written daily, rather than a monthly calendar, might be needed.

To assist the client in finding his or her room, directional arrows can be placed in the hallway, and tape indicating the route to his or her room can be placed on the floor. Key landmarks can be pointed out and made more salient with arrows or colored tape.

The therapist needs to immediately reinforce initiation or use of any of these external cues by praising the client (or rewarding points), and each time the client initiates the use of an external cue, the therapist should keep track of it by recording it on a chart or visual graph. The use of external cues should be gradually faded until the orientation information is internalized. In addition, the person should be trained to look for orientation cues (e.g., clocks, calendars) in different environments. Spaced retrieval techniques can be used to train use of strategies and external aids, such as using a daily calendar. Spaced retrieval involves systematically lengthening the period of retention and recall. There is evidence that this technique is more effective than cueing hierarchies in treating people with dementia (Bourgeois et al., 2003).

Attention

Attention is a multidimensional capacity that involves several components:

1. *Detect/react:* the ability to detect and react to gross changes in the environment, such as a telephone ringing, a name being called, or a ball that is thrown.
2. *Sustained attention:* the ability to consistently engage in an activity over time, such as reading for 15 minutes without losing concentration. Repetitive and predictable activities, such as stuffing envelopes or folding letters, place less demands on sustained attention.
3. *Selective attention:* the ability to attend to relevant stimuli while inhibiting distractions or irrelevant information. Examples include selecting specific locations on a map, finding items within a certain price range on a menu, choosing all the red or even playing cards, and finding specific ingredients in a closet. Selective attention demands are increased as the number of items presented simultaneously is increased and as the saliency of the target stimuli is decreased.
4. *Shifting of attention:* the ability to shift or alternate attention between tasks with different cognitive and/or

motor requirements. Examples include the ability to shift between adding and subtracting when balancing a checkbook, answering the telephone and typing, and making a salad while cooking something on the stove.

5. *Mental tracking:* the ability to simultaneously keep track of two or more stimuli during ongoing activity. Examples include keeping track of what has already been done in a multistep cooking task and listening to the radio while cooking a meal.

During evaluation (see Table 57.1) and intervention, it is important to keep these different aspects of attention in mind.

Attentional symptoms vary with anxiety and fatigue as well as with the task and context. Symptoms that reflect impairments in attention include distractibility; impulsivity; attentional lapses; and a tendency to become sidetracked, wander off task, overfocus on parts of a task, omit details, and lose track of something that was just done. In general, routine and repetitive activities place fewer demands on attentional capacity than do activities that are unfamiliar or unpredictable. For example, attentional symptoms might not be observed in basic self-care activities, but the same client might show attentional symptoms during a higher-level activity such as searching on the Internet for information.

Evaluation

Because attention is a multidimensional skill, therapists should ensure that they evaluate all components for potential impairments. More severe impairments in components such as sustaining attention may be easily observable in functional performance; however, more subtle impairments might be missed. Assessments such as the Test of Everyday Attention (Robertson, Ward, Ridgeway, & Nimmo-Smith, 1994) evaluate multiple components of attention.

Intervention

STRATEGY TRAINING FOR ATTENTION. Attention strategy training involves helping a person learn to control, monitor, or prevent the emergence of attentional symptoms. For example, awareness training techniques described earlier, including self-prediction, self-questioning, specific goal setting and self-evaluation, can be embedded within strategy training to help a client monitor and regulate attentional lapses. Strategy training can be integrated into a wide range of simulated or occupation-based activities, during which the practitioner assists the client in monitoring and recording the frequency with which the targeted strategy or behavior is initiated and used. Examples of simulated functional activities include looking though a random stack of greeting cards for a particular holiday card; looking through a stack of recipe cards for recipes that match ingredients on a list; and looking up information in a telephone directory, calendar, or TV guide while

simultaneously keeping track of the items found or while listening to the radio.

Strategies that may be emphasized include the following:

◆ Taking a time-out from a task when concentration begins to fade
◆ Remembering to get a sense of the whole situation before attending to the parts
◆ Monitoring a tendency to become distracted by internal thoughts or external stimuli
◆ Monitoring the ability to stay on task
◆ Remembering to look all over and actively search for additional information before responding
◆ Self-instruction or saying self-cues or each step of a task (aloud and then to self)
◆ Time pressure management techniques (Fasotti, Kovacs, Eling, & Brouwer, 2000)

Evidence supports the effectiveness of attention training for people with traumatic brain injury, in the postacute phase of rehabilitation. Successful interventions included strategy training, self-awareness techniques such as training participants to recognize when they are experiencing information overload or when they are off task (Cicerone et al., 2005). Similarly, Silverstein and colleagues (2005) demonstrated that attention training for people with schizophrenia combined with shaping techniques, including specific goal setting and feedback regarding on task behaviors, was more effective than attentional exercises alone.

ADAPTATIONS OF TASK OR ENVIRONMENT. Adaptations can be used to minimize attention demands within everyday activities. Techniques that include increasing saliency of items that require attention and reducing or limiting the amount of information presented to the client at one time can be used. Examples include the following (Toglia, 1993a):

◆ Modifying the environment to reduce visual clutter, interruptions, and auditory distractions
◆ Simplifying task instructions so that only one step is presented at a time
◆ Reducing the number of items or choices presented to the client at one time
◆ Preselecting relevant objects needed for tasks
◆ Task segmentation (e.g., presenting only one component of a task at a time) (Moulton, Taira, & Grover, 1995; Toglia, 1993a)
◆ Placing colored tape on house keys or on operating buttons of appliances

The enhancement of salient cues in the environment can be used to promote desired behaviors. In the task of brushing teeth, for example, unnecessary items should be removed from the sink, and the items that are required for use should be made salient with contrasting colors. The contrasting colors of the toothbrush, toothpaste, and cup

ETHICAL DILEMMA

How Can a Practitioner Balance Conflicting Ethical Obligations?

Mr. Grahm, who sustained a stroke and has resulting left hemiparesis and unilateral left neglect, is receiving outpatient occupational therapy services. He is driven to therapy by a daughter who lives nearby, but Mr. Grahm is living alone. Mr. Grahm tells you that although his daughter took his car keys, he has another set that she doesn't know about and he plans on driving to visit a friend this weekend. The occupational therapist knows that the driving assessment, completed when Mr. Grahm was an in-patient, advised him not to drive owing to his left neglect.

Questions

1. The occupational therapy practitioner has obligations and duties to several individuals and groups. Identify them. Which group or individual should receive the highest priority? Why?
2. What are the ethical principles that are in conflict in this situation?
3. What legal obligations might the therapist have in addition to ethical obligations?

provide a cue to assist the client in attending to the different items.

Unilateral Neglect

Unilateral neglect is a failure to orient to, respond to, or report stimuli that are presented on the side contralateral to the cerebral lesion in clients who do not have primary sensory or motor impairments (Heilman, Watson, & Valenstein, 2003). The term *neglect* connotes a volitional component to the disorder, but this is a misnomer. The client with unilateral neglect is unaware of the incompleteness of his or her perception of, and responses to, the environment. He or she often behaves as though one half of the world does not exist (Corben & Unsworth, 1999). For example, following right-hemisphere strokes, clients often begin scanning on the right side and miss or fail to explore most of the stimuli on the left. Asymmetry may be observed in functional activities, drawing tasks, reading, or writing. In severe cases, clients may eat food on one side of their plate, shave half their face, or dress half of their body without recognizing that anything is wrong. In milder cases, they may misread the first letter of a particular word or fail to attend to information while crossing a street, shopping, or driving (see the Ethical Dilemma). Many clients with unilateral neglect also exhibit anxiety or flattened affect.

Unilateral neglect has been identified as a major factor impeding functional recovery in clients who have sustained strokes (Chen Sea, Henderson, & Cermack, 1993; Cherney, Halper, Kwasnica, Harvey, & Zhang, 2001). Those with unilateral neglect have more difficulty resuming activities of daily living, have longer hospital stays

(Gillen, Tennen, & McGee, 2005; Katz et al., 1999), and are at increased risk for accidents (Webster et al., 1995).

Unilateral neglect has been described as a heterogeneous disorder that includes different clinical subtypes and behavioral components (Mesulam, 1994; Pierce & Buxbaum, 2002; Stone, Halligan, Marshall, & Greenwood, 1998). Unilateral neglect can involve one or more modalities, may vary with the nature of the stimuli (e.g., verbal versus nonverbal), and can encompass single objects or different spatial frames of space: extrapersonal or large space, peripersonal or space within reach, and personal or body space (Mesulam, 2000; Plummer, Morris, & Dunai, 2003). For example, some clients demonstrate neglect symptoms in large spaces, such as a room (extrapersonal neglect), but do not have reduced awareness of their body (personal neglect) or difficulty on paper-and-pencil tasks (peripersonal neglect). Neglect subtypes have also been proposed that involve internal mental images (representational neglect), decreased movement into or toward the contralesional space (motor neglect), or decreased ability to perceive sensory stimuli in contralesional space (sensory neglect) (Mesulam, 1994).

Evaluation

Occupational therapists evaluating clients with unilateral neglect must first distinguish between hemianopsia and unilateral neglect. Visual field cuts (hemianopsia) are hemiretinal, while neglect is hemispatial. Clients with visual field cuts typically have awareness of their visual field loss and make compensatory head movements and turns. Unilateral neglect may exist with or without hemianopsia, and one syndrome does not cause the other. Assessment of unilateral neglect typically involves cancellation tasks that

require detection of target stimuli, distributed on both sides of space (see Table 57.1). Typically, the majority of targets on the contralesional side of space are missed. The complexity of unilateral neglect symptoms is not fully captured by traditional tests of neglect. Therefore, it is important not to rely completely on test instruments in identifying unilateral neglect. The different behavioral manifestations and subtypes of neglect need to be kept in mind during observation of performance (Appelros, Nydevik, Karlsson, Thorwalls, & Seiger, 2003; Plummer et al., 2003).

Dynamic assessment of unilateral neglect provides information about task conditions that increase or decrease the symptoms of unilateral neglect as well as the person's ability to respond to different types of cues or implement and carryover learned strategies to different situations. Toglia (2005) has described a dynamic object search task that analyzes the ability to learn and apply a strategy across a series of search tasks in people with unilateral neglect.

Intervention

Specific skill training is emphasized in this section because evidence exists to support the use of visual scanning training to remediate disorders of unilateral neglect.

In unilateral neglect, clients demonstrate decreased eye movements to the affected side. This decrease in eye movements reflects a decrease in attention to one side of the environment (Antonucci et al., 1995; Toglia, 1991b). A scientific literature review by Cicerone and colleagues (2000, 2005) concluded that there is level 1 evidence to support use of visuospatial interventions that include practice in visual scanning because it improves compensation for unilateral neglect and generalizes to everyday activities. Therefore, they recommended visuospatial rehabilitation with visual scanning as a practice standard for clients with visual neglect after right-hemisphere stroke. The combination of forced limb activation or movements of the left arm or hand on the left side of space in conjunction with visual scanning also shows positive results (Cicerone et al., 2005; Robertson, Hogg, & McMillan, 1998). Intervention appears to be most effective when a wide combination of intervention activities, including everyday tasks, is used (Antonucci et al., 1995; Pizzamiglio et al., 1992). Programs with greater levels of intensity have generally produced more positive outcomes. However, even with intensive training, it has been demonstrated that people with unilateral neglect have poorer functional outcome than do other people with stroke (Paolucci, Antonucci, Grasso, & Pizzamiglio, 2001).

Weinberg and colleagues (1977) designed systematic training techniques that incorporated a combination of remedial worksheets and strategy training techniques during reading and scanning tasks. For example, they used graded anchoring, pacing the speed of scanning, feedback, and decreasing the density of the stimulus. Anchoring, or teaching the person to use a spatial reference point, such as a colored line on the left side, is a common strategy in visual scanning training.

Gross motor activities involving vestibular input and whole-body movement in space increase general arousal and alertness and have been used in combination with visual scanning activities to increase gaze and attention to the affected side (Cappa, Sterzi, Vallar, & Bisiach, 1987). Activities such as balloon volleyball, with the client hitting the balloon with his or her hands clasped together, is an example of such an activity.

Other intervention techniques that have been recommended for clients with unilateral neglect include use of prisms and visual occlusion techniques (Pierce & Buxbaum, 2002). Prisms cause an optical deviation of the visual field to the right so that objects appear to be moved farther to the right than they actually are (Redding & Wallace, 2006). Partial visual occlusion methods attempt to force the person to use the neglected visual field by patching the eye ipsilateral to the lesion, patching the nonneglected half field of eyeglasses (Beis, Andre, Baumgarten, & Challier, 1999), or darkening the nonneglected half field of eyeglasses (hemispatial sunglasses) (Arai, Ohi, Sasaki, Nobuto, & Tanaka, 1997).

Recently, computer-assisted training programs for street crossing and wheelchair navigation have been described. Trained subjects with unilateral neglect performed better on real-life tasks after virtual reality training than control subjects did. The use of virtual reality–based technology appears to show potential for clients with unilateral neglect (Katz et al., 2005; Webster et al., 2001).

STRATEGY TRAINING. Strategies for unilateral neglect can be practiced within everyday tasks such as setting a table for several people, dealing a deck of cards to six people, identifying appointments on a wall calendar, reading a newspaper, addressing envelopes of different sizes, or identifying all the pictures or chairs in the room. Because unilateral neglect symptoms vary with the size of space, arrangement of space, and amount and density of information presented, these activity parameters need to be matched with the neglect symptoms and systematically varied and graded in treatment. In some cases, treatment activities should emphasize large-space activities; in other situations, activities should focus on tabletop tasks that involve visual detail. In general, activities that are unpredictable or involve stimuli randomly scattered on a table or page are more sensitive to the symptoms of unilateral neglect than are activities that are arranged in a predictable, structured, or horizontal array (Ferber & Karnath, 2001). Intervention should include practice in identifying situations in which neglect symptoms are most likely to occur, such as filling multiple bowls with salad, placing cookie dough on a baking sheet, or arranging photographs in a picture album.

Individuals with unilateral neglect do not always know when they are attending to the left side. Intervention

needs to assist clients in finding external cues that will provide feedback about when they are indeed attending to the left. An emphasis in intervention should be teaching the client to find the edges of a page or a table or the periphery of stimuli before beginning a task and to mark it with spatial point of reference, such as colored tape, a colored highlighter, a bright object, or placement of his or her arm on the left border. Auditory cueing, utilizing a beeper or alarm device, can be combined with strategy training to remind the person to use a strategy or visual cue. The alarm device can require the client to scan space and attend to the left to turn off the sound (Seron, Deloche, & Coyette 1989).

Other intervention strategies for unilateral neglect include tactile search, use of mental imagery, and general alerting techniques. Tactile search includes teaching the client to feel the left side of space with eyes closed or to feel the left edges of objects before visual search. Visual imagery teaches imagining and describing familiar scenes or routes and using mental images during movement of limbs or visual scanning (Niemeier, 1998; Smania, Bazoli, Piva, & Guidetti, 1997). For example, reduction in neglect symptoms and increased performance on functional tasks were reported after a mental imagery program that involved teaching people with neglect to imagine their eyes as sweeping beams of a lighthouse from left to right across the visual field. Clients were cued to use this mental image during functional and therapy training tasks (Niemeier, 1998; Niemeier, Cifu, & Kishore, 2001). In addition to strategies specifically aimed at facilitating attention to the left side, strategies that focus on the general ability to sustain attention have also been found to reduce unilateral neglect. For example, Robertson, Tegner, Tham, Lo, and Smith (1995) taught clients with chronic unilateral neglect to mentally tell themselves to "pay attention" and to tap loudly on a table.

It has been observed that response to strategy training depends on whether people with unilateral neglect show improvements in their awareness (Tham et al., 2001; Robertson & Halligan, 1999). This underscores the importance of deeply embedding awareness training techniques, such as those described earlier, into all intervention activities.

ADAPTATIONS OF TASK OR ENVIRONMENT.   To minimize the need to attend to the left, it has been suggested that the environment be rearranged so that key items (e.g., the telephone, the nurse call button) are on the unaffected side. However, a study by Kelly and Ostreicher (1985) found no significant difference in functional outcome in clients whose hospital rooms were rearranged in this way. Lennon (1994) described the successful use of large colored paper markings on the edges of tables, corners, and elsewhere to prevent collision for clients with unilateral neglect. The client was trained to look for these markers. Markers were gradually faded. Performance improved and was maintained with removal of markers; however,

effects did not generalize to other environments. Calvanio, Levine, and Petrone (1993) described the use of an adapted plate to increase feeding skills in a client with a severe case of left inattention and a dense left hemianopsia. The plate was mounted on a lazy Susan so that it could be rotated. As the client pushed at the food with a fork, the plate rotated so that all the food eventually came into view, thus eliminating the need for scanning to the left. Other environmental adaptations include placing red tape on the client's wheelchair brakes or placing brightly colored objects such as a napkin or cup on the left side (Golisz, 1998).

Visual Processing

Visual perception is viewed on an information-processing continuum involving the reception, organization, and assimilation of visual information. On one end of the continuum, simple visual-processing tasks such as matching shapes or objects occurs quickly and automatically, with minimal effort. On the opposite end of the continuum, complex visual tasks that include unfamiliar stimuli or subtle discriminations within visually crowded arrays require slower and effortful processing. In this conceptualization, visual-processing dysfunction is defined as a decrease in the amount that the visual system is able to assimilate at any one time (Toglia, 1989). To understand the client's **visual perceptual** skills and the effects of impairments on functioning, we need to analyze the activity conditions (complexity, amount, familiarity, and predictability) rather than the type of activity (visual spatial, visual discrimination, visual motor, or visual gestalt).

Problems in simple visual processing include difficulty in discriminating between objects, pictures of objects, and basic shapes; difficulty in detecting gross differences in size, position, direction, angles, and rotations; decreased ability to visually locate single visual targets in space or judge gross distance between two objects; and decreased ability to detect simple part-whole relationships in objects or basic shapes. The person may have difficulty in familiar and routine activities and may easily misinterpret or misidentify objects. Failure to recognize an object is labeled visual **agnosia**. Toglia (1989) proposes that labels such as visual agnosia are too broad for the purposes of intervention because there are many different underlying reasons for object recognition difficulties. For example, a person might fail to attend to the critical feature of an object or the part of the object that tells what it is (e.g., prongs of a fork). Attention might be captured by salient but irrelevant aspects of the object (e.g., the utensil's decorative handle). There might be an inability to process the overall shape and the details simultaneously, so the person might miss important details.

Complex visual processing skills are required in visually confusing environments; when there is abstract, unfamiliar, or detailed visual information; or in conditions under which the distinctive visual features are partially

obscured (e.g., the object is rotated and partially hidden on a crowded desk). Dysfunction of complex visual perceptual skills may include decreased ability to detect subtle differences in abstract shapes and objects or angles, size, distance, and position. A client might have difficulty making sense out of ambiguous, incomplete, fragmented, or distorted visual stimuli. The client might misinterpret an object when it is in an unusual position or partially hidden. The person might experience increased difficulty in visually confusing or crowded environments. Functional tasks such as finding items in a crowded closet, drawer, desk, or supermarket shelf and locating key information on a bill, map, or schedule might present difficulty. On these tasks, the person might misinterpret information, miss key visual details, or become sidetracked by irrelevant visual stimuli.

Visual Motor

Visual motor skills include drawing tasks (e.g., drawing a map, copying a design) or construction of three-dimensional figures (e.g., assembling a coffeepot). Clients may demonstrate difficulty on visual motor tasks for many reasons. For example, a client might have difficulty constructing a block design because of a poor ability to scan the complete design, decreased planning and organization, unilateral neglect, or impaired discrimination of size, angles, and rotations. The term *constructional apraxia* is used to refer to difficulty with drawing or assembly tasks that cannot be attributed to primary motor or sensory impairment, ideomotor apraxia, or general cognitive impairments (Farah, 2003). Constructional abilities are closely related to ADL performance (Neistadt, 1992a; Warren, 1981). Clients may have difficulty dressing (dressing apraxia), orienting clothes correctly on a hanger, or assembling a sandwich or coffeepot. People with left-hemisphere parietal lesions tend to omit individual pieces or details in constructional tasks, whereas those with right-hemisphere lesions demonstrate spatial disorganization of the pieces and lose the overall gestalt (Kramer, Kaplan, & Blusewicz, 1991). Constructional apraxia is not a unitary syndrome. Impairments in different types of perceptual processing or spatial relations are thought to underlie constructional apraxia in both right- and left-hemisphere lesions (Laeng, 2006).

Evaluation

Evaluation for people with visual perceptual impairments should examine visual foundations skills, visual abilities without a motor response, and visual motor skills. Visual foundation skills, including visual acuity, oculomotor skills, and visual fields, should be evaluated prior to a visual-processing evaluation to screen out visual problems that will interfere with the accuracy of perceptual testing (Cate & Richards, 2000). Several clinical observations during functional tasks can alert occupational therapists to the need for a formal visual assessment: compensatory head movements and tilting, squinting, shutting of one eye, or a tendency to lose one's place while reading. A basic screening can be performed by the occupational therapist (i.e., visual acuity, range of motion of the eyes, ocular alignment, visual pursuits or smooth tracking of moving objects, saccades or quick eye movements to place an object of interest in view, and visual-scanning functions). Any disruptions of these foundational skills will affect interpretations of higher level visual-processing assessments (Warren, 1993).

Standardized nonmotor assessments of visual perception (see Table 57.1) categorize visual perception into specific skills such as figure-ground, position in space, form constancy, spatial relations, and visual recognition. Adults with neurological lesions may have difficulty performing various types of visual processing tasks for similar reasons (e.g., a tendency to overfocus on parts, a tendency to miss visual details, failure to simultaneously attend to the details as well as the whole). Therefore, Toglia (1989) recommends an approach that conceptualizes visual processing on a continuum and evaluates both conventional and unconventional objects under a variety of different activity conditions. In a dynamic approach to visual perception, the therapist systematically manipulates activity parameters and analyzes responses to cues to understand why a client is having difficulty accurately discriminating objects or visual stimuli (Kline, 2000; Toglia, 1989; Toglia & Finkelstein, 1991). Visual perceptual assessment should examine responses to activities with and without a motor response to examine differences in performance. Visual motor skills are typically evaluated with block designs, puzzles, or copying designs. The therapist needs to observe how the person begins and how he or she proceeds. For example, does the client begin by drawing the details rather than attending to the overall shape of the figure? Informal observations in tasks such as copying a map route, assembling a coffeepot or woodworking project, wrapping a package, packing a lunchbox, or folding clothes can provide additional information on visual motor abilities (Figure 57.2). Symptoms may include angular deviations; improper position, location, spacing, or alignment of parts; and spatial distortions. The client's ability to recognize and correct errors in alignment or position should be investigated. For example, some clients do not recognize visual spatial errors even when attention is directed to the problem area, whereas other clients recognize errors but are unable to correct them.

Intervention

Interventions may address visual foundations skills or visual processing skills with or without a motor response.

Visual Foundation Skills.   Treatment of visual foundation skills such as visual acuity and contrast sensitivity, oculomotor skills, and visual fields generally involves adaptations a such as large-print reading materials; mag-
FIGURE 57.2 Organizing the components of a ratchet tool kit requires perception of size and shape as well as organizational skills.

nifiers; talking devices; increasing contrast of edges, borders, or backgrounds; and changes in lighting. However, remedial exercises may be recommended for individuals with oculomotor or visual field deficits. For example, range-of-motion eye exercises to the involved muscle have been advocated for individuals with eye muscle paresis. Occlusion of the intact visual field with eye patching has been used to force use of the impaired visual field (Warren, 1993).

STRATEGY TRAINING. Strategies that maximize the client's ability to process visual information can be trained within everyday activities that involve choosing among objects that are similar in shape and size (e.g., matching socks, sorting teaspoons and soupspoons); locating information within supermarket circulars, calendars, maps, or schedules; arranging information within grids or spreadsheets; copying patterns in arts and craft activities; or finding information in crowded draws, shelves, tables, or bulletin boards.

Strategies can include getting a sense of the whole before looking at the parts; teaching the person to partition space before localizing details; using one's finger to scan, trace visual stimuli, or focus on details; covering or blocking visual stimuli when too much information is presented at once; verbalizing salient visual features or subtle differences; and mentally visualizing a particular item before looking for it (Toglia, 1989, 1998). Intervention involves careful manipulation of activity parameters. Activities that involve familiar items or contexts, high contrast (e.g., red socks and white socks), distinctive features, little detail, and solid colors or backgrounds require less attention, effort, and visual analysis than do activities that involve choosing among items that have low contrast (e.g., light beige and white socks), are in unusual posi-

tions, are embedded within crowded or distracting visual backgrounds, or are partially obscured. Changes in the familiarity, number of items, and degree of detail can place greater demands on visual processing. In addition, verbal mediation, including repeating a list of step-by-step instructions during a functional activity such as dressing, capitalizes on strengths in verbal abilities and can be effective in facilitating functional performance (Sunderland, Walker, & Walker, 2006).

ADAPTATION OF TASK OR ENVIRONMENT. The key guideline in minimizing the effects of visual perceptual difficulties is to make the distinctive features of objects more salient with color cues. An example is placing colored tape on buttons to operate appliances or using salient color cues on objects to make them easier to locate and discriminate (e.g., bright pink tape on a medication bottle). Cues such as colored marks or tape at spatial landmarks (e.g., tape recorder, wheelchair footrests, or label of a shirt) reduce spatial demands and make it easier to orient and align parts of an item. Visual stimuli such as items on a shelf or sentences on a page that are large and arranged in an organized manner with large spaces between items are easier to perceive. Consistent locations for objects in the refrigerator, closet, or drawer or a countertop increase predictability and provide contextual cues for recognition. Significant others should be instructed to decrease visual distractions in the room or within a task by limiting designs and patterns and by using solid colors with high contrast. Patterns, designs, and decorations make it harder to select and recognize critical features of an object. Significant others should also be trained to introduce only a small amount of visual information at one time.

Motor Planning

Motor planning, or praxis, is the ability to execute learned and purposeful activities. **Apraxia** is defined as a disorder of skilled movement that cannot be adequately explained by primary motor or sensory impairments, visual spatial problems, language comprehension difficulties, or cognitive problems alone (Heilman & Rothi, 2003). Damage to the association areas of the brain (affecting the cognitive aspects of motor control) is thought to cause apraxia (Kertesz, 1982). Apraxia may be seen after strokes in either hemisphere, although it is more commonly seen in clients who have sustained a left-hemisphere lesion. Aphasia is often associated with apraxia, since the left hemisphere is also dominant for language (Heilman & Rothi, 2003). People with apraxia can improve performance of skilled movement over time (Basso, Burgio, Paulin, & Prandoni, 2000); however, they frequently continue to have significant functional limitations in both the learning of new motor tasks, such as one-handed shoe tying (Poole, 1998), and in the performance of motor acts to verbal command or demonstration (Poole, 2000).

Roy (1978) identifies two major subsystems in apraxia: the conceptual and the production subsystems. The symptoms of apraxia may reflect disorders in one or both of these subsystems. The production aspect of motor planning, traditionally called *ideomotor apraxia,* involves generating the action plan, sequencing and organizing the appropriate elements, and carrying out the plan (e.g., reaching for a glass of water to take a drink). The greatest difficulty is observed when the client is asked to pretend use of a tool or object or to perform limb gestures. Some improvement may be seen when the client is asked to imitate the motion or perform the motion with the actual object, but the movement is still imprecise. These clients know what they want to do, but actions are carried out in an awkward, inefficient, or clumsy manner. Errors of preservation, sequencing, or omissions may be observed.

The conceptual aspect of motor planning (Roy, 1978) includes knowledge about the functional properties of an object, the object action, and the sequence of action. Conceptual errors, traditionally called *ideational apraxia,* involve object function, action knowledge, and knowledge of sequence. Clients might be able to accurately identify and match objects, but inappropriate use of objects is frequently observed. For example, the client might try to brush his or her hair with a toothbrush. Although object recognition may be intact, the person might be unable to associate the object with its correct action plan.

Dressing apraxia and constructional apraxia are additional subtypes of apraxia, previously described in the section on visual processing. Traditional labels of apraxia are narrow in scope and do not account for the wide range of skills that underlie motor planning and constructional abilities.

Evaluation

The classic definition of apraxia includes motor-planning problems that cannot be accounted for by weakness, increased tone, incoordination, sensory loss, or other cognitive-perceptual impairments. The clinician is urged to analyze underlying reasons for difficulties in performance rather than attempting to classify clients within traditional categories. In clinical practice, most clients have associated difficulties that contribute to difficulty in motor planning. Information on the client's language skills should be obtained from the speech-language pathologist or be screened for by testing for "yes" or "no" comprehension and ability to follow one-step commands, since apraxia and aphasia often coexist.

In evaluating apraxia, the clinician typically observes the client's performance of different types of movements, noting the method of evocation (e.g., command, imitation, or object use) and type of errors made (Haaland, 1993). Assessments for apraxia are listed in Table 57.1. An observational method for assessing apraxia in ADL activities, adapted from the Arnadottir OT Neurobehav-

ioral Evaluation (A-ONE), has been validated for people with stroke (van Heugten et al., 2000).

A dynamic assessment approach attempts to identify the activity conditions under which the limb apraxia symptoms emerge, the client's response to cueing, and the client's awareness of his or her activity performance (Toglia, 1998).

Intervention

Interventions to overcome motor-planning deficits may emphasize either the production aspect or the conceptual aspect of motor planning (Roy, 1985). Techniques that address the orientation of an object or limb in space or the timing, sequence, and organization of the motor elements aim to enhance the production aspect of motor planning. For example, the practitioner might provide physical contact (i.e., hand-over-hand assistance or light touch) to limit inappropriate or extraneous movements while simultaneously using guiding methods to facilitate a smooth motor pattern or to guide the manipulation of objects. Through repeated practice in different tasks, the client begins to learn the movement patterns that feel "right," and the practitioner gradually withdraws assistance. Deep proprioceptive input and contact have an inhibitory effect on normal people, whereas light touch tends to have a more facilitatory effect (Farber, 1993).

Familiar tasks that are performed in context are easier for people with motor-planning disorders because the context provide cues that facilitate the desired action (Ferguson & Trombly, 1997). Interventions can be graded by gradually introducing activities and environments that have less stability and predictability, such as negotiating around obstacles in a crowded store.

Intervention addressing the conceptual aspect of motor planning focuses on facilitating the client's understanding of how an object is used or how a gesture is performed (Helm-Estabrooks, 1982; Pilgrim & Humphreys, 1994; Smania, Girardi, Domenicali, Lora, & Aglioti, 2000).

STRATEGY TRAINING. Clients may be taught to use verbal, visual, or tactile cues to enhance movement. For example, before performing an activity, the client might mentally practice or imagine the task performance; or the client might imagine how an object should look in his or her hand before picking it up. Incorrect patterns of movement, such as holding an object the wrong way, can also be visualized, with an emphasis on having the client mentally practice correcting the movement. Talking a client through action sequences or use of step-by-step written lists or illustrations can be useful in facilitating functional performance in tasks such as drinking from a cup (Butler, 1999). The person can be taught to verbally rehearse an action sequence or associate the movement with a rhyme, rhythm, or musical tune with a gradual fading of the verbalization. Self-monitoring strategies can be used to teach

a client to monitor unnecessary cocontraction, incomplete actions, or difficulty in switching direction of movements. Preliminary studies indicate that strategy training is effective in improving everyday function (Donkervoort, Dekker, Stehmann-Saris, & Deelman, 2001; Geusgens et al., 2006). For example, in a randomized study design, changes on nontrained ADL activities were greater in a group of people with stroke who had received strategy training as compared with those receiving usual occupational therapy. This suggests that the strategies generalized to everyday activities (Geusgens et al., 2006).

ADAPTATION OF TASK OR ENVIRONMENT. Simple adaptations to objects that draw attention to the critical features of the object or activity can facilitate action and motor planning (e.g., colored tape on the knife handle or toothbrush handle). Patterns and designs on utensils or clothing might draw attention to the wrong detail and result in an inappropriate motor response.

Tool use should be minimized (Poole, 2000), and adaptive equipment should be selected with caution for the apraxic client. For example, some adaptations, such as a button hook, one-handed shoe tying, or a one-arm-drive wheelchair, might be confusing for clients with apraxia and place greater demands on motor-planning abilities. Other adaptations, such as adaptive clothing closures, may simplify the task or motor pattern required to manipulate or hold objects, reduce the number of steps, and facilitate function in the client with apraxia.

Other adaptations include training the caregiver to modify instructions so that the activity is broken into one command at a time (Unsworth, 2007). Simple whole commands (e.g., "Get up") can put the activity on an automatic level and effectively enhance motor planning (Zoltan, 1996).

Memory

Memory gives us the ability to draw on past experiences and learn new information (Toglia, 1993a). This provides us with a sense of continuity in the environment and frees us from dependency in here-and-now situations. Memory is conceptualized as a multistep process involving encoding (i.e., input of information), storage (i.e., holding information), and retrieval (i.e., getting information) (Levy, 2005b). There are different types of memory. Working memory is the temporary storage of information while one is working with it or attending to it. It includes the ability to recall information immediately after exposure. It allows one to focus conscious attention and keep track of information as one is performing an activity. Declarative memory is one aspect of long-term memory and includes conscious memory for events, knowledge, or facts. Procedural (nondeclarative) memory involves the ability to remember how to perform an activity or procedure without conscious awareness. Prospective memory involves the ability to remember intentions or activities that will be required in the future (Levy, 2005b).

Evaluation

It is important to distinguish whether everyday memory problems are due to failures to recall past events or conversations or failures in carrying out future activities (e.g., prospective memory). A comprehensive evaluation of memory, whether static or dynamic, must address the different types of memory and methods of retrieval (Table 57.1). Assessments must consider factors such as the modality in which the information is presented (auditory or visual), the type of instructions (general or specific), the amount of stimuli presented, the familiarity and meaningfulness of the information, the presence of contextual cues during recall phases, the type of information to be remembered (factual or skill related), and the length of retention. Dynamic assessment of memory, such as Toglia's (1993b) Contextual Memory Test, evaluates awareness of memory capabilities and use of strategies.

Intervention

Memory impairments can be closely related to other cognitive impairments, particularly attention. Some investigators have suggested that an indirect approach that addresses other cognitive skills, such as attention or organization, rather than memory, may be effective. For example, Sohlberg and Mateer (1989a) reported improvement in memory function after attentional training. Interventions for memory impairments include memory strategy training, external aids and devices, and adaptations, as well as techniques of errorless learning, vanishing cues, and spaced retrieval that were discussed earlier in this chapter.

STRATEGY TRAINING. Training of internal memory strategies is most appropriate for people with mild memory deficits or those in whom other areas of cognition are intact (Cicerone et al., 2000, 2005). The client practices one or two targeted memory strategies in a variety of different tasks, such as remembering telephone numbers, news headlines, a sequence of errands, items that need to be bought in a store, or instructions to an activity. During practice on different memory tasks, a variety of awareness training techniques may also be used. Memory strategies may be directed primarily at encoding operations (i.e., getting information in) or the retrieval phase of memory (i.e., getting information out). Encoding strategies include the following:

- Chunking or grouping similar items
- The story method, or linking a series of facts or events into a story
- Rehearsal, or repeating information over and over silently

- Rhymes, or recalling a fact by changing the fact into a rhyme
- Visual imagery

Retrieval strategies include the following:

- Alphabetical searching, or going through the alphabet to find the first letter of a forgotten item
- Retracing one's steps to find a missing object or to recall an event
- Thinking of associated information to cue the recall of a new fact or event
- Self-generating words, concepts, or items to improve learning and memory (Chiaravalloti & DeLuca., 2002)

MEMORY EXTERNAL STRATEGIES AND AIDS.   External aids such as notebooks, tape recorders and computers store information that the person might have difficulty remembering. Other aids such as pagers or alarm signals serve to remind a person to perform an action (prospective memory) (Toglia, 1993a). The success of an intervention program that utilized a combination of external aids and strategies with awareness training to improve prospective memory was recently described by Fleming, Shum, Strong, and Lightbody (2005). External memory aids include the following: timers, tape recorders, devices with preprogrammed alarms or alarm messages, electronic devices such as pagers, mobile phones, palm pilots, and cell phones, computers, pill box organizers, lists, daily planners, and notebooks (Figure 57.3). Case studies have documented the effectiveness of external aids (McKerracher, Powell, & Oyebode, 2005; Wade & Troy, 2001; Wilson, Emslie, Quirk, & Evans, 2001). Intervention is most effective when the client is motivated, involved in identifying the memory problem, and fairly independent in daily function (Cicerone et al., 2000, 2005).

FIGURE 57.3   Use of a list of clothing and other items to pack assists this client with memory and executive function impairments.

Evidence obtained from case studies supports the use of memory notebooks and other external aids in reducing everyday memory failures for people with moderate to severe memory impairments (Cicerone et al., 2000, 2005, McKerracher et al., 2005; Wade & Troy, 2001; Wilson et al., 2001). However, the successful use of an external memory aid may require extensive training. The client may need to practice initiating and using the aid in a variety of different situations.

The use of external aids might need to be graded. In the initial stages, the client might be expected to use the aid only when it is initiated by another person. Gradually, the client might be trained to initiate the use of the aid independently. Errorless learning, spaced retrieval, and other task-specific training methods that capitalize on procedural memory, may be used in training clients with moderate or severe memory impairments to use an external aid.

The most commonly used external memory strategy is the memory notebook. The memory notebook needs to be designed with the person's needs and lifestyle in mind (McKerracher et al., 2005). Sample sections in a memory notebook are as follows: personal facts, names of people to remember, calendar and schedule, things to do/important events (daily, within the next week), daily log of important events, conversations, summary of readings (articles, newspaper), medication schedule, and directions to frequently traveled places. Initially, the notebook should begin with one or two sections and gradually increase.

Memory notebook training needs to take place in the context of a variety of everyday activities. Therapy sessions should include role-playing and practice in use of the notebook. In addition, the client may be asked questions that involve reviewing and rereading the memory notebook. Specific memory notebook training protocols have been described in the literature (Donaghy & Williams 1998; Sohlberg & Mateer, 2001).

ADAPTATIONS OF TASK OR ENVIRONMENT.   Tasks and environments can be rearranged so that they place fewer demands on memory:

- Cue cards or signs in key places (e.g., a sign on door where it will be seen before leaving: "Take keys and . . .")
- Labeling the outside of drawers or closets to minimize the need to recall the location of items
- Providing step-by-step directions to reduce memory demands
- Providing checklists to assist in keeping track of task steps

Significant others can be trained to use methods that increase the likelihood that the client will remember material, such as asking the client to repeat any instructions or important information in his or her own words; encouraging the client to ask questions; and presenting material in small groups, clusters, or categories (Levy, 2005a).

Executive Functions, Organization, and Problem Solving

Executive functions are a broad band of performance skills that allow a person to engage in independent, purposeful, and self-directed behavior. Higher-level cognitive skills, including planning, cognitive flexibility, organization, problem-solving, and self–regulation, are fundamental components of executive function (Katz & Hartman-Maeir, 2005). Lezak and colleagues (2004) identifies four primary components of executive functions: volition, planning, purposeful action, and self-awareness and self-monitoring. Impairments are associated with prefrontal lesions and may be seen in all of these components, with one or two areas of impairment especially prominent (Lezak et al., 2004). Volition is the capacity to formulate an intention or goal and to initiate action. Planning involves the ability to efficiently organize the steps or elements of a behavior or activity and includes the ability to look ahead, anticipate consequences, weigh and make choices, conceive of alternatives, sustain attention, and sequence the activity. Purposeful action is the translation of an intention into an activity, requiring the ability to initiate, switch, and stop sequences (flexibility), as well as self-regulation. Self-regulation involves the ability to monitor, self-correct, and evaluate performance.

Executive function impairments significantly influence social participation, daily activity, and functional outcome (Goverover, 2002, 2004; Reeder, Newton, Frangou, & Wykes, 2004). Clients who display executive dysfunction may be able to verbalize plans but have difficulty carrying them out. There is often a disassociation between stated intentions and actions. This creates gaps between what a person needs to do or wants to do and what the person actually does (Eriksson, Tham, & Borg, 2006). Decreased initiation, flexibility, impulsivity, or **perseveration** may be observed during performance. Often, the client's approach is haphazard or consists of trial and error, and there is decreased ability to maintain goal-directed actions and to monitor or modify behaviors. For example, when grocery shopping, the client might proceed in an unorganized manner, not using a list or the aisle headings and reentering the same aisle multiple times. The client might have difficulty deciding on appropriate substitute items, buy items that are not needed, and forget items that were needed (Sohlberg & Mateer, 2001). Rempfer, Hamera, Brown, and Cromwell (2003) found that grocery shopping accuracy and efficiency were significantly associated with measures of executive functions in people with chronic schizophrenia. In addition, limitations in the ability to view information from different perspectives, generate alternative solutions, and respond flexibly can reduce the ability to cope, adapt to everyday demands, and relate to others.

Executive functions impairments represent a distinct challenge because they can be masked within familiar ADLs or routines but are most apparent when the client is required to function in situations that are less structured, require multitasking, or require dealing with novelty and unexpected situations (Burgess et al., 2006; Katz & Hartman-Maeir, 2005). Examples of activities that might present difficulty include following directions to a new location; selecting and ordering a gift from a catalogue; organizing a day's activities; planning a menu, lunch, picnic, vacation, or social gathering; investigating and comparing prices for delivery of flowers; mailing a package; or purchasing an electronic device.

Evaluation

Most standardized cognitive assessments are structured and do not adequately examine the area of executive functions (Sohlberg & Mateer, 2001) (see Table 57.1). Several assessments for executive functions have recently been developed (Bamdad, Ryan, & Warden, 2003; Birnboim & Miller, 2004; Wilson, Alderman, Burgess, Emslie, & Evans, 1996). Although these assessments appear more "ecologically valid" (i.e., able to predict behavior in everyday situations) than previous assessments were, further research data on the reliability and validity of these assessment tools are needed.

Intervention

STRATEGY TRAINING.   Strategies that maximize executive functioning can be practiced in a variety of unstructured tasks that require initiation, planning, organization, and decision making, such as organizing medications according to a schedule, planning an overnight trip and packing a suitcase, obtaining and organizing a list of local business phone numbers, and organizing tools (Figure 57.4).
FIGURE 57.4   A checklist helps this young client to ensure that he obtains all the required information as he makes phone calls.

Verbal mediation has been reported to be an effective strategy in improving executive function and self-regulation deficits. For example, Cicerone and Wood (1987) reported the successful use of a self-instructional procedure in a client with impaired planning ability and poor self-control secondary to brain injury. Intervention involved requiring the client to verbalize a plan of action before and during execution of a task. Gradually, the client was instructed to whisper rather than talk aloud. Generalization to real-life situations was observed after an extended period of time that included training in self-monitoring.

Training in problem-solving strategies involves teaching the person to break down complex activities into smaller, more manageable steps. Strategies may also aim to help the person to maintain the focus of goals and intentions (Katz & Hartman-Maeir, 2005). An evidenced-based review (Cicerone et al., 2000, 2005) concluded that there is evidence to support the use of formal problem-solving training with application to everyday activities. The authors recommended such training as a practice guideline for people with stroke or brain injury during postacute rehabilitation. The intervention goal is to replace an impulsive, disorganized approach with a systematic and controlled approach to planning activities, maintaining goal intentions, and solving problems. The steps of the problem-solving process are reinforced with use of self-questioning techniques. For example, self-questioning cue cards with the following types of questions can be used during problem-solving tasks: What do I need to do? Do I need more information? What do I have to do next? Have I identified all the critical information? Do I understand the problem? What are all the possible solutions? Did I choose the best one?

Broad checklists or task guidance systems are commonly used to assist the client in initiating, planning, and carrying out an activity systematically. Checklists may be specific to a particular activity (e.g., following steps to operate a computer program), or they may be designed broadly so that they can be used in a variety of similar activities (e.g., a checklist for food preparation or cooking activities).

Interventions should incorporate practice in identifying the situations or activities in which use of a checklist could be helpful. The client may be given the opportunity to practice the same activity with and without the use of a checklist to enhance awareness. Initially, the goal might be to have a client follow a checklist established by the practitioner or significant other. Eventually, the client might be given checklists with missing steps and be asked to review the lists to identify the missing components. Finally, the client might be required to create a checklist independently. Burke, Zencius, Wesolowskis, and Doubleday (1991) describe four cases of individuals with executive dysfunction for whom checklists were successfully used to improve the ability to carry out routine vocational tasks.

Decreased initiation, one of the hallmark features of executive dysfunction, can significantly interfere with the ability to use and apply a learned strategy. For example, a person with deficits in executive functions might use a strategy effectively when cued but not use the strategy spontaneously because of a failure to initiate its use. External cues such as alarm signals can be used to prompt the client to initiate a task, switch to a different task component, or use a particular strategy within an activity (Evans, Emslie, & Wilson, 1998; Manly, Hawkins, Evans, Wodlt, & Robertson, 2002).

ADAPTATIONS OF TASK OR ENVIRONMENT.   Adaptations that minimize demands on executive functions include training a significant other to preorganize an activity or activity materials. For example, all the items needed for grooming can be prearranged on the sink in the sequence in which they are used. As an alternative, one task step can be introduced at a time. These adaptations limit the need for planning and organization (Sohlberg & Mateer, 2001).

People who have difficulty with initiation, organization, and decision making require structure. Open-ended questions such as "What do you want to eat" should be avoided. Clients who have difficulty in initiation will have a great deal of difficulty in answering open-ended questions. Questions should provide a limited number of choices whenever feasible.

A predictable and structured daily routine enhances the client's ability to initiate tasks and should be established and monitored by a significant other. Audiotape instructions that cue the client to initiate an activity and perform each step at a time in its proper sequence have been reported to be successful within the context of daily routines (Schwartz, 1995).

GROUP INTERVENTIONS

Cognitive rehabilitation principles and strategies can be incorporated within group programs and combined with psychosocial or psychoeducational interventions. The group format can be used to target specific cognitive skills, or it can be used to teach compensatory strategies (Revheim & Marcopulos, 2006; Schwarztberg, 1999; Stuss et al., 2007). Group activities can emphasize interpersonal skills within cooperative tasks, such as planning a bake sale or publishing a newsletter, or role-playing scenarios involving interviews, conflicts, or on-the-spot problem solving. Strategies that include monitoring the tendency to respond impulsively, become stuck in one viewpoint, or wander off task can be practiced within social contexts (Toglia, 2005). Group programs that center on teaching self-monitoring techniques and strategies for paying attention, remembering, organization, or problem solving can be applied to a wide spectrum of clients. Activities such as remembering names and facts about group members, recalling directions for operating a new electronic device, or creating a checklist for a complex task can provide opportunity to practice

Evidence and Expanding Literature on Executive Function, Awareness, and Subtle Cognitive Impairments

Throughout this chapter, we cited evidence-based reviews (Cappa et al., 1987, 2005; Cicerone et al., 2000, 2005) and studies that support the effectiveness of interventions designed to address different cognitive perceptual symptoms. In this section, we highlight the evidence regarding executive functions and awareness. We also discuss the expanding literature on cognitive impairments across different populations and its implications.

Executive impairments have been found to consistently predict function (Boyle, Paul, Moser, & Cohen, 2004; Goverover, 2004; Laes & Sponheim, 2006; Royall, Palmer, Chiodo, & Polk, 2004). Significant relationships between executive function and social participation (Laes & Sponheim, 2006; Ucok et al., 2006; Yeates et al., 2004), academics (Biederman et al., 2004), IADLs (Jefferson, Paul, Ozonoff, & Cohen, 2006; Rempfer et al., 2003), employment (DeBattista, 2005; Eriksson et al., 2006), and quality of life (Sherman, Slick, & Eyrl, 2006) have been documented. The strong association between executive impairments and function that has been documented across different ages and populations highlights the critical need for occupational therapists to include executive function in evaluation and intervention planning.

Most standardized ADL assessments are structured and are not sensitive to the effects of executive function problems. Occupational therapists are encouraged to embrace the challenge of investigating tasks that adequately capture the cognitive demands of higher-level real-life activities. The use of ecologically relevant problem and situational simulations to examine the demands of higher-level everyday functioning is an important and promising direction for future research.

Self-awareness has been linked to daily functioning, involvement in productive activities, and outcome (Hoofien et al., 2004; Petrella, McColl, Krupa, & Johnston, 2005). Recently several pilot studies (Fleming et al., 2006; Goverover, Johnston, Toglia, & DeLuca, 2007; Ownsworth, Fleming, Desbois, Strong, & Kuipers, 2006; Tham et al., 2001) have investigated the use of occupation-based intervention to enhance self-awareness and occupational performance.

Occupation-based self-awareness studies support the premise that awareness gradually emerges within activities that are familiar because clients have a benchmark of comparison for self-evaluation (Ownsworth et al., 2006; Tham et al., 2001). This is important for occupational therapists because occupation-based self-awareness intervention appears to have potential for enhancing functional outcome. However, it is important to note that more research is needed to increase sample size and employ a more rigorous methodology to enhance the level of the evidence.

Although initial research in cognitive rehabilitation has been in the area of traumatic brain injury and stroke, cognitive rehabilitation principles are now being applied to other populations, such as those with schizophrenia (Penades et al., 2006), multiple sclerosis (Chiaravalloti, DeLuca, Moore, & Ricker, 2005), Parkinson's disease (Sinforiani, Banchieri, Zucchella, Pacchetti, & Sandrini, 2004), lupus (Harrison et al., 2005), learning disabilities (Cermak, 2005), mild cognitive impairment, and Alzheimer's disease (Bier, Desrosiers, & Gagnon 2006) and the well elderly population (Willis et al., 2006; Winocur et al., 2007).

Recently, subtle cognitive impairments that affect the ability to learn and integrate new information have been identified in people without brain injury, including conditions such as rheumatoid arthritis (Appenzeller, Bertolo, & Costallat, 2004), chronic fatigue syndrome (Capuron et al., 2006), Lyme disease (Fallon, Keilp, Prohovnik, Heertum, & Mann, 2003), cardiac failure (Vogels, Scheltens, Schroeder-Tanka, & Weinstein, 2006), muscular dystrophy (D'Angelo, & Bresolin, 2006), amyotrophic lateral sclerosis (Ringholz et al., 2005), diabetes (Munshi et al., 2005), critical illness (Hopkins & Brett, 2005), chronic obstructive pulmonary disease (Orth et al., 2006), and fibromyalgia (Katz, Heard, Mills, & Leavitt, 2004). In addition, subtle cognitive changes have been associated with chemotherapy treatments (Bender et al., 2006; Jansen, Miaskowski, Dodd, Dowling, & Kramer, 2005), radiation (Spiegler, Bouffet, Greenberg, Rutka, & Mabbott, 2004), and hemodialysis (Murray et al., 2006). Although cognitive impairments have been recognized as a core feature of schizophrenia, cognitive impairments are also now identified in across a wider range of mental health conditions, including depression (Kiosses, Klimstra, Murphy, & Alexopoulos, 2001), bipolar disease (Martinez-Aran et al., 2004), and obsessive-compulsive disorder (Boldrini et al., 2005), as well as in people with past histories of substance abuse (Davies et al., 2005).

different strategies and share experiences within a group context. Group members can be encouraged to reflect on performance and identify strategies that would be useful in their everyday activities. Group interventions that simultaneously address subtle cognitive difficulties and emotional issues have demonstrated value in improving self-awareness, self-efficacy, coping skills, psychosocial skills, and perceived daily functioning (Harrison et al., 2005; Rath, Smon, Langenbahn, Sherr, & Diller, 2003; Toglia, 2005).

SUMMARY

Recently, there has been a move away from intervention programs that focus exclusively on remediation of cognitive impairments. There is increasing evidence that supports the use of comprehensive and holistic cognitive rehabilitation programs that address a combination of cognitive, emotional, functional, and social participation skills in people with brain injury (Cappa et al., 2005; Cicerone et al., 2005, Cicerone, Mott, Azulay, & Friel, 2004; Sarajuuri et al., 2005; Tiersky et al., 2005). The need to blend cognitive interventions with those that address interpersonal and real-world functioning has been emphasized in recent literature; however, the outcome of cognitive rehabilitation is most commonly measured at the impairment level. As occupational therapists return to more community-focused intervention, we need to widen our perspective on the influence that cognitive perceptual impairments have on our clients' ability to engage in the occupations they need or want to do within the contexts of their lives. We need to explore the effect of cognitive rehabilitation on occupational engagement and social participation, for even subtle cognitive impairments can decrease satisfaction, participation, and quality of life, preventing our clients from leading enriching lives (McDowd, Filion, Pohl, Richards, & Stiers, 2003).

The outcome or benefit of cognitive rehabilitation needs to be examined broadly across different populations, including effects on changing existing habits; routines or increasing productive activity patterns; increasing the frequency and quality of social participation; decreasing caregiver assistance, stress, or burden; improving subjective well-being, including self-efficacy, self-esteem, satisfaction and quality of life; and preventing functional decline.

PROVOCATIVE QUESTIONS

1. The neuropsychologist reports that the client performed within normal ranges on a standardized test of executive function. Your occupational therapy evaluation included observation of real-life activities, during which the client showed difficulties in initiating, planning, and organization. How would you explain this discrepancy to team members? Explain how executive skills are linked to performance areas, providing examples. Describe how these skills can be evaluated and addressed in a client-centered intervention program within an inpatient or outpatient setting.

2. Your client who sustained a traumatic brain injury and has both hemiplegia and cognitive limitations tells you that he wants to work only on improving his arm movement. He appears unaware of his cognitive limitations and refuses to work on any activities that involve memory or problem solving because it is "not necessary." The client's family is concerned about his cognitive limitations and ability to return to his previous job, drive in his community, and be left alone at home. How would you respect your client's right to autonomy while addressing his impairments? What would be the goals of intervention? What might your intervention plan look like for this client?

Sensation and Sensory Processing

WINNIE DUNN

Learning Objectives

After reading this chapter, you will be able to:

1. Identify the major features of sensory systems.
2. Explain the alerting and discriminating aspects of each sensory system.
3. Describe the mechanisms of receiving, organizing, and using sensory input.
4. Categorize patterns of sensory processing based on evidence.
5. Link sensory-processing patterns to behaviors in everyday life.
6. Appreciate the significant contribution of sensation and sensory processing to one's ability to function during occupational performance.

SENSATION AND SENSORY PROCESSING ARE CRITICAL ASPECTS OF PERFORMANCE

There are many ways to characterize the human experience. We can consider the psychological, physical, and cognitive aspects of being human. Regardless of which perspective we take, sensation is the fuel that feeds all of these experiences. The way we have information about our psychological, physical, and cognitive experiences is from our senses. This is why occupational therapists must understand how the sensory systems work. We cannot understand people's experiences in their lives without understanding how their nervous systems are receiving, processing, and making meaning out of the sensory information that is available to them. Sensation and sensory processing provide the infrastructure for our experiences and therefore also provide critical tools for occupational therapy practice.

BASIC PRINCIPLES UNDERLYING THE FUNCTIONS OF THE SENSORY SYSTEMS

The sensory systems are the input mechanisms for the nervous system. The nervous system has several functions that direct how the sensory systems operate, including **centrifugal control** and balancing **excitation** and

inhibition. When we understand these neurological actions, we can also understand how to design activities that will take advantage of how the brain operates, thus creating an internal mechanism for supporting the person's performance.

Centrifugal Control

Centrifugal control is the most basic operation of the central nervous system (CNS) and is the brain's ability to regulate its own input. The brain accomplishes centrifugal control with suppression, divergence, and convergence (Noback & Demarest, 1981).

Suppression is the ability of the CNS to dampen some stimuli so that others are easier to detect. People receive continuous and variable sensory input; with suppression, we can filter through all the input to the brain, which determines which stimuli warrant attention and which can be ignored safely. Distractibility is related to poor suppression. Difficulty staying on a task occurs because attention is distributed to all the stimuli that are available in the environment.

Divergence is the brain's ability to transmit sensory input to many parts of the brain so that the input can affect multiple places at once. When a person is in danger, a small stimulus (e.g., the faint smell of smoke) needs to recruit lots of activity; we refer to these high activity levels as a *fight-or-flight response.* Divergence also allows an entire muscle works rather than one muscle fiber.

Convergence is the phenomenon of bringing input together from many sources. It is as if the brain is seeking confirmation by getting information from several sensory systems and is being careful to act only when there is enough input to tell a clear story. Convergence prevents us from reacting inappropriately when only partial stimuli are available and keeps us from reacting to every stimulus that comes along. In the sensory systems, inputs from multiple sensory inputs converge so that the brain can create a more organized response.

Balance of Excitation and Inhibition

The brain depends on a balance of excitation and inhibition to mediate input and output. With too much excitation, we overreact; and with too much inhibition, we will fail to notice and respond to the world around us. At each synapse and within neuron systems, there is a continuous negotiation between the excitation and inhibition messages that are available. There has to be enough excitation to override the inhibition in order to get an action.

When we consider this balancing at a systems level, we also see a balance of power in the complementary functions of the brain as a whole. Some parts of the brain are responsible for increasing our attention, while others are responsible for scanning the environment. These systems remain balanced because of the excitation and inhibition patterns between these parts of the brain. When brain injury disrupts typical function, people experience a release phenomenon. This means that one function is set free from the excitatory and inhibitory controls of its complementary parts of the brain. Heightened or dampened reactions occur when there is a release phenomenon.

Another way to balance excitation and inhibition is through feed forward and feedback mechanisms. The brain has connections that enable it to "listen in" to input and reactions. This allows the brain to monitor itself and make adjustments in plans for acting. Feed forward circuits send a message ahead of the primary sensory message either to alert higher centers about incoming input (i.e., "pay attention") or to create an inhibitory path so that the sensory message gets stronger (i.e., "notice only THIS"). Feedback circuits send a message back to modulate the strength of a response (Dunn, 2000). For example, feedback occurs after you have completed a movement and allows the brain to evaluate how effective that movement was to reaching your goal. On the basis of feedback, the system will make adjustments in how the message gets sent the next time (e.g., "a little more of those muscles, a little less of these muscles").

BASIC FEATURES OF SENSORY SYSTEMS IN THE NERVOUS SYSTEM

Even though each sensory system has unique functions, they have basic functions that they share. They all have an input structure that transmits information into the nervous system, and each sensory system has multiple types of input to transmit. They all have several levels in the brain for processing the input. Every sensory system operates to make the brain aware of stimuli that are available in the environment (i.e., the arousal/alerting function), and to construct maps of the body and the environment (i.e., the discriminating and mapping function). With this information and the maps that are created, a person can design effective responses to the demands of life.

Under typical circumstances, the arousal/alerting and discriminating/mapping functions complement each other, forming a balance of power. People use their sensory maps to figure out what is happening and how to react appropriately. The discriminating/mapping function guides behavior during everyday activities. The arousal/alerting function enables people to become aware of a new, unfamiliar, or potentially harmful stimulus so that they can be more aware and possibly create alternative responses (e.g., fight-or-flight responses). Arousal/alerting stimuli generate "noticing" behaviors, that is, attention is drawn toward the stimulus, which can disrupt ongoing behavior. Arousal/alerting stimuli make it possible for the brain

to orient to stimuli in case a protective response will be needed.

Discriminatory/mapping stimuli make it possible to gather data that will support and design functional behaviors. The information combines to create maps of body and environment, which can be used to create purposeful movement. Discriminating and mapping stimuli are more organizing for the brain.

Table 58.1 provides a summary of the arousal/alerting and discriminating/mapping components of each sensory system, with a simple definition and example of each. Table 58.2 is in the same format and provides information about when to use each sensory component in a therapeutic way. Remember that every sensory input can be useful or harmful. When we understand the characteristics of each sensory input, we can harness that input positively for a therapeutic purpose, that is, to support occupational performance.

SPECIFIC FEATURES OF SPECIFIC SENSORY SYSTEMS

Each sensory system has specific functions. The sensory neurons transmit information into the nervous system, and this information reaches higher brain centers. However, we must remember that **sensory processing** is different from sensory input itself. Sensation involves transmitting physical properties of a stimulus to the brain. Once in the brain, stimuli are changed (through excitation and inhibition),

TABLE 58.1	AROUSAL/ALERTING AND DISCRIMINATION/MAPPING DESCRIPTORS OF THE SENSORY SYSTEMS	
Sensory System	**Arousal/Alerting Descriptors***	**Discrimination/Mapping Descriptors†**
For all systems	*Unpredictable:* The task is unfamiliar; the child cannot anticipate the sensory experiences that will occur in the task.	*Predictable:* Sensory pattern in the task is routine for the child, such as diaper changing—the child knows what is occurring and what will come next.
Somatosensory	*Light touch:* gentle tapping on skin; tickling (e.g., loose clothing making contact with skin) *Pain:* brisk pinching; contact with sharp objects; skin pressed in small surface (e.g., when skin is caught in between chair arm and seat). *Temperature:* Hot or cold stimuli (e.g., iced drinks, hot foods, cold hands, cold metal chairs). *Variable:* Changing characteristics during the task (e.g., putting clothing on requires a combination of tactile experiences). *Short duration stimuli:* Tapping, touching briefly (e.g., splashing water). *Small body surface contact:* Small body surfaces, as when using only fingertips to touch something.	*Touch pressure:* Firm contact on skin (e.g., hugging, patting, grasping). Occurs both when touching objects or persons, or when they touch you. *Long duration stimuli:* Holding, grasping (e.g., carrying a child in your arms. *Large body surface contact:* Large body surfaces include holding, hugging; also includes holding a cup with the entire palmar surface of hand.
Vestibular	*Head position change:* The child's head orientation is altered (e.g., pulling the child up from lying on the back to sitting). *Speed change:* Movements change velocity (e.g., the teacher stops to talk to another teacher when pushing the child to the bathroom in his wheelchair). *Direction change:* Movements change planes, such as bending down to pick something up while carrying the child down the hall. *Rotary head movement:* head moving in an arc (e.g., spinning, turning head side to side).	*Linear head movement:* Head moving in a straight line (e.g., bouncing up and down, going down the hall in a wheelchair). *Repetitive head movements:* Movements that repeat in a simple sequence (e.g., rocking in a rocker).

Continued

TABLE 58.1 AROUSAL/ALERTING AND DISCRIMINATION/MAPPING DESCRIPTORS OF THE SENSORY SYSTEMS *Continued*

Sensory System	Arousal/Alerting Descriptors*	Discrimination/Mapping Descriptors[†]
Proprioception	*Quick stretch:* Movements that pull on the muscles (e.g., briskly tapping on a muscle belly).	*Sustained tension:* Steady, constant action on the muscles pressing or holding on the muscle (e.g., using heavy objects during play). *Shifting muscle tension:* Activities that demand constant change in the muscles (e.g., walking, lifting, moving objects).
Visual	*High intensity:* Visual stimulus is bright (e.g., looking out a window on a bright day). *High contrast:* A difference between the visual stimulus and surrounding environment (e.g., cranberry juice in a white cup). *Variable:* Changing characteristics during a task (e.g., a TV program is a variable visual stimulus).	*Low intensity:* Visual stimulus is subdued (e.g., finding objects in the dark closet). *High similarity:* Small differences between visual stimulus and its surrounding environment (e.g., oatmeal in a beige bowl). *Competitive:* The background is interesting or busy (e.g., the junk drawer, a bulletin board).
Auditory	*Variable:* Changing characteristics during a task (e.g., a person's voice with intonation). *High intensity:* The auditory stimulus is loud (e.g., siren, high volume radio). *Competitive:* The environment has a variety of recurring sounds (e.g., the classroom, a party)	*Rhythmic:* Sounds repeat in a simple sequence/beat (e.g., humming; singing nursery songs). *Constant:* The stimulus is always present (e.g., a fan noise). . *Noncompetitive:* The environment is quiet (e.g., the bedroom when all is ready for bedtime). *Low intensity:* The auditory stimulus is subdued (e.g., whispering).
Olfactory/gustatory	*Strong intensity:* The taste/small has distinct qualities (e.g., spinach).	*Mild intensity:* The taste/smell has nondistinct or familiar qualities (e.g., cream of wheat).

Note: *Arousal/alerting stimuli tend to generate "noticing" behaviors. The individual's attention is at least momentarily drawn toward the stimulus (commonly disrupting ongoing behavior). These stimuli enable the nervous system to orient to stimuli that may require a protective response. In some situations, an arousing stimulus can become part of a functional behavior (e.g., when the arousing somatosensory input from putting on shirt becomes predictable, a discriminating/mapping characteristic).

[†]Discriminatory/mapping stimuli are those that enable the individual to gather information that can be used to support and generate functional behaviors. The information yields spatial and temporal qualities of body and environment (the content of the maps), which can be used to create purposeful movement. These stimuli are more organizing for the nervous system.

Source: Dunn, W. (1991). The sensorimotor systems: A framework for assessment and intervention. In F. P. Orelove & D. Sobsey (Eds.), *Educating children with multiple disabilities: A transdisciplinary approach* (2nd ed.). Baltimore: Paul H. Brookes. Reprinted with permission.

organized, and compared to past experiences to determine the meaning of the sensory input. This is the sensory-processing part of the actions and is the aspect that we consider when observing behavior.

SENSORY INPUT MECHANISMS

The sensory systems are designed to transmit an exact kind of information. The chemical senses transmit information about tastes and smells. The body senses inform the brain about the skin, muscles, and body placement. The environmental senses provide information about the surround.

The Chemical Senses

The chemical senses separated into taste (gustatory) and smell (olfactory) when organisms moved from the sea to land during evolution. The taste system was the final check point for foods entering the body, while the smell system served to identify the location and direction of food or predators (Coren, Porac, & Ward, 1984).

TABLE 58.2   REASONS FOR INCORPORATING VARIOUS SENSORY QUALITIES INTO INTEGRATED INTERVENTION PROGRAMS*

Sensory System	Arousal/Alerting Descriptors	Discrimination/Mapping Descriptors
For all systems	*Unpredictable:* To develop an increasing level of attention to keep the child interested in the task/activity (e.g., change the position of the objects on the child's lap tray during the task).	*Predictable:* To establish the child's ability to anticipate a programming sequence or a salient cue; to decrease possibility to be distracted from a functional task sequence (e.g., use the same routine for diaper changing every time).
Somatosensory	*Light Touch:* To increase alertness in a child who is lethargic (e.g., pull cloth from child's face during peek-a-boo). *Pain:* To raise from unconsciousness; to determine ability to respond to noxious stimuli when unconscious (e.g., flick palm of hand or sole of foot briskly). *Temperature:* To establish awareness of stimuli; to maintain attentiveness to task (e.g., use hot foods for spoon eating and cold drink for sucking through a straw). *Variable:* To maintain attention to or interest in the task (e.g., place new texture on cup surface each day so child notices the cup). *Short duration:* To increase arousal for task performance (e.g., tap child on chest before giving direction). *Small body surface contact:* To generate and focus attention on a particular body part (e.g., tap around lips with fingertips before eating task).	*Touch pressure:* To establish and maintain awareness of body parts and body position; to calm a child who has been overstimulated (e.g., provide a firm bear hug). *Long duration:* To enable the child to become familiar, comfortable with the stimulus; to incorporate stimulus into functional skill (e.g., grasping the container to pick it up and pour out contents). *Large body surface contact:* To establish and maintain awareness of body parts and body position; to calm a child who has been overstimulated (e.g., wrap child tightly in a blanket).
Vestibular	*Head position change:* To increase arousal for an activity (e.g., position child prone over a wedge). *Speed change:* To keep adequate alertness for functional task (e.g., vary pace while carrying the child to new task). *Direction change:* To elevate level of alertness for a functional task (e.g., swing child back and forth in arms prior to positioning him or her at the table for a task).	*Linear head movement:* To support establishment of body awareness in space (e.g., carry child around the room in fixed position to explore its features). *Repetitive head movement:* To provide predictable and organizing information; to calm a child who has been overstimulated (e.g., rock the child).
Proprioception	*Quick stretch:* To generate additional muscle tension to support functional tasks (e.g., tap muscle bell of hypotonic muscle while providing physical guidance to grasp).	*Sustained tension:* To enable the muscle to relax, elongate, so body part can be in more optimal position for function (e.g., press firmly across muscle belly while to objects being manipulated). *Shift muscle tension:* To establish functional movements that contain stability and mobility (e.g., prop and reach for a top; reach, fill, and lift spoon to mouth).

TABLE 58.2 REASONS FOR INCORPORATING VARIOUS SENSORY QUALITIES INTO INTEGRATED INTERVENTION PROGRAMS* *Continued*

Sensory System	Arousal/Alerting Descriptors*	Discrimination/Mapping Descriptors†
Visual	*High intensity:* To increase opportunity to notice object; to generate arousal for task (e.g., cover blocks with foil for manipulation task). *High contrast:* To enhance possibility of location object and maintaining attention to it (e.g., place raisins on a piece of typing paper for prehension activity). *Variable:* To maintain attention to or interest in the task (e.g., play rolling catch with a clear ball that has moveable pieces inside).	*Low intensity:* To allow visual stimulus to blend with other salient features; to generate searching behaviors, since characteristics are less obvious (e.g., find own cubby hole in back of room). *High similarity:* To establish more discerning abilities; to develop skills for naturally occurring tasks (e.g., scoop applesauce from beige plate). *Competitive:* To facilitate searching; to increase tolerance for natural life circumstances (e.g., obtain correct tools from equipment bin).
Auditory	*Variable:* To maintain attention to or interest in the task (e.g., play radio station after activating a switch). *High intensity:* To stimulate noticing the person or object, to create proper alerting for task performance (e.g., ring a bell to encourage the child to locate the stimulus).	*Rhythmic:* To provide predictable/organizing information for environmental orientation (e.g., sing a nursery rhyme while physically guiding motions). *Constant:* To provide a foundational stimulus for environmental orientation, especially important when other sensory systems (e.g., vision, vestibular) do not provide orientation (e.g., child recognizes own classroom by fan noise and calms down). *Competitive:* To facilitate differentiation of salient stimuli; to increase tolerance for natural life circumstances (e.g., after child learns to look when his or her name is called, conduct activity within busy classroom).
Olfactory/gustatory	*Strong intensity:* To stimulate arousal for task (e.g., child smells spaghetti sauce at lunch).	*Noncompetitive:* To facilitate focused attention for acquiring a new and difficult skill; to calm a child who has been overstimulated (e.g., move child to quiet room to establish vocalizations). *Low intensity:* To allow the auditory stimulus to blend with other salient features; to generate searching behaviors since stimulus is less obvious (e.g., give child a direction in a normal volume). *Mild intensity:* To facilitate exploratory behaviors; to stimulate naturally occurring activities (e.g., smell of lunch food is less distinct, so child is encouraged to notice texture, color).

Source: Adapted from Dunn, W. (1991). The sensorimotor systems: A framework for assessment and intervention. In F. P. Orelove & D. Sobsey (Eds.), *Educating children with multiple disabilities: A transdisciplinary approach* (2nd ed.) Baltimore. Paul H. Brookes. Reprinted with permission.

The Gustatory System

We identify tastes by how the chemicals break down within our systems in the categories of sweet, salty, sour, and bitter (Coren et al., 1984). Taste buds receive the chemicals; 10,000 taste buds are available to young people, and the number diminishes with age. Taste goes from the taste buds to the brain stem, then to the thalamus, and on to the sensory homunculus in the parietal lobe (Heimer, 1983). Taste is compromised when there is brain stem trauma and with degenerative diseases that affect the thalamic and cortical regions that serve taste.

Taste on the tongue has been mapped many times, but functionally, food appeals to us because of the overall experience we have with the food, including not only the taste, but also the texture, temperature, and smell (i.e., intersensory integration of other senses with taste). People do not have universal reactions to tastes; for example, researchers have reported that some people taste caffeine and others do not (Blakeslee & Salmon, 1935; Coren et al., 1984; Hall, Bartoshuk, Cain, & Stevens, 1975). Older adults often complain about foods being bland; this is because the reduction of taste receptor viability. Because the taste receptors recover in about 10 seconds, changing the flavors in the mouth during the meal (e.g., salty, then sweet) can keep food interesting.

Olfactory Sense

We identify smells from the environment through a chemical reaction with the cells at the top of the nose. These cells project directly to higher brain centers, bypassing the thalamus; this is the only sensory system that does not relay through the thalamus en route to the cortex (Coren et al., 1984). Olfaction is the most sensitive system, but researchers have yet to be able to categorize the way in which people smell. We have a tendency to take our smell sensations for granted, but smell is critical to many human functions. With the connection of the olfactory system to the limbic system, smells associate with our emotions and with our memories. An odor can bring back very vivid images of past events. The olfactory system is also directly linked to arousal mechanisms, which is why it can be so helpful in getting a response out of people who are comatose.

It is this powerful influence on our emotions and memories that we must keep in mind in practice. Clients might react strongly to smells that we are not even aware of, including personal hygiene products that we use. An acutely ill person or a person with severe disabilities might recognize people by their smells as well, providing grounding and comfort in a confusing world. We must also be aware of the unfamiliar odors of a sterile environment and the comfort of familiar odors, even if those odors are unpleasant to us. Entering a family's home can expose the therapist to many unfamiliar odors; we might need to set our discomfort aside to consider how this olfactory environment is affecting the family members.

The Body Senses

The body senses tell the brain about where your body parts are and what they are doing. The somatosensory, or touch, system tells where you end and where the world begins because the receptors are within your skin. The proprioceptive system tells where your muscles and joints are, thus contributing additional information about the body's positions in space. The vestibular system tells where you are in relation to gravity; this adds a dynamic dimension to the body map.

The Somatosensory System

There are many types of touch receptors, and this variety allows the brain to know exactly what is happening to the skin. There is an elaborate system of receptive fields on the skin whose job it is to locate the touch experiences. A receptive field is the area on the surface of the skin served by one sensory neuron. In some places on your skin, the receptive fields overlap a lot (i.e., the mouth, face, hands, genitals); in other places, they barely overlap (e.g., the back). The brain compares the receptive fields of all the active neurons to detect the location of the touch; so when they overlap a lot, we know exactly where touch occurs, and when they overlap little, we can tell only the general area of touch. When we have an itch on a high-density area, we can get right to the spot to scratch, but when we have an itch on our back, we have to feel around a little to find the right spot. This is because of the receptive fields.

Since the touch receptors are all over the body surface, these sensory neurons transmit information into and up the spinal cord. Information travels to the brain stem, the thalamus, and then the sensorimotor cortex, specifically the parietal lobe. Traditionally, neuroscientists divided this system into the posterior and anterolateral systems, the posterior portion being responsible for touch pressure and proprioception (see the next section) and the anterolateral portion being responsible for light touch, pain, and temperature reception. We now understand that those divisions provide general guidance and recognize that individual experiences are unique.

Generally, the dorsal column system provides specific information about the surface of the skin and about the muscles and joints (see the section on proprioception). In reference to Tables 58-1 and 58-2, this system transmits the discriminating and mapping information. The input that travels through the dorsal columns goes directly to the thalamus and on to the parietal lobe in a very specific pattern, creating the sensory homunculus (a map of the body from a sensory point of view).

The anterolateral system transmits information for arousal and alerting the brain (see Tables 58.1 and 58.2 for examples). This input travels into the spinal cord and from there to the reticular formation of the brain stem. The reticular formation is responsible for generalized arousal of the brain, so these connections are less specific and more diffuse. The anterolateral input is important

when people need more arousal to participate, and it is input to be avoided when people are already agitated or have heightened responsiveness.

The Proprioceptive System

Inside the muscles, tendons, and joints are sensory receptors that keep track of what is going on with your body parts. They detect how long a muscle is, how fast it is moving, and the direction in which the limb is moving, which creates knowledge about where the body parts (particularly the limbs) are in space. We always think about the muscles and joints as part of the musculoskeletal system, but the sensory part of this system enables us to know where and how our bodies are moving. We do not just move; we have awareness of our own movements from the proprioceptive sensory receptors.

The muscle spindles detect length changes in the muscle. The muscle spindles are the sensory component of the reflex arc that supports muscle tone. The motor centers of the brain control the actions of the muscles by dampening the activity of the reflex arcs. When the motor centers of the brain are damaged, the reflex arc continues to activate without inhibitory control; this mechanism creates spasticity (Crutchfield & Barnes, 1984).

The Golgi tendon organs (GTO) are the sensory receptors in the tendons around the joints. The GTO detects changes in tension of the muscle pulling on the tendons. This action is important in cramp relief. During cramping, the muscle contains a high degree of tension. When you slowly and consistently stretch a cramped muscle, you pull on the tendon, which activates the GTO. This sensory message creates increased inhibition to the muscle, enabling the muscle to relax. This is the mechanism that we are harnessing when we use sustained stretch with people who have spasticity (Crutchfield & Barnes, 1984).

The cerebellum plays an important role in processing proprioceptive information. The cerebellum receives sensory input before the input is processed in the higher brain centers. This raw sensory input enables the cerebellum to be very precise in how it organizes motor actions. The cerebellum makes adjustments on the basis of what is actually happening (as told by the sensory input), which is why our motor planning can be so accurate. The cerebellum also gets information from the brain about the proposed movement plans and compares the plan and the sensation to determine whether an alteration must occur (Dunn, 2000). We can make just the right step because the cerebellum is fine-tuning the plan just before we need to act.

The Vestibular System

The vestibular system is responsible for our orientation in space. By detecting our relationship to gravity, the vestibular system keeps track of the body's movements. The vestibular organ, which is housed in the inner ear, contains one structure (the semicircular canals) that responds to angular movement such as swinging, spinning, and rolling and another structure (the chambers) that responds to linear movement such as jumping and running. Together, they record direction, angle, and speed of movement, with particular attention to the position of the head (Goldberg & Fernandez, 1984; Heimer, 1983; Kornhuber, 1974).

Like the proprioceptive system, the vestibular organ sends sensory input to the brain stem and cortex as well as the cerebellum. The connections with the cerebellum contribute to postural control through a continuous processing of sensory input (i.e., where the muscles and joints are, where the head is). Postural control is a basic building block for human behavior; although we tend to think of postural control as a motor operation, it is important to remember that postural control is built on accurate sensory input. Sometimes poor postural stability is due to weakness of muscles or poor biomechanical positioning, but equally likely is the possibility that inaccurate or unreliable sensory input makes it impossible to create postural control. When sensory processing is the source of the problem, our interventions must involve sensory-based strategies in order for postural control to improve. Without postural control, all other actions will be poorly orchestrated because there will be no stability on which to build movements. The sensory systems are the silent partners during occupational performance, creating a background on which to build purposeful movement (Kornhuber, 1974).

Another important function of the vestibular system is to coordinate with the visual system. Head position and eye position have to be in concert with each other to stay oriented in space. In addition to connecting with the cerebellum, vestibular input connects with the cranial nerves that serve the eye muscles (specifically cranial nerves III, IV, and VI). These connections enable us to determine whether our eyes are moving, our head is moving, or the world is moving. People who have motion sickness have more difficulty resolving this potential conflict.

The Environmental Senses

The environmental senses are responsible for providing information about the world around us. Technically, we could say that all sensation comes from the environment, but the function of the chemical and body senses is ultimately related to the body (e.g., determining how to get food for fuel, whether something is edible, where one's body is). The environmental senses map the world for us. The visual system informs us about the objects and people around us in a spatial context, and the auditory system informs us about the world in a temporal way. The visual system is concerned with size, shape, color, and placement. The auditory system is concerned with distance, intensity, and range. These senses work in concert with the chemical and body senses by providing the maps about where

we are so that we can understand what our bodies might need to do in response to environmental demands.

The Visual System

The visual system is responsible for mapping the spatial relationships in the world for us. The visual system has three characteristics that make it unique among the sensory systems. First, with more sensory nerves than all the other sensory systems, the visual system is very prominent and important to human function. Second, the visual pathways move from front to back in the brain, making it an excellent marker for site of lesions in the brain (Kandel, Schwartz, & Jessell, 2000). Third, the retinal cells, which are the input receptors for the visual system, can be seen by looking into the eyeball, making this the only place that we can view the central nervous system directly. Because of this accessibility, physicians use the retina to determine what might be going on systemically in the brain.

The visual pathways include the optic nerve, which carries information from each eyeball separately; the optic chiasm, which contains the combined fibers from both eyeballs as the pathways converge together; and the optic tract, which contains a new configuration of fibers from each eyeball. The optic tracts contain fibers from both eyes; the fibers in the left optic tract transmit information from the right visual world, and the fibers in the right optic tract transmit information from the left visual world. This pattern of fibers converging and reorganizing leads to specific visual losses with brain damage; occupational therapists must understand these patterns so that they can hypothesize about what functional challenges an individual might face with particular losses. For example, without use of the left eye (close your left eye to see what it is like), the person cannot see to the left side. The right eye's visual span covers part of the space in front of the left eye, so the person does not lose all vision to the left. Neuroscience textbooks have diagrams that break down the visual pathway losses and corresponding visual losses (e.g., Kandel et al., 2000). Figure 58.1 illustrates the classic lesions and visual deficits patterns.

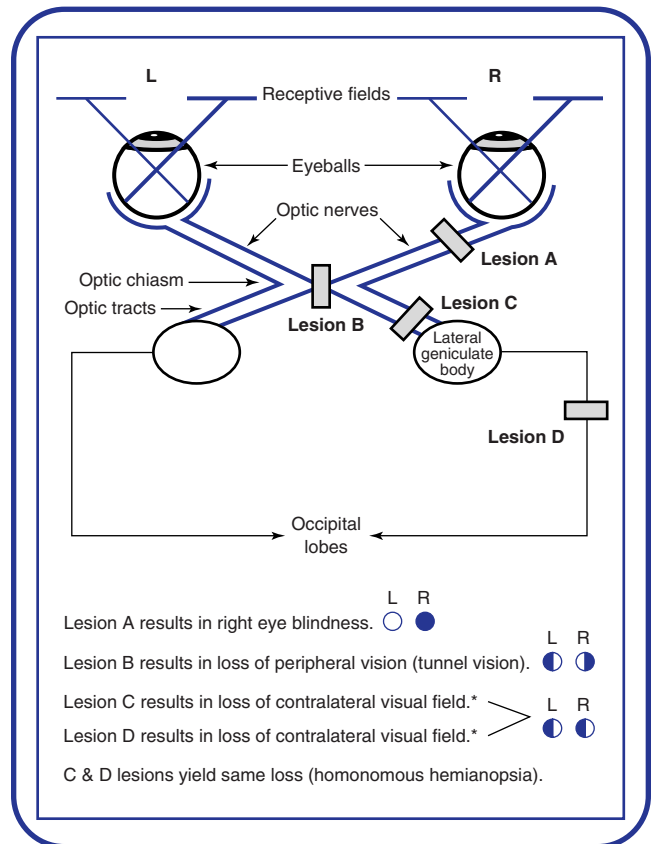
The visual system is designed to recognize contrasts (Dunn, 1997; Kandel et al., 2000). The cells search diligently for the most contrasting areas, just as a digital camera searches for contrast to focus itself. The eyeball is moving continuously so that new retinal cells can be activated, keeping a steady flow of input to the brain about the visual world. The visual system is most challenged by lack of contrast (e.g., misty, homogeneous environments) and also by overly busy environments (e.g., the contents of the junk drawer). Knowing this, therapists can be attentive to the contrasts in the visual environment to increase the chances that the person can detect important cues. For example, we can place a dark cloth on the work table to highlight white paper and writing utensils. We can also offer organizing strategies (e.g., sectioning off draw-


FIGURE 58.1 Neural lesions of visual field deficits.

ers) to increase the chances of finding things when they are needed.

The Auditory System

The auditory system processes sounds by detecting distance, direction, and sound quality; this enables us to orient within the environment (Kiang, 1984). The auditory system transmits air waves into pressure waves within the auditory receptors in the inner ear. The cochlea is shaped like a snail, and the different parts are situated so that we can detect all different tones.

The unique characteristic of the auditory system is the bilateral connections within the nervous system. Other sensory system input crosses to the opposite side of the brain when traveling to the cortex. When auditory input reaches the brain stem, information travels bilaterally to the cortex. This is important because bilateral connections create a safeguard for auditory input; both sides of the brain receive sounds from both sides of the world. When some auditory input is lost, we lose the ability to

localize sounds, but the brain continues to receive input bilaterally. The auditory system also has a feedback loop that sends information back to the cochlea; this feedback loop dampens the actions of some noises so that other sounds can be processed more clearly. This process, called *auditory figure-ground perception,* enables people to focus on the important sounds (e.g., the musician) and dampen the potentially interfering sounds (e.g., the person whispering next to you).

Other professionals serve as experts about how the auditory system works. Occupational therapists consider the functional use of auditory input. We might choose a quieter auditory environment if someone is more distractible to sounds. We might also work in a natural environment with random background noise to increase a person's ability to manage in a classroom, worksite, or social situation. By considering the contribution or interference of the auditory input, we increase the capacity of our interventions to be successful. For example, we might suggest that a worker use earphones with music during work hours to increase focus on work and decrease distraction from other environmental sounds (because the music will be louder in the ears). We might suggest that a teacher give a student easier seatwork when working in the classroom and send the student to do more challenging work in the library. Thus, we can manipulate the auditory environment in many ways to support performance.

Summary of Sensory Input Mechanisms

Each sensory system processes a certain type of input to inform the brain about our bodies and the world around us. Occupational therapists need to understand these input mechanisms because they provide the brain with all the material that is needed to design adaptive responses that enable us to participate successfully in our lives. When sensory input is impaired, the brain has inaccurate or unreliable input, and this can lead to maladaptive behaviors. When occupational therapists understand the sensory systems, they can design and adapt activities and environments to support more successful participation.

A MODEL FOR SENSORY PROCESSING

Once we understand the sensory input mechanisms, the next step is to understand how the brain manages this information. Sensory processing is the mechanism of organizing, making meaning, and responding to sensory experiences. The sensory systems themselves are important because people have specific reactions to touch, sounds, and other input. However, we also have learned that the brain has ways of responding that are separate from the sensory systems; these ways of responding reflect how the brain detects input and how the brain regulates the input for responding.

In studies with infants, toddlers, children, and adults, Dunn and colleagues (Brown, et al. 2001; Dunn 1997; Dunn 1999; Dunn 2001; Dunn 2002; Dunn & Bennett 2002; Dunn & Brown 1997; Dunn, Myles, et al. 2002; Dunn, Saiter, et al. 2002; Ermer & Dunn 1998; Kientz & Dunn 1997; McIntosh, et al. 1999; Myles, Hagiwara et al. 2004; Pohl, Dunn et al. 2001) identified four ways in which people process sensory information. The four patterns reflect a combination of nervous system thresholds and self-regulation strategies.

Underlying Concepts for Sensory-Processing Patterns

The sensory processing patterns are based on how the nervous system reacts to input (i.e., the neurological thresholds) and how the person responds to input (i.e., the self-regulation strategies).

Nervous System Thresholds

Individual neurons, neuron groups, and systems within the brain all have thresholds for responding. This means that it takes a certain amount of excitatory input to activate the neurons. For some people, it takes very little input to activate neurons, so we say that they have low thresholds. For other people, it takes a lot of input to activate the neurons, so we say that they have high thresholds. Thresholds for responding occur along a continuum rather than at extremes, and a person may have lower thresholds for some inputs and higher thresholds for other inputs. For example, one might be more sensitive to touch input yet might not notice sounds as easily.

Self-Regulation Strategies

In addition to thresholds, we act on the basis of self-regulation strategies. Some people actively control the amount of sensory input they receive; other people are passive, letting things happen and then responding. Self-regulation also occurs along a continuum rather than as only active or passive responding. For example, one person might leave the room to actively limit the amount of auditory input he or she is receiving, while another person might become irritable because of too much sound.

Patterns of Sensory Processing from Dunn's Model

Where the neurological thresholds continuum and the self-regulation continuum intersect, there are four basic patterns of sensory processing. **Sensation seeking** represents high thresholds and an active self-regulation strategy. **Sensation avoiding** represents low thresholds and an active self-regulation strategy. **Sensory sensitivity** represents low thresholds and a passive self-regulation strategy. **Low registration** represents high thresholds and a passive self-

COMMENTARY ON THE EVIDENCE

Linking Neuroscience to Everyday Life with Sensory Processing Knowledge

The neuroscience literature provides a wealth of knowledge about how the brain and nervous system work to support the human experience. One of the definitive texts to have as a reference is *Principles of Neural Science* by Kandel, Schwartz, and Jessell (2000); this text provides clear explanations of brain anatomy and function and summarizes the studies that have demonstrated the phenomena that are under discussion. As occupational therapists, we rely on the evidence provided by neuroscientists about how the nervous system operates.

When we take the neuroscience knowledge and begin to apply it to the human condition, this is where we create and test our hypotheses. The studies that have used the Sensory Profile measures have provided evidence that there seem to be specific patterns of sensory processing and that these patterns are present in people of all ages, from infants to older adults, who do not have disabilities (Dunn & Brown 1997; Dunn 1999; McIntosh, Miller et al. 1999; Dunn 2001; Dunn & Daniels 2001; Pohl, Dunn et al. 2001; Brown & Dunn 2002; Dunn 2002). Studies have also shown that people with specific disabilities demonstrate some of the same patterns of sensory processing but are more likely to experience extreme versions of the same patterns (Kientz & Dunn 1997; Ermer & Dunn 1998; Brown, Tollefson et al. 2001; Dunn, Myles et al. 2002; Myles, Hagiwara et al. 2004). Some authors have tested the validity of the sensory-processing patterns in Dunn's model of sensory processing and have found relationships between particular patterns of brain activity (using skin conductance measures) and Sensory Profile scores (Brett-Green, Schoen et al. 2004; Brown, Tollefson et al. 2001; McIntosh, Miller et al. 1999; Schaaf, Miller et al. 2003). These findings suggest that the Sensory Profile questionnaires are capturing behavioral responses that are consistent with differential brain activity. Further studies with more advanced technology will provide additional evidence of this validity.

We can also apply neuroscience knowledge within practice. Several recent studies have demonstrated preliminary support for applying our knowledge about sensory processing within natural environments. In two studies, researchers showed that using weighted vests in school contexts contributed to increased attention on task behavior and decreased self-stimulation (Fertel Daly, Bedell et al. 2001; VandenBerg, 2001). Both of these studies also present a rationale for linking the sensations from the vest to organizing nervous system responses. In a related preliminary study with adults who have sensory sensitivities, researchers report that providing deep pressure in the form of a weighted blanket mediates skin conductance responses to normal levels (Smith, 2005). Researchers have also demonstrated that using ball chairs for seating improved students' on-task behaviors in children both with and without disabilities (Schilling, Washington, et al. 2003). These authors hypothesized about the relationship between the sensory activation and the children's behaviors. Taken together, these studies provide some evidence that applying neuroscience knowledge within the natural context can be an effective way to support participation.

---

regulation strategy. These four patterns exist in people without disabilities across the life course, so we cannot think of them as a dysfunction or characteristic of disability. Although it is true that people with particular disabilities (e.g., autism, Asperger syndrome, schizophrenia) exhibit more intense sensory-processing patterns in general, we must remember that the patterns themselves reflect the general human experience. Our personal sensory-processing patterns can contribute to or interfere with our ability to participate in our daily lives. Let's discuss each pattern in turn. Figure 58.2 illustrates Dunn's model of sensory processing.

Sensation Seeking

People with a sensation-seeking pattern of sensory processing select behavior to increase the amount and intensity of the sensory experiences in their daily routines. They might add movement, sound, tactile input, or visual input to an experience, such as humming and rubbing the wall while skipping down the hall or chewing on a pencil or fiddling with objects during work. They engage in these behaviors to increase their sensory experiences during life routines and derive pleasure from the additional sensory input.

PRACTICE DILEMMA

MOVING EVIDENCE INTO EVERYDAY PRACTICE

A family has been reading on the Internet and tells you that they want you to provide a sensory technique that you know has no evidence to support it. Discuss how you will handle this situation. Include how you will talk about the technique to the family, what other information you might provide for them, and alternatives that you might offer.

Because they have high sensory thresholds, more sensory input enables people with sensation-seeking patterns to reach their high thresholds and therefore be more responsive within their daily activities. For sensation seekers, it is more comfortable to have more sensory input. People with sensation-seeking patterns might play music while cooking or layer their clothing to provide more input to the skin throughout the day.

Sometimes people lack insight about their need for sensation seeking. They might get distracted from their daily life activities as they seek sensory input. For example, a person who seeks movement and body position input might be distracted from his desk job tasks because sitting at the computer does not provide enough input. This person might get up many times during the day to get more vestibular and proprioceptive input; if the person has a desk job, these frequent breaks could affect productivity. An occupational therapist might suggest that this person sit on a flexible cushion or a rocking chair at the desk to provide needed sensory input while working. We might also suggest that the person work at a standing desk to increase body input while working. We support participation when we find ways to provide needed sensory input within daily activities so that sensation seekers can continue to participate while getting the sensory experiences they need.

Low Registration

People with a low registration pattern of sensory processing fail to detect sensory experiences around them, so their behaviors might seem mismatched to situations. They will be calm in situations that would be disconcerting to others. It might also seem that people with low registration are uninterested, when in fact they are not noticing things that others notice quickly. For example, a person with low registration would be slower to intervene with children who are bickering, which could have the effect of providing time for the children to work things out for themselves.

People with low registration will be comfortable in more situations than others will. Because it takes a lot of sensory input for them to notice, they have a much wider range of tolerance. Behaviors that might be noticeable or irritating to others will go unnoticed, so some situations will not become charged for a person who has low registration. One family member could be watching TV while another is listening to the radio in an adjoining room; for a family member with low registration for sounds, this situation would be fine for continuing to pay bills or write a letter.

People with low registration are not getting enough activation to meet their sensory thresholds; and with a passive self-regulation strategy, they are less likely to pursue additional sensory input. Missing cues around them could interfere with their daily routines. For example, a person might burn parts of the dinner, missing the fact that what is in the pot is getting dry or the oven timer has been beeping. When low registration interferes with a person's daily life participation, occupational therapists can provide sup-

Neurological thresholds	Self Regulation Strategies	
	PASSIVE	**ACTIVE**
HIGH	Low registration	Sensation seeking
LOW	Sensory sensitivity	Sensation avoiding

FIGURE 58.2 Dunn's model of sensory processing. Source: Reprinted with permission: Dunn, W. (1997). The impact of sensory processing abilities on the daily lives of young children and families: A conceptual model. *Infants and Young Children, 9*(4), 23–35.

port by creating ways to intensify the sensory environment to make it easier to notice what is happening. In the kitchen example, we could change to a cooking timer that has an irregular sound (rather than even beeping sounds) and make it louder. We could also add a programmable timer that talks to indicate when it is time to check on the food. Adding music could also increase sensory intensity, making it easier for the person to notice what is going on in the kitchen. As with sensation seekers, we want to make it possible for the person with low registration to continue participating while getting the increased intensity they need.

Sensation Avoiding

People with a sensation-avoiding pattern of sensory processing select behavior to minimize the chances for new or unexpected sensory experiences. Sensation-avoiding people will withdraw from situations to reduce sensory input. When withdrawing is not possible, they might become aggressive to get others' help to remove them from the overwhelming situation. Having only predictable and familiar sensory input is the most comfortable situation for a person with sensation-avoiding patterns.

Because they have low sensory thresholds, less sensory input enables people with sensation-avoiding patterns to be more responsive within their daily activities. For avoiders, doing things the exact same way every time is comforting; the sensory experiences of getting dressed in the same clothing would be desirable. New clothing would represent new and unfamiliar tactile input.

Sensation avoiding can interfere with daily routines because it is hard to have everything be the same from day to day. If the person feels the need to withdraw at the first sign of unfamiliar sensory input, it can be hard to get any tasks completed. Occupational therapists can provide support for participation in several ways. First, we can help the person to identify ways to get respite from intense sensory environments during the day (e.g., a getaway space at home, a place to take a walk). Second, we can learn what sensations are acceptable for the person and work together to find ways to increase these sensations during daily routines. For example, if a person is overwhelmed by light touch on the skin, we can work on developing a wardrobe that provides even, firm touch pressure input to the skin. (Remember that light touch activates the arousal mechanisms and therefore can become overwhelming very quickly, while touch pressure provides more organized body scheme input without providing additional arousal.) We can suggest Lycra undergarments and stretchy, form-fitting shirts and tights; the additional benefit of these suggestions is that touch pressure input makes it harder to receive the arousing input that is bothersome. So we support participation for sensation avoiders when we find ways to provide acceptable sensory input while reducing the chances for difficult sensory input during daily routines.

Sensory Sensitivity

People with a sensory sensitivity pattern of sensory processing react to the sensory experiences around them. They notice sensations quite readily, so they can seem distractible or bothered a lot of the time. People with sensitivity will comment on the things that are going on around them because they are so aware of sensations. For example, at a concert, the person will notice others pulling out a tissue, shuffling their feet, flipping through the program, and adjusting in their seats. Sometimes the sensation from all these associated actions can keep the person from being able to hear and enjoy the concert.

People with sensory sensitivity do best with precise circumstances. They are less likely to withdraw like avoiders yet still want to keep their sensory experiences within ranges they can handle. For people with sensory sensitivity, it is more comfortable when they know their own limits and can manage the amount of sensory input that is comfortable in each life circumstance. For example, they will plan a family outing in great detail to make sure everything is just right for them. (An avoider will get out of going altogether.)

When a person has sensitivity, precision in everyday life becomes important. A person might go through several showerheads, towels, soaps, and other hygiene products before finding the ones that are "just right." These individuals may also be unhappy when companies change their product lines because it means finding another acceptable product. Occupational therapists can support people with sensitivity by helping them to characterize the details of their sensory needs and to find additional products, furniture, supplies, and situations that contain what sensory input they need without containing too much sensory input or undesirable sensory input. For example, we could look at all the person's personal hygiene products to identify similarities among them and then collaborate to identify other products, foods, and supplies that have these characteristics. If all the items are unscented and creamy, we can use this information in other situations. Knowing the sensory characteristics is a powerful tool for people with sensitivity.

PROVOCATIVE QUESTIONS

1. Think about your daily routines as a continuous sensory-processing experience. What do you gravitate toward? What do you shy away from? What sensory-processing strategies are embedded in your daily routines? What sensory experiences seem to interrupt your flow?
2. Think about a situation that you find very difficult to deal with. Using a sensory-processing point of view, how could you change that situation to make it more manageable for you?

CASE STUDY: *Danielle, Please Join Us for Dinner*

Danielle is a 5-year-old girl who lives with her older sister and her parents. Her mother, Sandy, wants some help in figuring out how to get Danielle to be engaged with the family during the evening meal. This is the only time when all the family members are together and can check in with each other about their days.

In an initial phone conversation, Sandy tells Mona, the occupational therapist, about what happens when they get home. Typically, the older sister is in her room on her computer, listening to music and talking on the phone. Danielle comes home with Sandy, and although they talk in the car, Danielle becomes less interactive once they get home. Sandy gets busy working on dinner, and Danielle watches TV. Dad is not home from work yet.

They sit down to dinner, and Danielle has to be called several times to get her to the table. Once Danielle gets to the table, she hangs on the chair and lays her head on the table, and her parents continue to have a hard time getting her attention.

Mona comes to the house for a dinnertime visit so that she can observe the family routines and gather more information. She also sends the parents a Sensory Profile to complete about Danielle, because she wonders whether low registration might be making it hard for Danielle to stay engaged within her contexts. Mona notices that Danielle is talking to Sandy when they come in the door, but then Danielle gets more placid as she lies in front of the TV. When Mona asks Danielle to sit up on a pillow, this seems to help a bit, and when they both start talking back to the TV show to answer the questions the program asks of its audience, Danielle becomes a little more animated. Mona knows that her being new in the home is also contributing to Danielle's higher engagement.

Mona's hypothesis about low registration turns out to be correct; the Sensory Profile scores, the parents' descriptions, and Mona's observations all converge to paint a consistent picture of a child who needs more intense sensory input to stay engaged. Because Danielle responds to prompting by others (e.g., to sit up, to talk back) and becomes more engaged, this gives Mona some ideas about how to help this family.

When Mona and Sandy meet, they discuss Danielle's need to have more sensory input. Mona explains that when they are in the car, Sandy is talking, pointing out things to look at, and playing the radio, and all these things help to keep Danielle active and engaging. When they get home and Danielle is left on her own, she does not seek extra input for herself, so she becomes less engaged and misses things going on around her. This is not a good situation leading up to dinner, because Danielle cannot get enough sensory input from just walking into the dining room.

Mona makes several suggestions for increasing the sensory experiences Danielle has leading up to dinner that could make it easier for her to interact during the meal. They talk about ways in which Danielle can help with dinner, such as stirring pots, getting out utensils, and carrying plates to the table, so that Danielle's system can have continuous sensory input from walking, carrying, talking, and feeling the objects as she works. Mona also explains that using contrasting placemats and plates with the food will make the table more visually interesting. Sandy really responds to the plan and even starts to add her own ideas. She puts food coloring into Danielle's milk to surprise her at the table, and the family starts a guessing game about what foods are in the dishes. All these things keep Danielle engaged because she is getting a continuous and intense amount of sensory input while they are preparing and eating the meal. This enables Danielle to stay alert at dinner and talk with her family more actively.

Questions

1. Do you have other ideas that Danielle's parents could try to increase Danielle's sensory input before or during dinner?
2. Mona would need to help the parents know how to detect overstimulation as well. What would be some behaviors that might be warning signs to the parents that Danielle is getting overstimulated?

3. What evidence in the literature supports the changes you might make in your life to make a situation more manageable for you?

Sensory Integration

SUSANNE SMITH ROLEY AND S. ESSIE JACOBS

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the significance of sensory processing to learning and behavior.
2. Identify concepts that are central to sensory integration theory.
3. List ways to assess sensory integrative dysfunction.
4. Distinguish intervention using sensory integration principles from those using other frames of reference.
5. Recognize the evidence that supports and guides the use of sensory integration theory and principles in occupational therapy practice.

INTRODUCTION

Sensory integration (SI) theory is a dynamic and ecological theory that specifies the critical influence of **sensory processing** on human development and function. This theory emphasizes a person's ability to appropriately process sensory information from the body and integrate it with information about what is going on around the person so that he or she can effectively act on the environment. It contributes to our understanding of how sensation affects learning, social-emotional development, and neurophysiological processes such as motor performance, attention, and **arousal**. Occupational therapists commonly use sensory integration theory in practice as a frame of reference that can be used to both assess and intervene with people who have sensory integrative or sensory processing dysfunction that adversely affects function (Parham & Mailloux, 2005). It is important to be clear what one is referring to when using the term *sensory integration,* as this singular term has been used to refer to a theory, a neurological process, a disorder, and an intervention approach (Bundy, 2002; Mulligan, 2003).

The theoretical principles that support the use of this frame of reference draw on evidence from neuroscience as Dr. Ayres recognized that behavior and emotions are regulated by brain mechanisms. Advances in neuroscience continue to expand and support Dr. Ayres' original hypotheses, contributing to evidence-based practice (Bauman, 2005; Schneider, 2005). Dynamic systems theories have emerged that provide an understanding of the complexity of development (Thelen & Smith, 1994) and

help to explain the complexity of the way in which this intervention effects change in children (Spitzer, 1999). SI is now commonly applied in educational settings with children who have learning and behavior disorders (American Occupational Therapy Association, 2003), as well as in private settings.

While education in sensory integration theory and intervention principles is part of the entry-level curricula for occupational therapists and occupational therapy assistants, postgraduate training is recommended for those specializing in the use of SI intervention in clinical practice. Occupational therapists with sensory integration certification and mentorship with a master clinician are best prepared to evaluate and provide SI intervention. Occupational therapy assistants may provide intervention using SI principles with appropriate supervision by an occupational therapist (Miller-Kuhaneck & Smith Roley, 2005).

A. JEAN AYRES

In the 1960s, Dr. A. Jean Ayres (1920–1988), an occupational therapist and educational psychologist, recognized and described hidden disabilities, referring to them as *dysfunction in sensory integrative processes* (Ayres, 1963, 1968) and later as *sensory integrative dysfunction* (Ayres, 2005). Her insights and subsequent theory development were made through keen observation of behavior; review of the neurophysiological underpinnings of behavior; synthesis of literature from neurology, psychology, neurophysiology and education; ongoing research on assessment; and statistical analysis of patterns of dysfunction (Ayres, 1972, 1974) (Figure 59.1).

In 1979, Dr. Ayres published *Sensory Integration and the Child,* a book "to help parents recognize sensory integrative problems in their child, understand what is going on, and do something to help their child" (2005, p. 12). Dr. Ayres anticipated that as our understanding of the central nervous system advanced, our understanding of the neurological basis of sensory integration theory, assessment, and intervention would become more refined. The basic premises of her work stand today. In the 25th Anniversary Edition of *Sensory Integration and the Child: Understanding Hidden Sensory Challenges* (2005), Dr. Ayres is described as a "developmental theorist" (Knox, 2005), a "pioneer in affective neuroscience" (Schneider, 2005), a "pioneer in our understanding of developmental **dyspraxia**" (Cermak, 2005), "one of the original perceptual-motor theorists" (Smith Roley, 2005), and "an astute observer of human behavior and neurological development" (Bauman, 2005). Her work made major inroads into our understanding of clinical neuroscience, the importance of experience in brain development, the role of **tactile defensiveness** and **sensory modulation** disorders as contributors to behavioral disorders, and the impact of **sensory registration** in autism, among others.
FIGURE 59.1 Dr. Ayres applied her theories through precise evaluation that guided the intervention that is characterized by playful self-motivated motor engagement in sensory activities.

SENSORY INTEGRATION THEORY

Dr. Ayres developed a theory of sensory integration to explain the link between the nervous system and behavior. Five basic assumptions formed the theoretical basis for Dr. Ayres' thinking:

1. The remarkable potential for change of the developing brain, or **neuroplasticity**, which has recently been found to be true of the adult brain as well (for reviews, see Buonomano & Merzenich, 1998; Cruikshank & Weinberger, 1996; Gross, 2000)
2. Interactions between the "higher-order" (cortical) areas of the brain and those in the "lower" subcortical areas as fundamental to adequate sensory integration
3. Neurophysiological development of sensory integrative functions that occur in a natural order and follow a basic sequence
4. An **adaptive response**, which is "the ability to adjust one's action upon environmental demand" (Ayres, 1972, p. 8) and promotes a higher level of integration as a consequence of the **feedback** to the central nervous system

5. Presence of an **inner drive** to meet and master a challenge, which fosters the development of sensory integration

Neuroplasticity

Dr. Ayres' appreciation of the importance of experience as a major determinant of cortical organization and resulting function remains a bedrock principle in the field of neuroscience today. This "experience-dependent plasticity in the cerebral cortex reflects the importance of learning in our mental life and behaviors" (E. K. Miller, 2000, p. 1067). During the period when Dr. Ayres studied neuroplasticity, researchers thought that the brain's ability to be modified was robust during childhood but, after a critical period of development, became quite limited. It is now known that the brain has the capacity to be modified throughout the life course (Bear, Connors, & Paradiso, 2006; Gilbert & Wiesel, 1992).

Organization of the Brain

Although our nervous systems are almost constantly being bombarded by sensation, not all of this sensation reaches the cortex. If the cortex had to process every sensation a person experienced, it would not be able to perform higher-level tasks, such as thought and action. Neuroscientists have long explored the hierarchical organization of the brain. Dr. Ayres understood that higher brain levels, as they develop, remain dependent on lower brain levels (Ayres, 1972, 2004, 2005). Before many of the incoming sensory messages ascend or somewhere along their ascent toward the thalamus and then the cortex, other neurons are acting on them to either dampen their activity (**inhibition**) or, in some cases, enhance their activity (**facilitation**). Dr. Ayres described this process of inhibition and facilitation as a central nervous system process of self-organization (2005). In this way, the subcortical structures are important drivers of the information that higher cortical levels might have to act on.

On the basis of her understanding that perception of any sensory input requires facilitation of some input and inhibition of other input, Dr. Ayres designed intervention that would incorporate these mechanisms and would therefore promote more integrated functioning of the brain as a whole. Using stimuli that have an inhibitory effect and using a task on which the child can focus that elicits an **adaptive response** were proposed by Dr. Ayres as early therapeutic principles to advance central nervous system organization. These principles remain today as core elements of occupational therapy using a sensory integration approach.

To date, there has been no change in our appreciation of the role of the subcortical structures to provide the foundation for efficient functioning. However, there is currently a greater focus on the reciprocal interdependence between higher and lower brain levels (Middleton & Strick, 2000; Wall, Xu, & Wang, 2002). This interplay of activity between the higher-level cortex and subcortical structures (in particular, the thalamus) further contributes to the self-organizing processes of the brain. In this way, the brain is able to develop representations that impart deeper meaning than is provided by the multisensory information alone. For example, suppose we have an object that is orange and round (vision), has a citrus scent (olfaction), and has a slight bumpiness along its surface (tactile); the interplay in the brain contributes to our associating these qualities with an orange.

Dr. Ayres believed that the therapeutic use of appropriate multisensory activities might be the most effective way to promote sensory integration. The research that guided her thinking suggested that there were common integrating sites within the central nervous system where information from separate sensory sources converged onto neurons that had the potential to respond to inputs from multiple sensory sources. These were referred to as "convergent" or "polysensory" neurons and were considered important sites for the coordination of several different types of information (Ayres, 1972). Over the past 25 years, there has been extensive research into cross-modality or multisensory convergence, and findings demonstrate that this process takes place at sites in the midbrain, thalamus, and cortex (for a review, see Stein and Meredith, 1993). At every such site, there is the opportunity for cross-modality or multisensory integration.

One of the best-studied groups of multisensory neurons is in the superior colliculus (SC) (Sparks & Groh, 1995; Stein, 1984; Wallace, Meredith, & Stein, 1993). This midbrain structure is classically divided into superficial layers predominantly containing visual neurons and deep layers containing multisensory (visual, somatosensory, and/or auditory) and premotor neurons. Investigation into the SC has demonstrated how signals from the different senses are combined and used to guide adaptive motor responses, such as hearing a sound and turning to visually locate the source (King & Palmer, 1985; Meredith & Stein, 1986; Stein, Meredith, Huneycutt, & McDade, 1989; Stein, Huneycutt, & Meredith, 1988; Wallace et al., 1993). In this example of the orienting response, when the auditory and visual stimuli occur close together in space and time, their combination enhances the ability to detect and identify the external stimuli. Conversely, cross-modality cues that are significantly discordant (e.g., spatially disparate) can have the opposite effect and depress responses (Stein et al., 1989). Whether the response is enhanced or depressed, an important behavioral consequence of the synthesis (or discordance) of the sensory information is closely related to changes in attention (Stein et al., 1989).

Recent studies by Stein (2005) exploring multisensory integration demonstrate that the cortex plays an important role in mediating convergence of sensory inputs at the level of the superior colliculus. By temporarily deactivating the

information flow from the cortex to SC neurons, response enhancement is compromised. As a consequence, the ability to use cross-modal stimuli to enhance SC-mediated behavioral performance is also compromised. As Dr. Ayres suspected and the ongoing research has confirmed, the process of multisensory integration is highly adaptive, "knitting together information from different sensory channels to better detect, identify and react to environmental events. . . . Sensory integration is critical to perception and behavior" (Stein et al., 1989, p. 12).

We have come to recognize that primary sensory pathways, rather than merely transmitting sensation in an inflexible manner, are sending impulses that are constantly being adjusted in relation to attention, arousal, and anticipation as well as thought and planning. Eide notes that "when the sensory system is working effectively, crossmodality improves our responsiveness and interaction with our environment. However, when sensory systems are underactive or overactive (**sensory defensiveness**), attention becomes inappropriately directed or diverted" (2003, pp. 1–2). Eide proposes that therapeutic interventions focused on environmental adaptations and appropriate sensory strategies "are often children's best hope of reducing bodily "distractions" so that they can focus on learning and socialization" (2003, p. 2).

Over the past two decades, findings from neuroscience research indicate that sensory information (such as that which allows us to perceive an object as an orange) is distributed as serial and parallel streams of information (Felleman & Van Essen, 1991; Pons et al., 1987; for a review, see Mesulam, 1998). Even though this distributed processing model of brain structure and function was not specified at the time, in 1972, Dr. Ayres wrote, "Organization must and does occur vertically among the levels of the brain as well as horizontally between two structures at the same level" (p. 27), demonstrating an understanding of the integrative and reciprocal complexity of the brain. Bundy and Murray (2002) comment that a systems approach to nervous system organization, in which "systems interact, and both cortical and subcortical structures contribute to sensory integration" (p.11), is consistent with Dr. Ayres' theory.

Developmental Progression

Viewing development as a process that the brain undergoes, Dr. Ayres noted that "each child's brain is designed to follow an orderly, predictable, interrelated sequence of development that results in the capacity for learning" (1972, p. 4). Given an enriched, supportive environment, children will grow and develop sensory and motor memories that help the children adapt to their own growth and interests in the context of an ever-changing environment. Whereas Dr. Ayres focused on the first seven years of life as the time frame in which this occurred, we now know that the brain continues to develop throughout the life

course (Bear et al., 2006; Gilbert & Wiesel, 1992). A critical aspect of this process is that the child experience sensations, which places a demand on the brain to organize the incoming stimuli into **percepts**. Depending on the context in which the stimuli are experienced, the child might focus on and attend to the input (**sensory detection** as a central nervous system process; sensory registration as inferred from the child's behavior), or if they are not relevant, the stimuli might be ignored (inhibition centrally, sensory modulation behaviorally) (Lane, Miller, & Hanft, 2000; Miller & Lane, 2000). For example, a child who is riding a bicycle typically attends to visual and auditory inputs along the ride (sensory registration) while ignoring the feel of the shirt as it is blown by the wind (inhibition). If the child's brain is unable to organize incoming sensation efficiently, these "filtering out" and "attending to" processes might be inadequate. In this example, the child who is unable to tolerate the tactile input from the shirt's movement against the body will have difficulty attending to the important visual and auditory information in the environment that are necessary for both safety and skill. Until the tactile sensation is discriminated as "safe," the child is considered to remain in a more primitive "fight-or-flight" mode. In general, this primitive state undermines both the development of skills and emotions as it is through the ability of the brain to organize sensations that "the child gains control over his emotions" (Ayres, 2005, p. 14).

Adaptive Response

Our ability to make adaptive responses to ever-changing environmental demands and challenges allows us to learn something new and, in turn, change the environment (Ayres, 1972, 1979, 2005). Spitzer (1999) discusses the congruence between the concept of self-organization in dynamic systems theory with Dr. Ayres' concept of the adaptive response in sensory integration theory. In both theories, feedback from the individual's spontaneous, active adjustments contributes to self-organization of the brain (Smith & Thelen, 1993; Ayres, 1979, 2005). Dr. Ayres stressed the importance of "organizing adaptive responses to increasing complexity" (1972, p. 128) as a key component of intervention. She was guided by neuroscience research suggesting that inefficiency in **synaptic activity** along anatomical pathways might be contributing to poor integration of sensory information and proposed that focusing on eliciting a response that was not yet well developed might enhance **synaptic function** (Ayres, 1972; Katz & Shatz, 1996; Schlaug, 2001). While an adaptive response occurs most typically during a motor task, it is also apparent with demands arising in other domains (e.g., emotional regulation, cognitive, and social interaction).

"Therapy using a sensory integration approach is a natural process" (Ayres, 2005, p. 140). Dr. Ayres stated that if

the child is not able to integrate his or her nervous system successfully in typical environments, "[h]e needs a highly specialized environment, tailor-made for his nervous system" (Ayres, 2005, p. 141). This style of therapy requires that the occupational therapist or occupational therapy assistant design a rich set of sensory-based activities and facilitate the child's self-organization and physical engagement with the environment. While classic intervention using sensory integration is provided in a carefully designed clinic setting (Parham & Mailloux, 2005), sensory integration principles and activities can be adapted to be used in a variety of sensory-based activities in natural settings such as at home or at school (Pediatric Therapy Network, 2004). It is difficult to use SI interventions, however, if the child does not have room to safely move, jump, and crash or cannot rearrange the objects to interact in novel ways.

Inner Drive

A child cannot be forced to self-organize or to generate an adaptive response. Rather, it is the drive for mastery or the motivation to explore that elicits in the individual the willingness to participate. "Organizing and evincing an adaptive response which is more mature and complex than any emitted before requires effort—the kind of effort that a child gladly summons when he is emotionally involved in the task and believes he can cope with it" (Ayres, 1972, p. 127). Embedded in this statement are two important concepts of intervention. One is the concept of the "**just-right challenge**," whereby the task is beyond what the child is already capable of achieving yet is maximally demanding to promote central nervous system integration. The other concept is the child-led nature of SI-based intervention, during which the therapist allows the child the freedom to choose and engage in activities as long as they are appropriately challenging, foster increasingly complex adaptive behaviors, and generally further the development of sensory integration (Stein & Meredith, 1993; Stein, 1998).

SENSORY INTEGRATION AND OCCUPATION

Sensory integration is fundamental to interpreting information from the environment and for learning. Dr. Ayres defined sensory integration as "the neurological process that organizes sensations from one's body and from the environment and makes it possible to use the body effectively in the environment" (2004, p. 9). Sensation is used to guide an individual's engagement with people and objects in the environment, in other words, to engage in needed and desired occupations (Figures 59.2 and 59.3). Table 59.1 lists the functions of the different sensory systems.

FIGURE 59.2 Children need a variety of experiences to learn how to use their bodies in novel ways; balance, adjust, and coordinate their actions with the way things feel; and come up with new ways to interact with the environment. Interacting cooperatively with other people might require the most adaptive responses of all these skills.

OCCUPATIONAL THERAPY USING SENSORY INTEGRATION PRINCIPLES

The sensory integration frame of reference consists of three interrelated components of occupational therapy practice:

1. Application of theoretical concepts supporting evidence-based practice
2. Assessment tools to assess the sensory integrative functions in individuals, such as:
   - **The Sensory Integration and Praxis Tests** (SIPT) (Ayres, 1989), a series of 17 standardized tests designed to assess sensory discrimination and praxis including visual perception, visual motor skills, **vestibular** functions, **proprioception**, tactile discrimination, fine and gross motor skills, and praxis
   - Measures of sensory processing, particularly modulation, such as the Sensory Profile (Brown & Dunn, 2002; Dunn, 1999, 2002a, 2002b), Sensory Processing Measure (SPM)—Home (Parham & Johnson-Ecker, 2007), SPM School Editions (Miller-Kuhaneck, Henry, & Glennon, 2007) [portions previously published as the Evaluation of Sensory Processing (Johnson-Ecker & Parham, 2000)], and questionnaires completed by the caregivers that indicate a child's sensitivity and responsiveness to various sensations and sensory situations
   - Clinical observations of neuromotor functions, praxis, and play (Blanche, 2002; Windsor, Smith Roley, & Szklut, 2001), a series of structured and unstructured observations that include classic neuromotor abilities, sensory responsiveness, and **motor planning** abilities

 3. Intervention strategies (Bundy, Lane, & Murray, 2002; Koomar & Bundy, 2002; Smith Roley, Blanche, & Schaaf, 2001)

IDENTIFYING SENSORY INTEGRATION DYSFUNCTION

Dr. Ayres analyzed test scores and clinical observations of children with learning disabilities to empirically identify patterns of dysfunction (Ayres, 1974, 1989). Later, Mulligan (1998a, 1998b, 2000) conducted confirmatory factor and cluster analyses that supported Dr. Ayres' original patterns of dysfunction. Consequently, the strongest research in sensory integration is in the identification of the types and patterns of sensory integration dysfunction using the Sensory Integration and Praxis Tests (Ayres, 1989; Mulligan, 1998a, 1998b, 2000). Various types and patterns of sensory processing dysfunction continue to be

examined (Ayres & Tickle, 1980; Brown & Dunn, 2002; Dunn, 1999, 2002a, 2002b; Miller, McIntosh, McGrath, Shyu, Lampe, & Taylor, 1999; Miller & Summers, 2001). These studies suggest that sensory integrative dysfunction is not a single disorder but a spectrum of disorders (Parham & Mailloux, 2005) related to the following processes.

Sensory Modulation

Dr. Ayres (1979, 2005) proposed that the "combination of facilitatory and inhibitory messages produces modulation, which is the nervous system's process of self-organization" (2005, p. 36). Sensory modulation disorder is one type of SI dysfunction characterized by fluctuating or extremes in the responsiveness to the intensity of one or more sensations. Difficulties with sensory modulation are often observed during everyday activities such as grooming, social events, or transitions. Specific behaviors may include **auditory hypersensitivity or tactile defensiveness**, **gravita-**

TABLE 59.1   FUNCTIONS OF SPECIFIC SENSORY SYSTEMS

FUNCTIONS OF THE:

Vestibular System	Proprioceptive System	Tactile System	Visual System	Auditory System	Olfactory and Gustatory Systems
Detects gravity Detects head position and movement Modulates postural tone Head/neck/eye control Righting and equilibrium reactions Auditory connections for spatial orientation Arousal regulation	Provides sensations for **body scheme,** body concept Essential for precisely graded movement Interacts with vestibular system for postural control Interacts with the tactile system for finely graded movements	Emotional development Body scheme Skills associated with: Tactile perception Motor planning Sequencing Organization Visual perception	Bonding Spatial orientation Movement through space Social skills Communication	Language development Sound modulation Spatial orientation	Caregiver-infant bonding Protection from noxious substances Attraction to potentially nurturing substances

tional insecurity, **aversion to movement**, or feeling overwhelmed in high-stimulus environments such as shopping malls (Koomar, 1995; Weisberg, 1984). Sensory modulation disorders are seen in conjunction with arousal, external regulation, or **self-regulation** issues, including colic and poor rhythmic respiration, digestion, and elimination; arousal and attention deficits; hyperactivity; anxiety and other signs of emotional instability; and social problems (DeGangi, 2000; DeGangi & Greenspan, 1988; Schaaf & Anzalone, 2001; Schaaf, Miller, Seewal, & O'Keefe, 2003; Williamson & Anzalone, 2001; see also Chapter 59).

Sensory Discrimination

Sensory discrimination is the interpretation of sensory information that allows you to know efficiently and accurately where your body is, where other people are, and details about the environment from multiple sensory channels. Sensory discrimination disorders are a result of slow and inaccurate processing of one or more types of sensory information, **underresponsiveness** to sensation, inadequate perception formation, and poor sensory associations. Patterns of dysfunction that have been identified through factor and cluster analyses indicate that poor vestibular proprioceptive processing is often associated with poor anticipatory and reactive **postural control** and inadequate

bilateral integration and sequencing. Tactile discrimination deficits are often associated with poor fine motor skills and praxis. It is as if the child is trying to do precise work with his or her hands while wearing winter gloves. Visual perceptual deficits are associated with poor visual **construction ability** and visual motor skills. Auditory perceptual deficits often contribute to poor auditory language skills.

Praxis

Praxis is the ability to conceptualize, plan, and execute skilled tasks. It underlies engagement in purposeful activity. Any nonhabitual motor task that the child needs to think through requires praxis. The child who is learning how to dive needs to stand at the water's edge, get the arms in position over the head, shift the weight forward, tuck the chin against the chest, and then maintain this position as he or she falls head first into the water. All of this requires cognitive effort as well as physical coordination. Dr. Ayres (1972) hypothesized that sensory discrimination, particularly of tactile, vestibular, and proprioceptive sensations along with visual input, was the foundation for praxis. The resulting sensation from the activity is processed by the brain, and this further informs individuals about their body in relation to itself as well as to other people and objects in the environment (Ayres, 1989, 2004). Through

her factor analyses, she later found a consistent relationship, particularly between the tactile system and praxis.

There are a variety of different types of praxis disorders, including poor ideation of creative or novel activities (e.g., the child in the sandbox who shovels sand into the pail and then pours it out and repeats the process but does not come up with the idea that she can "make a cake" by filling the pail with sand and then turning the pail over to form a mound that she can then decorate); **somatodyspraxia**, or poor use of the body to motor plan action sequences; poor use of language for sequencing and planning; poor ability to modify an action while in motion to enhance skill and precision; poor visual construction (e.g., difficulty replicating a block design); and poor ability to organize behavior in future time and space. Conceptualizing an action, or forming the idea about *what* one wants to do, is a critical aspect of praxis. This is **ideation**, and it is a cognitive function

(May-Benson, 2001). Planning *how* one intends to engage in the task is also cognitive. A child observing a newly constructed playground with swings, slides, tree house, poles, and sand will have 101 ideas about what to do and will want to do them all. The actual execution of the activity is the part of praxis that we can observe, and this is the part that is assessed to determine a child's skill for motor tasks. The child then sequences these ideas into swinging, sliding, and digging activities and modifies the sequence or the challenge so that it is more fun and successful.

ASSESSMENT

The process of sensory integration cannot be observed directly, which is why Dr. Ayres used the term "hidden disabilities" when referring to SI dysfunction (Ayres, 2005).

CASE STUDY: *Larissa: A 3-Year-Old Girl Not Interested in Play with Others*

Referral

Larissa is an energetic 3-year-old girl who loves to play but does not seek out play with other children. She does not seem to mind them, but she is happy playing alone or alongside others. She has good attachment to her mother and relies on her for guidance and nurturing, which her mother readily and effectively provides. Larissa is happiest if she is close to her mother day and night. Household routines are difficult for the family. Larissa loves to take a bath and often does not want to get out. Larissa does not want to stop playing to do general hygiene tasks, making routine activities such as tooth brushing difficult. Errands, shopping, or spontaneous outings are problematic, as Larissa is overly active and tires easily when she has to stand in line or wait. Larissa's mother has learned to give her three children time to prepare for transitions; otherwise, Larissa or one of her older brothers, ages five and eight, might have a tantrum.

Larissa's mother requested an occupational therapy evaluation to determine whether services were available that provided assistance with parenting and to support her child's development. She reported that her life was very difficult. She had always had difficulty organizing herself, but now with three children and a husband, she sometimes felt that her life was unmanageable. She decided to focus on services for the youngest child first but felt that all of her children and herself needed assistance to varying degrees.

Occupational Profile:

When asked what Larissa likes to do during the day, her mother replied:

> "If I'm not in the room when she wakes up, she will cry or whine "Mommy" until I come in. She then wants to nurse until she is completely awake. I usually carry her downstairs, and she starts

playing with little toys. It's a little hard to stop playing, but she usually climbs into her chair for breakfast and eats neatly. When she's done, she sometimes puts her hands in her warm cereal and smears it on herself, the table, her head . . . and has a good time with it. She likes to touch everything wherever we go. She *loves* to play out back with water, dirt, and mud. She usually gets herself all wet with the hose and has several changes of clothes a day. She likes to play in the sand, lie in the sand with her face in the sand, and eat the sand. She loves the bath, but I usually have to take her out early for hitting her brothers or pouring water out of the tub. Then she screams, cries, and tries to get back in the bath. Eventually, she calms down and lies down or jumps on the bed. She never wants to put her clothes on, but when she is very tired, she will."

The therapist determined that Larissa's high activity level, anxiety, and sensory-seeking behaviors were interfering with her ability to cope with and engage in typical daily occupations. Additionally, her behaviors created situations in which her mother was unable to carry out her own daily activities without upset, contributing to family stress. The therapist recommended intervention and requested that a standardized evaluation using the Sensory Integration and Praxis Tests be completed in approximately one year when Larissa was old enough, in order to have standardized measures of her abilities. Her scores indicate a subtle but significant problem in sensory integration (Figure 59.4).

Analysis of Occupational Performance:

Larissa is an intelligent child who has subtle difficulties with vestibular-proprioceptive processing that affect fine motor skill development and **bilateral motor coordination**, age-appropriate social play, self-organization, and self-regulation. This may become more pronounced when she is expected to function independently and pay attention and engage in skilled tasks in high-stimulus social environments.

CASE INFORMATION

Child's first name: __Larissa__   Child's age: __3 years 2 months__

Child's year in school: __pre-K__   Parent/guardian(s) name: _____

EVALUATION

Reasons for referral (include the occupational concerns/desires for the child and family):

Clingy, tantrums easily, fights with siblings, difficulty taking her to grocery store, not interested in playing with other children.

Background Information

Medical history: OK

Developmental history: Normal milestones. Concerns regarding balance, activity level, self-regulation, and social skills

Educational history: N/A

Occupational history/profile: see above narrative

Evaluation of Occupational Performance

Interview Data

◆ Teacher report:
◆ Guardian Report:
   See above
◆ Others:

Observation Data

Strengths:
Bright
Affectionate
Good attachment with parents
Good fine motor
Enjoys tactile play

Challenges:
Does not seek interactions with other children
Sensitivity to sounds
Excessively seeks tactile play
Poor interactions with other children
Inattention to task
Poor sustained sitting
Difficulty adapting to transitions and high stimulus environments

Test Data

Structured assessments:
See SIPT scores

Unstructured assessment:
Mildly low muscle tone
Difficulty imitating movement sequences

Interpretation:
Vestibular and bilateral integration and sequencing issues

INTERVENTION

Goals and Objectives

By (date): To demonstrate improved fine motor and self-care skills, Larissa will use two hands to independently don and doff socks and shoes when given minimal physical assistance, 4/5 opportunities.

OT Intervention Plan

Includes the following:

Setting:
Specialized clinic 2x/wk

Duration:
6 months with reevaluation at that time to determine the need for further therapy

OT Intervention Process and Strategies

Therapeutic Activities:
In the process of play include:
Vigorous swinging using flexion swing, platform swing.

Continued

INTERVENTION

Goals and Objectives

By (date): To demonstrate improved organization of behavior during social interactions, Larissa will engage in play with another child, for 10 minutes of turn-taking interaction when given no more than 3 prompts, 4/5 opportunities.

By (date): To demonstrate improved balance and postural/protective reactions for increased preschool participation, Larissa will execute smooth and efficient movement patterns with her trunk and upper extremities (imitating motions to songs, etc.) while maintaining a cross-legged sitting posture on the floor for 5 minutes with minimal verbal and/or visual prompting, 4/5 opportunities.

OT Intervention Plan

Discharge plan:
Create an enriched sensory environment in the home and at school with a sensory diet in place that is adjusted as needed or at least every 6 months.

Referrals:
Psychoeducational testing

OT Intervention Process and Strategies

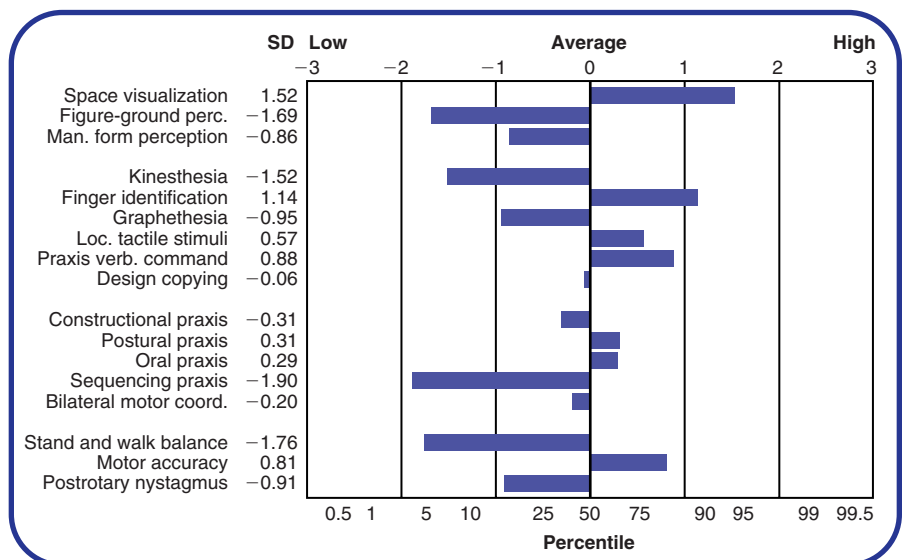
Therapeutic activities:
A variety of textures along with vibration toys and messy materials
Stereognosis games
Static and dynamic balance activities
Obstacle courses that include gross motor sequences

Environmental Modifications:
Provide picture/word schedule of daily routines
Provide swinging equipment in the home
Enrich the tactile play by including interactive and shape or object-identifying games
Mobile seating devices such as a peanut ball during mealtimes

OUTCOMES

Expected or Reported Outcomes

◆ Occupational Performance: Improve social skills, dressing skills, grooming activities, and participation in daily events without emotional outbursts
◆ Client Satisfaction: Mother report on usefulness of the information and strategies provided by the OT/OTA
◆ Adaptability/Generalized Skills: Improve tolerance to outings that include shopping, increased harmony in home due to acceptance of routine and changes in routine
◆ Impact on Family Life (including the occupations of other family members): Mother report of improved life satisfaction, stress reduction, improved coping, and improved organization

FIGURE 59.4 Larissa's SIPT scores at age five.


The therapist must rely on information from interviews, direct observations and structured and unstructured assessments of skills and abilities related to occupational performance in order to understand the way in which the individual is processing information (Windsor et al., 2001).

INTERVENTION PLANNING

Occupational therapy using a sensory integrative approach is guided by the evaluation data. On the basis of the information from the occupational profile, the therapist considers the identified occupationally related outcomes that are important to the client, the family, and the reimbursement agency. The analysis of performance provides detailed information on client factors, performance skills, and patterns that contribute to the development of client-directed interventions, therapeutic activities, and environmental modifications. Additionally, education and consultation are required so that the team understands the relationship of the child's sensory integrative functions to participation in daily life activities.

Therapeutic activities to address the identified deficits are designed with specific attention to the contribution of the tactile, proprioceptive, and vestibular sensations to function (Figures 59.5, 59.6, and 59.7).

◆ Special consideration is given to including proprioception in the form of active movement and heavy work activities. Proprioception exerts a regulatory influence on other sensations (Blanche & Schaaf, 2001).
◆ Vestibular activities are especially important so that the child can develop the capacity to hold the body upright against gravity while holding still and while moving (Ayres, 1972). Processing vestibular information is important for the development of the sense of space and navigation (Berthoz, 2000).
◆ Tactile information is essential for refined interactions with the external social and physical environment (Ayres, 1972, 2005; Montegue, 1986).

Tables 59.2, 59.3, and 59.4 provide information on the various considerations that should be used in grading sensory-based activities.

INTERVENTION

Central to intervention using sensory integration principles is a unique philosophy that reflects Dr. Ayres' sense of trust, compassion, and respect for children (Spitzer & Smith Roley, 2001). She proposed that intervention delivered in a playful style at the child's level could elicit the child's "inner drive" to learn and develop. In this way,
FIGURE 59.5   Rock climbing is a proprioceptive activity that requires muscular exertion, body awareness, and resisting the pull of gravity to help the climber stay organized and alert while concentrating on foot and hand placement.

FIGURE 59.6   Swings provide multisensory play opportunities that are both calming and alerting by providing deep pressure, vestibular sensations, and the opportunity for increased proprioceptive awareness.

FIGURE 59.7 Playing in a ball pit provides transient deep pressure tactile sensations and resistance to movement, increasing the child's body awareness.

ceiling beams and devices so that she could suspend equipment that allowed the child to swing safely through space. She invented this equipment as the need arose for individual clients.

Although a clinic filled with ceiling hooks, swings, mats, carpeted barrels, scooter boards, ramps, and pillows is commonly associated with pediatric occupational therapy using "classic" SI intervention methods, the environment alone is not sufficient to define intervention using sensory integration theory. Dr. Ayres described not only the environment, but also what might be considered the therapeutic alliance. Parham and her colleagues (2007) report that intervention using sensory integration principles should be faithful to the methods and principles that are considered essential and distinctive to this particular therapeutic method. The authors examined the literature and gathered expert opinion to specify the essential and distinctive sensory integration methods and principles. By using these principles, a therapist is demonstrating **fidelity** to the intervention. Classic SI intervention comprises both structural processes (e.g., length of the session, therapist's training, equipment used) and therapeutic processes (e.g., therapist creates an environment that invites play and ensures safety, fosters a therapeutic alliance). Establishing fidelity helps to clearly delineate the qualities that must be present to define the intervention as sensory integration, and for the practitioner, it clearly articulates the specific strategies and process that are linked to an underlying theoretical base and supporting evidence.

we facilitate enhanced neuronal growth and development that lead to increased skill and independence in daily life activities (Ayres, 1972). The therapeutic environment designed by Dr. Ayres was unique in its ability to safely provide opportunities for vestibular, proprioceptive, and tactile sensations and adaptive motor responses. She used simple and readily available objects such as tires, ropes, wood, hula hoops, and rocker boards and created unusual obstacle courses and games with them. She used

Transient	Isometric/isotonic	Stable
In motion	Speed, intensity	Moving
Static/dynamic	Duration/rate/rhythm	
Active/passive	Direction	
Effort exerted	Resistance	
Motivation or purpose	Tension/weight-bearing load	

Hallmark Features of Intervention Using Sensory Integration

Intervention using SI should include the following:

◆ A qualified therapist with an understanding of the neurobiological principles of sensory integration theory and its methods. Postgraduate certification in sensory integration is available for occupational therapists, speech and language therapists, and physical therapists only.

◆ The use of sensory opportunities that feature varied and appropriate vestibular, tactile, and proprioceptive sensations, including thick mats, large overstuffed pillows, swings, ramps, ladders, ropes, targets, manipulatives, balls, vibrating toys, various textures such as stretchy soft or furry fabrics, brushes, props, and materials that are used during daily routines.

◆ Opportunities to move through space so that the child can achieve increasingly complex somatomotor adaptive responses.

◆ The therapist's scaffolding of success emotionally, physically, cognitively, and socially.

◆ Facilitating the just-right challenge: The therapist collaborates with the child on choice and sequence of activities and equipment and adjusts the intervention accordingly to ensure success.

◆ Providing **environmental affordances** (the opportunities that the environment affords children to do things)

TABLE 59.4 VARIABLES RELATED TO TACTILE SENSATIONS		
Client Factors	**Types of Tactile Sensations**	**Environmental Condition**
Head	Light touch	Familiar versus unfamiliar object
Face including cheeks, mouth, tongue, and ears	Deep pressure	Familiar versus unfamiliar person
Hands	Texture	Intensity of other stimuli in the environment
Feet	Temperature	Task demands
Limbs	Sharp/dull/pain/numbness	Intention of person touching
Front	One- and two-point	Time of day
Back		Cultural norms

Self versus other initiated	Rhythm	
Prior experiences	Frequency	

that invite interactions with the environment, including space to move, jump, and crash and items that stimulate creativity and engagement.

◆ Assisting in organization of behavior relative to physically interacting with objects and people in time and space, including the opportunity to rearrange the environment and the way in which it is used (Parham et al., 2007).

Guiding Principles of the Actual Intervention

Intervention based on sensory integration theory is *child-directed.* This concept has often been misunderstood. It does not mean that there is no structure. Rather, it means that the therapist vigilantly observes the child to understand the child's current capabilities, structures the activities around the child's interests and abilities, and engages the child by eliciting his or her *intrinsic motivation* to play. Sensory integration methods are provided in the *context of play,* and the therapist, who is inviting the child's *active participation,* is focused on the desired outcome of an *adaptive response.* "When the therapist is doing her job effectively and the child is organizing his nervous system, it looks as if the child is merely playing" (Ayres, 2005, p. 142).

Basic Tenets of Sensory Integration

Following are the classic principles of intervention using a sensory integration approach:

◆ *Integrated sensation* is "nourishment for the brain" (Ayres, 1979).
◆ *Adaptive responses* are required to successfully meet challenges essential for growth and development (Ayres, 1972). The adaptive response is essential to increased sensory integration.
◆ The *inner drive* of the human being invites the experience of life. It is this motivation to enjoy life that Dr. Ayres wished to engage during intervention.
◆ *Active participation* promotes organization.
◆ *Artful vigilance* is essential on the part of the therapist to facilitate the just-right challenge.

When using sensory integration intervention strategies, the practitioner will provide a balance of structure and freedom so that the child has opportunities to problem-solve and make some of his or her own choices. Some essential characteristics that differentiate sensory integration methods from other frames of reference are freedom within the structure of a sensory-rich environment, the ability to physically move through space and move objects in space, and the assistance of the practitioner so that the child can learn to use his or her body in new and novel ways so that increasingly complex possibilities for physical engagement emerge. Sensory integration is not sensory stimulation, due to the imperative of the adaptive response

and modification of the activity based on the child's reaction (Anzalone & Murray, 2002). It is not adult planned and designed; rather, the adult sets up the structure and possibilities in which the child's interests and ability to cope with the sensory, motor, and organization demands dictate the level of challenge and intensity of the activities. Therefore, the equipment does not stay in the same place each time, and the therapy does not follow an orderly and predictable sequence, so each session is somewhat novel. The intervention is not provided with the expectation of a subsequent reward. The activities are intended to be fun and inviting and therefore are rewarding in and of themselves. Play is one of the most important and powerful parts of the process of intervention using sensory integration strategies and one that facilitates the intrinsic reward of this kind of occupational engagement (Bundy, 2002).

Sensory integrative dysfunction commonly occurs in children with diagnoses such as autism, fragile X syndrome, and cerebral palsy. These children will benefit from a variety of approaches in addition to sensory integration methods (Mailloux, 2001; Mailloux & Smith Roley, 2004; Schaaf & Smith Roley, 2006; Smith Roley et al., 2001). During a typical occupational therapy session, sensory integration methods are often used in conjunction with complementary methods such as neurodevelopmental treatment (Blanche, Botticelli, & Hallway, 1995), play-based approaches (Burke & Mailloux, 1997; Knox & Mailloux, 1997), developmental and behavioral approaches (Anzalone & Murray, 2002), and cognitive approaches such as the Alert Program for Self-Regulation (Williams & Shellenberger, 1996). This is especially true for children with multiple impairments.

GOALS OF OCCUPATIONAL THERAPY USING SENSORY INTEGRATION STRATEGIES

Sensory integration principles applied within occupational therapy practice results in improved occupational engagement and social participation (Figure 59.8).

To accomplish the overarching goals of occupational therapy, sensory integration strategies are used to facilitate adaptive responses in various domains. In addition to the somatomotor adaptive response described by Ayres (1972), Parham & Mailloux (2005, p. 393) identified the following expected goals as a result of intervention using SI that could be used as outcome measures:

◆ Increase in the frequency or duration of adaptive responses
◆ Cognitive, language, and academic skills
◆ Gross and fine motor skills
◆ Self confidence and self-esteem
◆ Enhanced occupational performance and social participation
◆ Enhanced family life

FIGURE 59.8   Following vigorous play, this child more easily engages in this activity with his mother that involves tactile media, spatial organization, and visual motor control.

The diverse array of possibilities makes it difficult to predict exactly the areas of life that may change as a result of intervention using sensory integration strategies (Mailloux et al., 2007). Traditionally, evaluations of the effectiveness of pediatric occupational therapy intervention have focused on performance skills such as improved handwriting or improved balance or ball skills. These measures are not sufficient to capture the potential change in an individual's quality of life. Reports from parents include comments such as the following:

"My life is easier."
"My child now has friends."
"I can actually cook dinner without disruption."
"My kids play together longer without needing me to intervene."
"I feel like I am brave enough to try a family vacation."

" Occupational therapy is the first place I've been where I feel like they understood what I'm going through."
"It is nice to see someone playing with my child, and it showed me another way to view my child in a more positive light."

Cohn, Miller, & Tickle-Degnen (2000) found that the outcomes identified by parents of children receiving services included those that support the child's participation in typical contexts and the way in which the child affects parenting and family life. In this study, the parents reported that they wanted strategies that supported and validated their parenting skills in addition to helping their child achieve increased social participation, self-regulation, and competence. In a subsequent study, Cohn (2001a, 2001b) found that parents valued an improved understanding of their child's behavior as well as the validation of their parenting efforts and being able to advocate for services for their children. She identified that the ritual of waiting for their children in the waiting room at the clinic site afforded the parents the opportunity to share resources, validate their experiences, and engage in social dialogue with others. In fact, this experience helped to reframe their views of their children. This work broadens the potential outcomes related to occupational therapy using a sensory integrative approach.

While structured and unstructured observations of occupational performance continue to be valid ways to measure progress, for certain children such as those with autism the progress will never approach normal development. Mailloux and colleagues (2007) propose that the method of Goal Attainment Scaling (GAS) might serve as a useful method to measure achievement. GAS is a method of setting achievable goals in conjunction with the family that may prove to be useful in capturing significant changes as the result of intervention.

CASE STUDY: *Todd: A 6-Year-Old-Boy Referred for a Developmental Evaluation*

Referral

Todd is a 6-year-old boy who was referred for a developmental evaluation because of difficulties with behavior and attention at school.

Occupational Profile

Todd's mother reported that as an infant, Todd liked being held. When he woke up at night, he had to be walked around because he did not calm easily just by having someone lie down with him. His motor skills were typical, although he used to bump into things and get hurt a lot, especially when his head was at the same height as the doorknob. She describes him as a quiet, happy child who is

easily frustrated and resistant to change. He likes to do things slowly and carefully. He likes to play with others once he knows them. When he is in a bad mood, it is hard to get him to recover. When he is frustrated, he loses his temper and sometimes hits or digs his nails into someone.

When asked about a typical day, Todd's mother provided the following narrative:

"He wakes up between 6 and 7 A.M. and starts playing with his older brother. Sometimes he wets the bed; otherwise, he wets the bed while playing. I try to prevent that by taking him to the bathroom, but he talks nonstop, and I have to yell to get him to hear me. He gets a reward for going to the bathroom. I get his sandals before he comes down, but he's too busy playing to remember or listen to me. I usually pull him downstairs and try

CASE STUDY: *Todd: A 6-Year-Old-Boy Referred for a Developmental Evaluation   Continued*

to get him to sit in the chair. He wants macaroni and cheese every morning for breakfast. He uses his fingers instead of his fork to eat, but when I remind him, he uses it a little. He spills a lot of food on the table and keeps moving around and falling out of his chair. I open a book in front of him on the table, and he starts reading and stops moving around so much. He's still a messy eater. He is happy playing by himself. The kids put their clothes on the night before so they don't have to get dressed in the morning. After playing outside and pulling on the plants, I finally get him into the car and drive 5 minutes to school. He says he is tired, cold, and bored and won't leave my side. He wanders around a little watching the other kids but not joining in or talking to anyone except maybe adults or little kids. He doesn't seem to hear when anyone calls his name. He is usually the last child to leave class when school is over. I often get calls that his stomach hurts, and after school, he is so sad he only wants to go home. He usually doesn't eat lunch but will eat dinner. After we go upstairs to get ready for bed, he sometimes gets very wild. I lie down with him, but he starts fidgeting, and eventually I leave and he gets back up out of bed."

Todd was referred for an occupational therapy evaluation to assess his development and determine the need for occupational therapy services. His mother described him as a loving child who just seems not to know what to do with himself. He constantly asks how to do something and wants his mother to show him. He will follow others and tends to play best with younger children (Figure 59.9).

Analysis of Occupational Performance

Todd is a bright, active, engaging little boy who has strengths in visual perception, fundamental motor skills, language, and cognition. He specifically demonstrated difficulty in discrim-inating vestibular-proprioceptive information and using that information rapidly, efficiently, and accurately; this impairs his ability to sort out everything that is going around him and figure out how to respond quickly. Todd's difficulties with vestibular-proprioceptive processing are interfering with ocular motor skills, focus (especially in busy environments), balance when an activity requires anticipating a postural adjustment to maintain balance or reacting to an unexpected postural change, and organization of actions, especially during transitions and social situations. He has difficulty in motor planning and organizing his materials. Although his sensory integrative problems significantly affect his development, they are not sufficient to explain all of his difficulties with social interactions and self-regulation.

Intervention Planning

Occupational therapy using sensory integration was recommended for two 60-minute sessions per week in the home and community settings. Specific activities were designed for Todd to engage in throughout his daily routine that included tactile activities combined with vestibular and proprioceptive activities to improve praxis and spatial awareness. Additional methods were incorporated to enhance his ability to participate more easily in daily routines without feeling sad or being disruptive.

Intervention

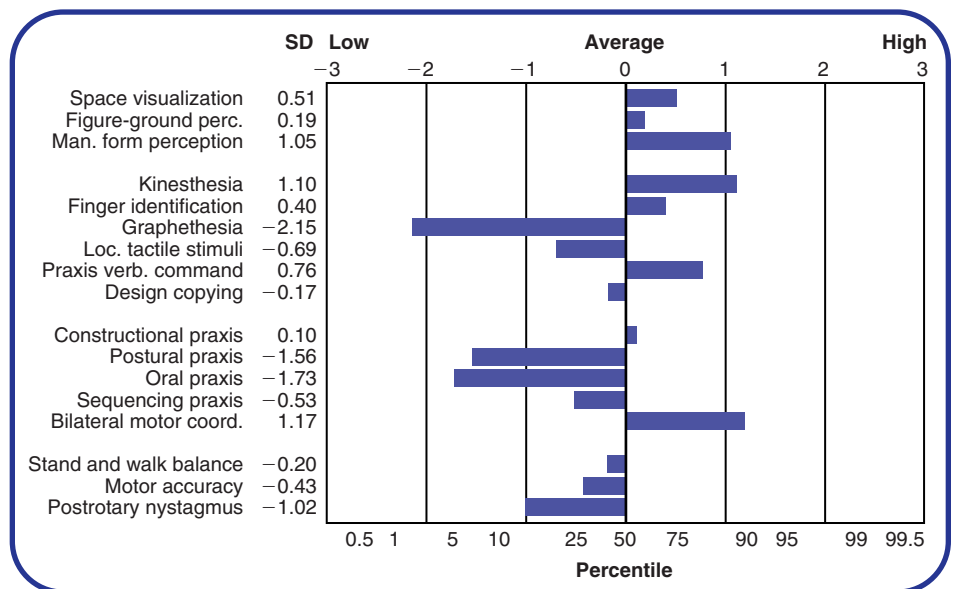
The occupational therapist scheduled consultations with the parents and the educational staff. In response to the evaluation results and the consultation, two separate


FIGURE 59.9 Todd's SIPT scores at age six.

CASE STUDY: *Todd: A 6-Year-Old-Boy Referred for a Developmental Evaluation* *Continued*

programs were developed: sensory-based modifications for the home and a sensory diet for the classroom. The therapist monitored Todd's reactions to the program to ensure that he was more organized and performed better. The occupational therapist provided direct service with consultation on a regular basis. The occupational therapist scheduled a reevaluation at the end of 6 months to ensure that Todd was making progress and to determine the need for continued intervention services.

For the home, the therapist worked with Todd to develop picture and word schedules of daily routines that included dressing, meal preparation, and clean-up and bedtime rituals. Todd posted them in the appropriate room and negotiated with his parents the times when they were to be done. He made a book with pictures of self-regulatory strategies that included high-intensity physical activities; tactile play; swinging; jumping; and building with pillows, blankets, and cushions. He also included activities such as drinking a warm glass of milk, taking a walk, reading a book, and asking his father for a wrestling match, a piggyback ride, or a foot massage. His parents broke down activities that required sequencing, such as shoe tying, so that he could learn the steps; they then provided other opportunities with tying ribbons and laces so that he could generalize the skill. Resources for additional information were provided (Ayres, 2005; Ayres, Erwin, & Mailloux, 2004; Coleman, Mailloux, & Smith Roley, 2005; Williams & Shellenberger, 2001).

The home environment was modified in the following ways: Todd's mother created a Lycra™ hammock that he could sleep in at night. She also provided flannel sheets and a heavy comforter with big pillows for his bed. She put an old mattress on the floor of his bedroom so that he could jump. A swing was attached to a beam on the back porch so that he could swing before school, before meals, and an hour before bedtime. His mother set aside soap foam and various brushes and textured toys to play with in the bath, including cups and soap crayons. He was given a battery-operated toothbrush. His parents were taught strategies for calming and for alerting and determined the times in his day when he would get more physical activity and active play and how much time was needed afterward with inhibitory activities for him to calm down and pay attention or sleep. To help him discriminate better tactually, a variety of tactile games were created, such as a memory box that he had to reach into and, without looking, find familiar objects that were buried in dried rice and beans.

For the classroom, the teacher, parents of other children in the class, and the teaching assistant were provided a short in-service focusing on appropriate expectations in planning and organization for first graders. Included was information on how to determine whether there were sensory integration problems such as developmental dyspraxia. Strategies to help children develop and follow through on typical daily routines were included that could be applied to all the children in the class, including beginning time management strategies. Also included were the concepts related to **information processing** and sensory motor development that contribute to the development of praxis skills. An emphasis was placed on the need for a balance between sedentary and active tasks. Discussion of research on the benefits of recess was included (Jarrett, 2002; Pellegrini, 1993).

The classroom was a creative kindergarten with several simultaneous activities and children moving about the class throughout the day. Todd's teacher created a picture schedule and allowed him a quiet area with pillows to which he could retreat when overwhelmed or if he needed to complete his work. He was provided a peanut ball and an inflated cushion that he could use to sit on if he chose. He had a sensory box that included a variety of tactile and proprioceptive activities that he could use as long as he was not disruptive. He was allowed to take movement breaks outside in which he could run to the water fountain and back, do 25 jumping jacks, or ride on a Playskool Sit 'N Spin located directly outside the classroom as long as he returned within five minutes to do his class work.

The teacher soon found that these strategies were beneficial to many children in her classroom and that some children needed them more than others. Along with other valuable information on sensory integration, the therapist gave the teacher the article on the use of mobile seating devices with children with attention problems (Schilling, Washington, Billingsley, & Deitz, 2003). The teacher adapted her room so that children could have these choices and reported to the occupational therapist that this had dramatically reduced the time she spent correcting behavior (Bissell, Fisher, Owens, & Polcyn, 1998; Coleman, Mailloux, & Smith Roley, 2006; Pediatric Therapy Network, 2004; Williams & Shellenberger, 1996).

Direct intervention consisted predominantly of engagement in a variety of somatosensory and vestibular activities that gave Todd the sensory feedback he needed about his body and the environment. During these activities, Todd often lined and stacked large equipment and would crawl, climb, and swing his way through the obstacle course sequentially in three-dimensional space. For example, incorporating the concept of "1-2-3-go!," the therapist helped Todd to plan ahead and then time his actions. Once

CASE STUDY: *Todd: A 6-Year-Old-Boy Referred for a Developmental Evaluation*   *Continued*

he had gone through it, Todd and the occupational therapy assistant (OTA) discussed what had gone well and what had not, made the necessary modifications, and then went back to do it again. At the end of the session, Todd and the OTA put together a picture sequence of the activities and planned what they might be able to do in the following session. She also helped him to think of ways in which he could use his new skills at home, asking him, "What do you have at home that you can use to do this amazing activity that you just finished? Let me know how it goes."

For the first three months, Todd spent the majority of his time in clinic-based services going from tactile activities to vestibular activities without accepting motor or motor-planning challenges. He was easily frustrated and acutely aware of his limitations. If the therapist encouraged him to do too much in these areas, he quit and wanted to go home. He preferred to sit and watch the therapist set up the activity and then passively enjoy the sensory play. He showed great imagination, and the therapist discovered that he had a lot of knowledge about a specific superhero. She asked him to teach her and show her what this superhero did. In this way, they together began to construct more complicated activities that included swinging from the trapeze into the ball pit but in which Todd had to move between pieces of equipment and figure out how to put things together in a way that was worthy of the special talents of the superhero. When something went wrong, it became the fault of those who wanted to thwart his powers. He eventually was so excited about his buildings that he began to draw them at home in preparation for the next therapy session. He wanted his mother and brother to come see one of the buildings once he had it working toward the end of the session. His self-esteem greatly improved, as did his muscle tone, balance, bilateral coordination, construction, and imitation skills. He began to think of ways in which he could use objects as tools to accomplish more than he could with just his hands.

Outcomes

Todd's mother reported that after three months of occupational therapy, Todd sleeps better; stays dry, sits still and listens, transitions better, is more organized, is more secure, is less clingy, has improved play skills, has increased family engagement in active physical play activities, has increased tolerance of calming physical contact, has increased awareness of sensory conditions and their effect on behavior, and has increased adaptation of the sensory environment for more optimal learning and engagement. Additionally, his mother reported less yelling in the household because Todd listens better and more time to play due to smoother transitions. The household is more organized because Todd's progress has freed up time for his parents, and they feel more secure about their child, who is less clingy. His improved play skills offer hope that he will be able to make and keep friends, including family friends.

Todd's teacher reported that within two weeks of his beginning occupational therapy, she saw a happier child. He continued to show a low tolerance for frustration, but he recovered more rapidly and actually seemed to enjoy school. He continued to need adult guidance to begin and complete his work, but he did so in less time. He watched other children on the playground and expressed his desire to play some playground games, such as handball. Because the children knew that Todd was the reason they had new things in the class, such as the therapy balls, they showed him a bit more admiration. His teacher gave him the responsibility of checking out this equipment. She even noticed that at times, he suggested to another child that they might be able to listen better if they had a fidget or put the cushion on their chair to sit on.

CASE INFORMATION

Child's first name: __Todd__   Child's age: __6 years 10 months__

Child's year in school: __1st__   Parent/guardian(s) name:_____

EVALUATION

Reasons for referral: Todd was referred for an occupational therapy evaluation to assess his development and to determine the need for occupational therapy services. His mother described him as a loving child who seems like he just does not know what to do with himself. He is inattentive and disorganized. He will follow others and tends to play best with younger children.

Background Information

Medical history: Todd was born full term, the product of a normal delivery. He had difficulty breathing and required resuscitation but recovered quickly and did not require any hospital stay.

Developmental history: Todd was a clumsy baby who fell a lot. He cried often and was sensitive to many foods. He sat at 6 months and walked at 12 months. His fine motor skills emerged slowly, and he continues to prefer finger feeding to using utensils. He is slow to acquire gross motor skills, such as bike riding without training wheels or ball skills. He does not like organized sports activities. His language emerged typically. He is socially and emotionally immature.

Educational and intervention history: Todd is in a typical classroom. He is currently in the process of evaluations with a suspicion of ADHD. He has received no prior therapy services.

Occupational history/profile: (see above narrative)

Evaluation of Occupational Performance

Interview Data

◆ Teacher Report:
Main concern was that she thought he might be depressed. He often seemed sad and pretended to be sick so that he could go home and be with his mother. His stomach-aches were worse when he had to do something that he hadn't done before or if there was an unfamiliar teacher leading the activity. He is a bright child but messy and often needed assistance to get his materials organized and an adult to help him get started on a project. Once started, he did well, and if he could sustain his attention, he completed the activity fairly well. His general knowledge is good.
◆ Guardian Report:
(see narrative above)
◆ Others:

Observation Data

Strengths:
Bright
Active
Plays well alone
Loving toward his family unless upset
Wants to please adults
Tries hard to do well
Likes routine and structure

Challenges:
Developmental dyspraxia
Motor planning
Time management
Sequencing
Imitation
Attention
Self-regulation
Often anxious and sad
Social skills
Poor use of tools such as utensils and writing implements
Slow performance

Test Data

Structured assessments:
SIPT (see scores)
ESP results indicated sensitivity to auditory and visual stimuli; seeks vestibular and proprioceptive activities and is sensitive to touch required in grooming activities but also seeks out touch by touching everything.

Unstructured assessment:
Immature play patterns. He waits to see what others are doing and then tries to imitate them. When he doesn't do it correctly, he gets mad, withdraws, whines, or yells. His neuromotor skills are age appropriate. He has slightly low tone, more so in flexor muscles. He has difficulty with ocular convergence.
Other:

CASE INFORMATION *Continued*

Intervention

Goals and Objectives

By (date): To demonstrate improved sequencing and motor-planning for increased school performance, Todd will independently begin an activity requiring 3 materials, such as pencil, paper, and scissors, and start the activity without adult assistance, 4/5 opportunities.

By (date): To demonstrate improved organization of behavior and attention for structured tasks, Todd will engage in games/activities/tasks with a peer, for 10 minutes of turn-taking interaction, when given no more than 3 prompts from the caregiver, 4/5 opportunities.

Given vestibular input, Todd will demonstrate a calm and alert state by following through on a 5-step familiar sequence without adult prompts during a necessary activity, 4/5 trials.

Todd will follow 3-step directions during selected activities with 1 or fewer verbal cues/rehearsals to remain on-task, 4/5 opportunities.

Given minimal cues (3 or fewer), Todd will engage for up to 10 minutes or until the activity is completed in tabletop activities without verbal complaint and/or leaving the activity, 4/5 opportunities.

OT Intervention Plan includes the following

Setting:

Duration:

Discharge plan:
Todd will engage in community-based activities that support his ability to adapt to novel environments and participate with peers in activities that are healthy, fun, and cooperative. It is estimated that occupational therapy will be discontinued within one year with systems in place at home, in the school, and in the community that will support his ongoing development. If concerns arise, occupational therapy services can be reinstated as needed.

Environmental modifications:

OUTCOMES

Expected or Reported Outcomes

◆ Occupational Performance: Ability to perform daily routines with minimal adult assistance.
◆ Client Satisfaction: Report
◆ Adaptability/Generalized Skills: Todd is able to adjust to routines in his new classroom and to extracurricular adult-led activities.
◆ Impact on Family Life (including the occupations of other family members): His mother is able to reduce the time getting ready to go to school by 30 minutes, and they arrive on time 100 percent of the time for the remainder of the school year.

REPORT PREPARATION

Sensory Integration

Dr. Ayres provided a model of evidence-based practice as she grounded her work in both basic and applied science and investigated her theory through rigorous methods of assessment and intervention (Henderson, Llorens, Gilfoyle, Myers, & Prevel, 1974). Consequently, sensory integration theory is the most widely researched area of occupational therapy (Mulligan, 2002, 2003; Parham & Mailloux, 2005).

Despite the volume of research in sensory integration (Mulligan, 2002, 2003; Parham & Mailloux, 2005), "evidence of the effectiveness of this intervention remains inconclusive" (Parham et al., 2007). Miller (2003) reported that over 80 studies addressed the effectiveness of sensory integration intervention methods. Most of these had one or more of the following deficiencies: (1) no homogeneous sample, (2) lack of replicable method of treatment that adheres to sensory integration principles, (3) inadequate outcome measures, and (4) methodological limitations (e.g. low power, lack of randomization, lack of control groups). Mulligan (2003) analyzed effectiveness studies or reviews of studies and found that these studies had mixed results.

A review of evidence on intervention using sensory integrative methods indicates that children with *autism* show less nonengaged behavior and more language and parallel play behavior with decreased self-stimulation after intervention (Ayres & Tickle, 1980; Case-Smith & Bryan, 1999); children with *mental retardation* showed gains in gross and fine motor skills as well as in postural control and stability (combined with neurodevelopmental treatment); and adults with *mental retardation* showed improved eye contact, vocalization, and postural control (Clark, Miller, Thomas, Kucherawy, & Azen, 1978; Montgomery & Richter, 1977; Norton, 1975). Schaaf, Merrill, and Kinsella (1987) presented a single case study of a child with a *learning disorder* that suggests that sensory integration approaches improved play, interactions with others and with toys and other objects, and tolerance for vestibular and proprioceptive sensations and led to greater sensory exploration of the environment.

By contrast, Polatajko, Law, Miller, Schaffer, and Macnab (1991) showed no difference in gains in academic or motor skills between children receiving the sensory integration versus perceptual-motor intervention, and Wilson, Kaplan, Fellowes, Gruchy, and Faris (1992) found no difference in academic or motor skills between sensory integration and tutoring in a randomized study. Although the sensory integration group did not make greater gains in the initial study, at follow-up two years later, Wilson and colleagues (1992) found that only the sensory integration group maintained their gross motor skills. Although an early meta-analysis of research on sensory integration treatment showed positive results (Ottenbacher, 1982), a later meta-analysis that included studies such as those mentioned above showed little or no effect (Vargas & Camilli 1999).

Recent studies have documented improved adaptive behavior and occupational performance (Roberts, King-Thomas, & Boccia, 2007) and improvement on cognitive, behavioral, and physiological measures (Miller, Coll, & Schoen, 2007) following occupational therapy using a sensory integration approach. Schilling and colleagues (2003) documented improved sustained sitting and improved writing legibility for the students with ADHD when they were seated on therapy balls that offer enhanced proprioceptive stimulation. Similar benefits in attention and engagement were found with children with autism spectrum disorder (Schilling & Schwartz, 2004). Smith, Press, Koenig, & Kinnealey (2005) demonstrated significantly reduced self-stimulating behaviors in children and youths with pervasive developmental delay when occupational therapy with a sensory integration approach was used compared to a control intervention of tabletop activities. The authors suggest that the sensory integration approach is effective in reducing self-stimulating behaviors, which interfere with the ability to participate in more functional activities.

Consistent with all areas of occupational therapy practice, sensory integration intervention requires further examination. For the field to move forward, collaborative research models that capitalize on researchers' strengths should be developed (Smith Roley et al., 2005). Parham and Mailloux (2005) suggest that further research is needed that predicts those who will respond best to sensory integration methods, determines more refined outcomes that can be expected, and elucidates potential types of long-term gains, especially those that are meaningful to families.

PROVOCATIVE QUESTIONS

1. How would you communicate your understanding of the evidence to parents who are seeking occupational therapy intervention that uses a sensory integration approach?

2. A characteristic behavior that is seen in children with autism is self-stimulatory behavior, such as hand flapping or repetitive rocking. How might you make the case that this is the result of inadequate neural inhibition? Can you make the converse case: that it is the result of inadequate neural facilitation?

3. What are the benefits to allowing a child to choose an activity versus guiding the child to an appropriate activity?

ACKNOWLEDGMENTS

We wish to acknowledge our mentors, Dr. A. Jean Ayres and Ginny Scardina, along with the many outstanding colleagues with whom we have collaborated.

Learning Objectives

After reading this chapter, you will be able to:

1. Describe why the environment is critical to occupational performance.
2. Identify useful measures to assess the physical environment in the contexts of home, school, community, and workplace.
3. Describe the process for addressing the physical environment while planning for and implementing interventions.
4. Describe interventions that can be applied in various contexts across the life course (home, work, school, community).
5. Describe the evidence supporting specific intervention approaches.

INTRODUCTION: THE ROLE OF THE PHYSICAL ENVIRONMENT IN OCCUPATIONAL PERFORMANCE

Occupational therapists recognize that occupational performance is a function of the individual's abilities, the activities being performed, and the environment in which the performance occurs (American Occupational Therapy Association, 2002; Canadian Association of Occupational Therapists, 1997; Law et al., 1996). The environment is complex and multifaceted and can either challenge or support a person's competencies and performance in daily life. For example, flat surfaces such as a level, accessible entry to a building can support the performance of someone using a mobility aid such as a wheelchair. By contrast, the environment can create barriers to performance, as when older adults with low vision have trouble finding their way and ordering food in a dimly lit restaurant. **Environments**, as described in the International Classification System for Functioning, Disability and Health (ICF) (World Health Organization, 2001), can include physical elements (human-made environments, natural environments, equipment, and technology), social elements (social support and societal attitudes), and cultural, institutional, and economic elements.

Although in practice, the environment must be considered in its entirety, the focus of this chapter is on the **physical environment**. For discussions

of social and political environments, refer to Chapter 63. Assistive technology, though part of the physical environment, is addressed in Chapter 62. We describe the assessment process as well as the role of occupational therapists in making **environmental modifications** to maintain and/or improve the occupational performance of their clients.

Not all health practitioners acknowledge the influence of the environment on performance. Medical models of health attribute disability (or the inability of individuals to perform daily activities) to the functional limitations caused by impairments. For example, a person who is blind is "disabled" merely due to loss of vision. In contrast, social models of disability suggest that disability is a construct imposed by circumstances, and consequently, the environment plays a role in performance (Stewart, 2003). In a social model, the disability occurs when the attributes of the person interact with an environment that is not compatible with the person's functional limitation(s). For an individual who is blind, a lack of Braille signage or audible cues in an elevator results in disability. With adequate environmental support, this person is just as "able" as his or her nonblind counterparts. In other words, people who use wheelchairs are not "disabled" on smooth, flat pathways. They become disabled when they encounter a flight of stairs.

Conceptually, disability can be viewed as a lack of fit between the person (P), the environment (E), and the person's daily occupations (O). In this approach, modifying the environment becomes an important intervention strategy to help manage chronic health conditions, maintain or improve functioning in daily life, and increase independence. Optimal **person-environment-occupation (PEO) fit** occurs when an individual's capacities are consistent with the demands and the opportunities of the occupation of interest and the environment (Law, et al., 1996). Conversely, when the demands of the environment exceed an individual's abilities, there is a lack of congruence, or lack of PEO fit.

How the environment influences an individual's ability to perform an activity was initially defined by psychologists as **environmental press** (Lawton & Nahemow, 1973). The environmental press model defines behavior and performance as functions of an individual's competence and environmental press. Thus, to optimize performance, environmental demands must match the individual's abilities. When demands are greater or less than an individual's skill level, negative outcomes or maladaptive behavior occurs, resulting in environmental interactions that minimize performance. For example, when a grab bar in a public washroom is located too far away (environmental demand) for a frail older person to reach (personal competency), the individual might lose his or her balance and fall or experience fear of falling. Consequently, the individual might require assistance in toileting or might avoid the toilet or that public location altogether (maladaptive behavior) (Lawton & Nahemow, 1973).

LEGAL RIGHTS TO AN ACCESSIBLE ENVIRONMENT

The rights of people with disabilities are typically protected in developed countries through human or civil rights laws. For example, the Americans with Disabilities Act (ADA, 1990) was designed to create equal opportunity and equal access to public environments, services, employment, accommodations, telecommunications, and transportation across the United States. The focus of this law, and of similar legislation in many countries, is to enable people with disabilities to achieve integration and independent living.

Titles II and III of the ADA outline how both public- and private-sector services, programs, and facilities must comply with and implement the ADA. The ADA/ABA (Architectural Board Act) Accessibility Guidelines provide the accessibility requirements for public and private facilities covered by Titles II and III (U.S. Access Board, 2004). Accessibility guidelines have also been developed for play areas, public rights of way, and outdoor recreation areas (U.S. Architectural and Transportation Barriers and Compliance Board, 2000).

In Canada, the National Building Code provides accessibility requirements, and all federally operated organizations and their owned and leased entities must comply with the Canadian standard of accessibility, "Accessible Design for the Built Environment" (Canadian Standards Association, (2004). In many Canadian provinces and cities, the accessibility requirements go beyond the federal requirements.

Building codes, guidelines, and standards all provide minimum levels of accessibility. However, they do not make accommodations for everyone. For example, most of the accessibility requirements for people with mobility impairments are based on the needs of young males with paraplegia. That is why we see one grab bar in the toilet stall of a public building rather than two pull-down bars, which would be better for many older adults who have to push themselves up off a toilet. Similarly, the space requirements in building standards and codes are based on the needs of a manual wheelchair user and not a power chair or scooter user (Ringaert, Rapson, Qiu, Cooper, & Shwedyk, 2001). These issues are important for the occupational therapist who is trying to understand accessibility in the built environment. Occupational therapists should become familiar with local legislation that promotes and supports accessibility and the inclusion of people with disabilities into all aspects of society, as these laws affect client expectations for occupational therapy services, and upon how we practice.

UNIVERSAL DESIGN

Universal design is a way to create products and environments that are more usable by everyone, regardless of age or ability (Mace, 1985). Universal design involves thinking

about a range of human abilities before the environment is built. Today, universal design is considered across most environments, including housing, office buildings, airports, restaurants, parks, streetscapes, urban planning, and museums. It recognizes human differences in shapes, sizes, ages, abilities, and cultures and promotes inclusion and ergonomic design for all people.

Seven principles of universal design (Center for Universal Design, 1997) assist in designing new products and environments to be accessible for all (Figure 60.1). These principles offer occupational therapists useful guidelines to use in developing interventions for clients or organizations seeking to improve the receptivity of the environment.

Terms such as *accessible design, adaptable design,* and *barrier-free design* tend to refer to specialized populations and in some cases are used to add features to a building (e.g., a ramp added after the building was built). However, universal design represents designs that provide inclusion of all people during the design process. For example, the level entrance and power sliding doors at the entrance to

---

The design of products and environments should be usable by all people, to the greatest extent possible, without the need for adaption or specialized design.

PRINCIPLE 1: Equitable Use
The design is useful and marketable to people with diverse abilities.

Guidelines:
1a. Provide the same means of use for all users: identical whenever possible; equivalent when not.
1b. Avoid segregating or stigmatizing any users.
1c. Provisions for privacy, security, and safety should be equally available to all users.
1d. Make the design appealing to all users.

PRINCIPLE 2: Flexibility in Use
The design accommodates a wide range of individual preferences and abilities.

Guidelines:
2a. Provide choice in methods of use.
2b. Accommodate right- or left-handed access and use.
2c. Facilitate the user's accuracy and precision.
2d. Provide adaptability to the user's pace.

PRINCIPLE 3: Simple and Intuitive Use
Use of the design is easy to understand, regardless of the user's experience, knowledge, language skills, or current concentration level.

Guidelines:
3a. Eliminate unnecessary complexity.
3b. Be consistent with user expectations and intuition.
3c. Accommodate a wide range of literacy and language skills.
3d. Arrange information consistent with its importance.
3e. Provide effective prompting and feedback during and after task completion.

PRINCIPLE 4: Perceptible Information
The design communicates necessary information effectively to the user, regardless of ambient conditions or the user's sensory abilities.

Guidelines:
4a. Use different modes (pictorial, verbal, tactile) for redundant presentation of essential information.
4b. Provide adequate contrast between essential information and its surroundings.
4c. Maximize "legibility" of essential information.
4d. Differentiate elements in ways that can be described (i.e., make it easy to give instructions or directions).
4e. Provide compatibility with a variety of techniques or devices used by people with sensory limitations.

PRINCIPLE 5: Tolerance for Error
The design minimizes hazards and the adverse consequences of accidental or unintended actions.

Guidelines:
5a. Arrange elements to minimize hazards and errors: most used elements, most accessible; hazardous elements eliminated, isolated, or shielded.
5b. Provide warnings of hazards and errors.
5c. Provide fail safe features.
5d. Discourage unconscious action in tasks that require vigilance.

PRINCIPLE 6: Low Physical Effort
The design can be used efficiently and comfortably and with a minimum of fatigue.

Guidelines:
6a. Allow user to maintain a neutral body position.
6b. Use reasonable operating forces.
6c. Minimize repetitive actions.
6d. Minimize sustained physical effort.

PRINCIPLE 7: Size and Space for Approach and Use
Appropriate size and space is provided for approach, reach, manipulation, and use regardless of user's body size, posture, or mobility.

Guidelines:
7a. Provide a clear line of sight to important elements for any seated or standing user.
7b. Make reach to all components comfortable for any seated or standing user.
7c. Accommodate variations in hand and grip size.
7d. Provide adequate space for the use of assistive devices or personal assistance.

FIGURE 60.1   The Principles of Universal Design: Version 2.0. [Source: Center for Universal Design (1997).]

a grocery store makes the store accessible to everyone. In this case, the entrance design accomodates people who are pushing the grocery carts, those pushing baby carriages, or those moving large objects on a cart as well as those using wheelchairs or mobility devices. Having good way-finding features, such as clear paths of travel, color cues, and clear signage, is useful for anyone, especially for visitors to a new location who cannot read the local language.

Occupational therapists have the skills to assist in design and postoccupancy evaluations of public places as well as home environments (Ringaert, 2003). Occupational therapists must think at a societal level, not only at the level of the individual, to ensure that all of their clients are able to participate fully in society.

PROCESS FOR ASSESSMENT AND INTERVENTIONS DIRECTED AT THE PHYSICAL ENVIRONMENT

Understanding and describing the range of environmental factors that affect the performance of individuals is difficult, given the immeasurable potential combinations of environments in which clients will perform. Occupations occur within a context that is unique to each individual's circumstance(s). Each human lives in a life space that is built on a system of environments. The environments include a mix of physical and social elements. Physical elements can include the built environment, objects within the environment, and the geographical and climatic features of the natural environment. Social elements consist of people, including their attitudes and cultural values as well as social support offered by these people. Policies and services are also social and political elements of the environment.

Occupational therapists can intervene in the environment at several different levels. How do we organize and think about the factors that determine how the changes will be made? One strategy to use in considering environmental issues is to use an environmental hierarchical continuum (Stark, 2004). This organizing scheme, based on the work of occupational therapists (Hagedorn, 2000; McColl, 1997) and environmental psychologists (Bronfenbrenner, 1977; Lawton, 1980) organizes the environment from proximal to distal, the most proximal environments consisting of personal places that are used frequently and distal being the wider more expanded layer of the environment that includes community.

While each of these layers of the environment contains physical and social attributes, the physical environmental attributes are the focus of this chapter. The most proximal layer includes personal spaces such as an individual bedroom or bathroom in a home or a personal car. These spaces are likely to have the greatest influence on the performance of an individual and are most likely to be influenced by an individual. The personal environment is

easily managed and manipulated by an individual and can be customized to an individual's needs. The second layer of the environment includes the semipersonal contexts. Semipersonal environments are the places through which individuals often move during their daily routines. These spaces can include workplaces, local stores that are visited often, or a religious institution. These places might be customized to suit an individual's needs. Individuals are likely known in these environments. These contexts naturally surround personal environments. Generally, these spaces provide less accommodation than personal spaces do but are often critical for the successful execution of occupational goals.

The third layer, the public sphere of performance, contains spaces an individual visits less frequently than those in the second layer. These are community spaces that are typically used by many individuals in a community, such as government facilities, arenas, or other areas of public accommodation. These are the places that are least likely to be customized to meet an individual's needs and more likely to meet general anthropometric guidelines.

To understand how the physical environment can affect the occupational performance of each individual, it is important to consider each element of the environment in the context that is relevant to that person. Although each of the elements can be assessed and modified, they continuously change and influence each other. Both people and environments are constantly changing. In part, the change is a result of the layers of the environment influencing each other.

ASSESSMENT OF PHYSICAL ENVIRONMENTS

Occupational therapy assessment follows a systematic process, starting with the identification of the client's occupational performance in valued activities (AOTA, 2002; Fearing & Clark, 2000). The next step involves analysis of the client's occupational performance, in which the goodness of PEO fit is examined. The assessment of the environment typically starts here. We have organized assessments of physical environments across home, school, workplace, and community settings and across the layers of proximity from personal spaces through to public spaces.

Table 60.1 lists standardized tools that have been designed to assess physical characteristics and features of the environment in the home, school, workplace, and community and indicates the purpose or focus of each tool, the targeted population and age group, and the methods for administration. Some tools focus on measuring discrete elements of the physical environment, such as those that affect accessibility or safety, while others assess the client's functional needs and abilities in relation to environmental factors for an examination of PEO fit. Assessment of the physical environment can utilize several approaches,

sometimes in combination. These include interviews with the client and/or designated people who know the client and/or the environmental setting well; observation of the client engaged in occupational performance within that setting, noting the environmental influences; and evaluation of specific aspects of the setting based on a set or list of criteria (e.g., standards). While most of these assessments have been developed for occupational therapy practice, some tools have broader applications (e.g., the Multiphasic Environmental Assessment Procedure is typically used by a multidisciplinary team to assess a congregate residential setting, and the ADA checklist is widely used by various groups to assess public access to buildings in the community). The clinical utility of these assessments is discussed in the following sections. For a detailed critique of these and other environmental assessments, see Cooper, Letts, Rigby, Stewart, and Strong (2005).

In most circumstances, occupational therapists should use standardized tools to assess the physical environment to ensure that the assessment has been comprehensive, valid, and reliable. However, suitable, well-designed tools might not always be available, and time constraints can limit what the therapist is able to achieve during assessment. A systematic approach to occupational performance analysis helps to ensure that the environmental factors that are influencing a client's performance are carefully examined.

Assessing the Home Environment

Occupational therapists assess clients' home environments to ensure that the home environment is safe and ready for the client on discharge from an institutional setting, to assess for and recommend home modifications, and to assess the home environment in terms of the client's ability to remain in the home. In the case of discharge planning, the purpose of the assessment is to determine whether the client will be able to manage functional activities while living in the home environment and/or to determine whether the home environment is suitable as a discharge location for the client. This could include assessment of a client's home prior to admission or assessment of a congregate living facility that the client and family are considering as a home after discharge. Further, it might be to determine whether modifications (major or minor) are required in the home to ensure that the client is going to be able to manage after discharge.

Another common home assessment occurs when clients are living in their own home but there is some question about whether or not safety or accessibility problems can be addressed. In many situations, home safety and falls prevention are key considerations of the occupational therapist.

In many home assessments, there is often overlap between assessments of activities of daily living (ADLs) and instrumental activities of daily living (IADLs) and the home environmental assessment. This overlap exists because

occupational therapists focus their home assessments on the functional abilities of the client in the home environment. ADL, IADL, and home-based leisure or productivity activities become a focus to help the therapist understand how the physical environment in the home is used, what the requirements of the environment are depending on the client's activities and preferences, and the meaning of home and its components to the client. This exploration of the occupational profile and analysis of occupational performance of the client provides information for the occupational therapist to then use in considering the need for home modifications (Siebert, 2005).

Home assessments often begin with a focus on the home's location within its community context. For example, is the home located in an urban, suburban, or rural setting? Is the client able to access the community resources he or she requires? How close are the local shopping district and medical offices? Specific to the home itself, there are some commonly assessed components of the home environment. These include entry to and exit from the home, including considerations of emergency exits, circulation within the home, and access within specific areas of the home, including the bathroom, kitchen, bedrooms, laundry, and living spaces. Although clinicians vary in the order in which they conduct assessments, an assessment typically moves from more public areas (entrances, living room, kitchen) to more intimate spaces (bathroom and bedroom).

A number of standardized instruments are available to guide home assessments (see Table 60.1). For example, if home safety is the focus of the assessment, an instrument such as the SAFER (Chui, Oliver, Marshall, & Letts, 2001), HOME-FAST (Mackenzie, Byles, & Higginbotham, 2000), or Westmead (Clemson, Fitzgerald, & Heard, 1999) might be selected. The Housing Enabler (Iwarsson & Slaug, 2001) or Ease 3.2 (Christenson, 2005) might be preferred if accessibility is the issue. If a congregate living facility is being assessed, the Physical and Architectural Features Checklist of the MEAP (Moos & Lemke, 1996) could provide useful information. Standardized home assessments can be used in conjunction with photographs of the home environment to document the current situation in the home. Photographs can be particularly useful when home modifications or renovations are being considered as part of the intervention. The therapist can use them as a means to recall the exact layout of a space and to provide justification for recommendations to the client, funders, and contractors with specific information about what needs to be modified.

Although standardized home assessments are not always used in clinical practice, they provide a significant advantage by ensuring that a comprehensive home assessment has been conducted, providing documentation of the assessment, providing useful information to justify the need for home modifications, and creating opportunities for evaluation of outcomes.

Assessing the School Environment

Occupational therapists play a critical role in enabling students with disabilities to succeed in the school environment and to participate in classroom, playground, and extracurricular activities (Mu & Royeen, 2004). The school team typically establishes the student's educational needs and goals, and the occupational therapist contributes to the analysis of the student's needs and school performance by examining the environmental influences on the student's school experiences.

In many jurisdictions, legislation requires that schools must be accessible to and usable by people with disabilities. The Americans with Disabilities Act Checklist for Readily Achievable Barrier Removal (Adaptive Environments Center, 1995) is a useful tool for assessing the accessibility of public buildings, such as schools, and provides a list of possible solutions for increasing a building's accessibility.

Few tools are available to the occupational therapist who needs to assess the environment for an individual student. The School Setting Interview was developed to explore school environment–student fit for students with physical disabilities ranging in age from 10 to 18 years (Hemmingsson, Kottorp, & Bernspang, 2004). It uses a semistructured interview covering the accommodation needs of students in 11 areas of school performance (e.g., writing, reading, examinations, and doing homework). The psychometric properties, in terms of interrater reliability and content validity, are good. The School Function Assessment (Coster, Deeney, Haltiwanger, & Haley, 1998) focuses on functional behaviors in elementary school environments, including the classroom, bathroom, and playground. Although this is not an assessment of the school environment, the scores reflect a child's participation in school activities and the need for adaptations to the school environment.

Assessing the Work Environment

An occupational therapist might be asked to assess the physical characteristics of the workplace environment for a client who plans to work or return to work in that setting or for the purposes of examining accessibility, safety, and ergonomic factors in a broader sense for a workplace injury prevention program. At the individual client level, the occupational therapist conducts a worksite analysis of the physical environmental factors that help or hinder that individual's work performance. The Work Experience Survey (Roessler, 1996; Roessler & Gottcent, 1994) can be used to assess worksite accessibility and job accommodation needs. The Workplace Environment Impact Scale (Kielhofner et al., 1998) facilitates dialogue about the individual's experiences and perceptions of the work environment, which is particularly useful in examining issues related to return to work. The Americans with Disabilities Act Checklist for Readily Achievable Barrier Removal (Adaptive Environments Center, 1995) and the ADA Work-Site Assessment (Jacobs, 1999) are also recommended for examining accessibility of the worksite.

At the broader level, occupational therapists are consulted by industry to assess the physical environment of the worksite for the purposes of injury prevention. The occupational therapist might be invited to do a job site analysis to identify workplace accessibility, physical hazards, and workstation design, among other factors such as ergonomics and the psychological demands of the work environment. Therapists who assume this role should familiarize themselves with standards and guidelines developed to prevent workplace injury in their community, such as those published by the National Institute of Occupational Safety and Health, which are available from the organization's Website: http://www.cdc.gov/niosh/homepage.html. For more detail about the role of the occupational therapist in the workplace, please refer to Chapter 52.

Assessing Community

There are a variety of reasons why occupational therapists assess community environments. Some of the variation relates to whether or not the therapist is working with a specific individual client or the community site is the "client." In community-based practice with a single client, a community assessment might be required as part of the process of understanding an individual client's abilities and limitations in different contexts. For example, it can be useful to observe a client while grocery shopping to better understand the environmental constraints and facilitators that the client experiences in the grocery store that the client most commonly uses. The occupational therapist can then make recommendations to modify the client's approach to the task, the client's abilities, or the environment itself.

Community assessments can also be focused on the experiences of the individual client within the home and community. Assessments such as the Craig Hospital Inventory of Environmental Factors (Craig Hospital Research Department, 2001; Whiteneck, Harrison-Felix et al., 2004) and the Home and Community Environment Assessment (Keysor, Jette, & Haley, 2005) provide means for clients to report on their experiences in these environments. These types of assessment results can help occupational therapists to better understand the experiences of the client and to set priorities with the client to enhance participation in occupational performance across a number of settings.

Alternatively, the community site or setting may be the client, in which case the needs of many people with different types and degrees of disability may be considered. Although this type of assessment can be more complicated because there is no single client whose individual needs are being considered, it offers an opportunity to suggest environmental modifications that might meet the needs of a larger group of users of the environment.

A number of assessments are available that focus on the accessibility of community settings. For example, AIMFREE (Rimmer et al., 2004) was developed to measure the accessibility of fitness and recreation facilities and has been standardized with initial testing of its psychometric properties. The ADAAG Checklist provides the assessor with the technical requirements from the ADA-ABA Accessibility Guidelines to conduct the evaluation (U.S. Access Board, 2004). Access Guide Canada provides a number of forms to evaluate community settings such as restaurants, financial institutions, entertainment venues, parks, and places of worship. These forms can be obtained from http://enablelink.org/agc/index.php. The Access Guide Canada Website and project are a valuable resource and a model of how information about accessibility can be readily shared with others using the internet. Users can search by province and community and can review information submitted by volunteers on the basic accessibility of sites within the community. The project provides people with disabilities the opportunity to promote the accessible spaces in their community and to participate more fully in the communities in which they live and visit.

Community settings also include playgrounds. An accessible playground provides play opportunities for children of varying abilities and can facilitate social integration (see Figure 60.2). Occupational therapists who work with children with disabilities will find the Guide to ADA Accessibility Guidelines for Play Areas (U.S. Architectural and Transportation Barriers and Compliance Board, 2001) an excellent resource when working within a community setting toward creating accessible play areas. Accessible playground components include accessible routes throughout the play area to both ground-level and elevated play structures and using accessible surfaces such as wooden ramps and rubber tiles. Play tables for sand and water play and vertically mounted panels with activities that are easy to reach and manipulate provide

FIGURE 60.2   In an adapted playground, the ramps and boardwalk provide access for all children.

access for children using wheelchairs and walkers. The playground should also be accessible for adults with disabilities. At times, there may be teachers, parents, or other caregivers at the play area who have disabilities and need to access different elements of the play area when children using the equipment need support, supervision, or help.

INTERVENTIONS

When the assessment process is complete, interventions focusing on the client's identified targeted occupational performance outcomes should be developed using a systematic approach such as the Occupational Therapy Practice Framework (AOTA, 2002) or the Occupational Performance Process Model (Fearing & Clark, 2000). The goal of improving PEO fit as it relates to occupational engagement guides the development of the intervention plan. Goals should be written to reflect the targeted occupational performance outcome (e.g., the client will be able to transfer using grab bars), not the intervention (e.g., install grab bars).

The client or person representing the end-user group plays an integral role in intervention planning and decision making (Ringaert, 2003). When addressing macro settings in the public sphere, the occupational therapist and other planners and designers consult with all end-user groups to help design an environment that is accessible and available to all.

In this section, we present various intervention strategies for the home, school, and workplace and for community settings. Although occupational therapists recommend interventions related to the context of an individual's home, there are several other important settings for environmental interventions. Some interventions can be applied at the personal or semipersonal level with individual clients, and others can be applied at the broader public level with communities or at a societal level.

Interventions in the Personal Environment: The Importance of Home

Home is the context for a broad range of occupations. These occupations can be basic and common, such as dressing and grooming, or complex, such as planning and executing family gatherings and celebrations, maintaining finances, and participating in sexual relations. Home is where we store and display treasured possessions and seek shelter from community stressors (Rowles, 2003). Home is frequently one of the most cherished environments in people's lives and has been associated with personal identity and values (Dovey, 1985). Often, the primary goal of most individuals in an inpatient setting is to go home; the goal of older adults with chronic conditions is to be able to stay home (American Association of Retired Persons, 2000). However, because of the cost of home visits by a

therapist, the home is often overlooked as a focus for intervention. Despite clinical reports of the value of home modifications (Siebert, 2005) and the evidence of the positive influence on occupational performance following intervention programs that occur in the home (e.g., Gitlin, Corcoran, Winter, Boyce, & Hauck, 2001; Mann, Ottenbacher, Fraas, Tomita, & Granger, 1999), therapists often rely on verbal reports from caregivers or clients to understand the complicated environmental influences facing a client who will be returning home. Ordering equipment or making recommendations for architectural modification without observing clients in context is not recommended, as this practice often results in poor outcomes for clients. Most individuals with new disabilities are not able to consider the range of possible barriers they will face in their home. As a result, many opportunities for useful modifications are missed.

Types of Homes

The range of housing options is considerable. Individuals can live in free-standing houses, mobile homes, townhouses, apartments, and condominiums. Homes can be designed for single or multiple families; can include retrofitted loft spaces in large cities or large single-family houses in rural farming communities. Homes can also be congregate living facilities such as assisted living facilities, homeless shelters, dormitories, and group homes. Unfortunately, most housing lacks features that support the performance of individuals with disabilities. Fewer than 10% of the 100 million existing private homes in the United States contain such modifications (Center for Universal Design, 1997), making home modification a priority for intervention for any client who will live with functional limitations as a result of a disability.

It is critical that the occupational therapist understands the policy and legal ramifications of making home modifications in various housing situations. For example, in a walk-up apartment, a person with a new spinal cord injury has the right under the Fair Housing Laws (U.S. Department of Housing and Urban Development, 2001) to add a ramp to reach the apartment building's front door at his or her own expense. Under the same law, an individual with multiple sclerosis who uses a support dog cannot be denied housing even if there is a "no pet" policy in a large apartment complex. The laws can vary depending on the housing situation. For example, dormitories and homeless shelters may be subject to the ADA (1990). Private housing may be subject to local building codes. It is important to understand individual rights with regard to accessible housing. If a law requires that accessible housing features be present but they are not, the therapist might have the role of assisting the client in advocating for accessible features.

Occupational therapists must also consider other residents in the dwelling who could be influenced by or will influence environmental modifications. People who live in single-family homes will likely have family members who cohabitate with them or visit on a frequent basis, apartment dwellers will share common space with other residents, and students might share bathroom facilities.

Person-Environment-Occupation Misfit in the Home

The goal of enabling clients with disabilities to live at home is threatened when the client's functional capacity does not match the demands of the environment. Often, the threat of occupational dysfunction can be attributed to a lack of environmental support (Connell, Sanford, Long, Archea, & Turner, 1993; Mann, Hurren, Tomita, Bengali, & Steinfeld, 1994). In some cases, valued occupations are relinquished because of environmental barriers. For example, a woman who is experiencing the complications of Parkinson's disease might no longer be able to wash her clothing independently because her laundry facilities are located in her basement. In other instances, clients might go to great lengths to continue doing vital activities of daily living, as in the example of an older woman who could no longer step safely into her large bathtub and would take trips to a fitness facility to safely use a walk-in shower. These are examples of poor PEO fit. The desired occupation is difficult or impossible, given the functional limitations of the client and the demands made by the environment. Many common environmental features, as shown in Table 60.2, become barriers when encountered by people with functional limitations.

How to Modify the Home

Home modifications can include changes to the physical environment (both spaces and objects within the environment), education about the physical environment and how to use it in a more efficient or safe way, or changing the social support in the environment to compensate for physical environmental barriers. Often, a blend of all three approaches is used in successful interventions. Interventions should be planned with consideration of the cultural, economic, institutional, political, and social context of the client and the family in relation to impairment and functional limitations associated with the client's acute or chronic condition.

Occupational therapists can use several approaches to change the physical environment in order to reduce demand. They can add features to an environment (e.g., add a bath bench), remove features of an environment (e.g., remove scatter rugs from a hallway), or modify existing features (e.g., paint the door frame a contrasting color). Features of the environment that are barriers to one individual might serve as supports to another. For example, an individual with back pain might benefit from the support that a 19-inch-high toilet (taller than a standard

TABLE 60.2   EXAMPLES OF BARRIERS IN THE HOME

ENTRANCES AND DOORWAYS IN THE HOME

Steps at entrances

Stairs with no railings or with inadequate railings

Narrow doorways

Heavy doors

Door hardware and locks that are difficult to manipulate

Thresholds over ½-inch high

GENERAL CIRCULATION THROUGHOUT THE HOME

Slippery floors

Uneven floor surfaces, multiple levels

Loose carpeting

Throw rugs

Poorly lit areas (e.g., hallway/stairway)

Lack of color contrast on edges of counters, doorways, etc.

Clutter on floors or stairs

BATHROOMS

Height of bathtub

Lack of grab bars by tub and toilet

Height of toilet

Lack of space in bathroom for wheelchair, walkers, assistant

Nonslip resistant flooring in bathtub/shower

KITCHENS

Counter heights either too low or too high

Lack of space for wheelchair, walkers

Height and depth of cupboards, shelves

Appliances that are difficult to use (e.g., handles/controls)

GENERAL

Loose cords (e.g., extension cords, cables)

Low-volume telephone/doorbell

Small-button telephone

Heights of seats including chairs, sofas

Small print on items (e.g., cleaning products/medications)

Sharp corners on furniture and fixtures

---

toilet) offers. The same 19-inch-high toilet might serve as a barrier to an individual who is short in stature and would need a step stool to achieve a sitting position. The goal of the intervention process is to determine the optimal environmental modifications that will support individuals with disabilities in achieving their occupational goals.

Adaptive equipment, such as a bath bench and hand-held shower for someone who is unable to enter and stand for a shower, is a common modification that occupational therapists provide. Adaptive equipment can include specialized medical equipment such as a raised toilet seat, specially designed equipment such as a reacher for someone who cannot bend or reach the floor, or off-the-shelf products that support performance such as an ultra-light vacuum cleaner for a person with arthritis. Architectural modifications range from simple modifications, such as adding stair handrails, to complicated modifications, such as the provision of ramps to enter the home, or the major remodeling of a home. Home renovations can include replacing a bathtub with a roll-in shower, adding an elevator, or building an accessible addition that includes a bedroom and bathroom for a family member who has a disability.

Occupational therapists can also modify how people use the physical environment by providing education about safety in the home. For example, they can teach individuals to make use of features of their existing environment in ways that make it safer or easier to perform daily activities. The conceptual framework for developing home modification developed by Sanford and Jones (2001) provides an organizing scheme to systematically analyze environmental features. The framework, as shown in Table 60.3, hierarchically organizes the architectural features of a room into the categories of spaces, products, controls, and hardware.

How to Decide Which Intervention Is Best

Once the therapist has identified potential intervention options that are most likely to support performance, the therapist reviews these with the client and presents the preferred interventions to potential funders. Often, there are multiple solutions to the occupational performance problems faced by the client. Consider this scenario: A young woman with multiple sclerosis has two primary occupational performance problems. She is unable to bathe independently and struggles to prepare simple meals. She has difficulty walking and uses a wheelchair for mobility. With the first problem, she is unable to transfer into her traditional-style bathtub and currently relies on an attendant to lift her into the tub and to bathe her. She finds the situation frightening and embarrassing and would like to be able to bathe independently. The occupational therapist met with this young woman and identified two environmental modifications that might support her occupational performance goal. The first option was a major

TABLE 60.3	ARCHITECTURAL FEATURES OF A ROOM
Spaces	**Described in terms of:** -Layout -Dimensions -Lighting -Ambient conditions (e.g., heat, light) -Finishes (carpet/wall covering) -Entry dimensions of a room or area **Examples:** -Rooms -Playground -Garage
Products	**Contained in the spaces and include:** -Fixtures -Appliances -Off-the-shelf items **Described in terms of:** -Type -Size -Force required to operate -Auditory or visual signals -Texture **Examples:** -Toilet -Refrigerator
Controls and hardware	Aspects of the environment where the human interfaces with the physical environment **Analyzed in terms of:** -Type -Fine motor skills (one versus two hands, pinch, grip strength) -Access to the item (height of dispenser) -Location of controls -Size -Force to operate -Operational characteristics (calibration/type of sensory feedback) **Examples:** -Doorknobs -Light switches

architectural renovation that involved removing her existing tub and building a roll-in shower with an integrated bench and adjustable hand-held shower. Her second choice was a transfer bench with a hand-held shower (Figure 60.3). Both options would help her to bathe independently. This scenario identifies numerous possibilities, but environmental constraints, such as economic, architectural, and social barriers, might influence the choices.

Funding is often the most challenging obstacle for individuals with disabilities who are attempting to make home modifications. Building renovations are expensive,

and funding currently is not available through most insurance companies for modifications to the home. People often rely on personal resources or social service agencies to fund the modifications. Occupational therapists should be familiar with their local social service agencies that provide for such modifications.

The decision to make architectural modifications in the home is generally expensive. Therefore, it is important to plan for modifications that will continue to meet the needs of the client (and their family members) over time. Therapists should consider the possible course of a chronic dis-

FIGURE 60.3   Bathroom aids: transfer bench and hand-held shower.

ease or how an individual with a disability might age and should recommend modifications accordingly.

The vast differences in housing construction methods can also pose challenges. Although therapists do not often oversee major modifications, they can advise their clients to consult building professionals to determine whether the home can accommodate the changes required before the clients proceed with implementing the recommendations. Questions of how to move plumbing or whether a structure will support a grab bar are important safety concerns and should be made in consultation with professionals.

The decision to make modifications to one's home can sometimes be difficult for homeowners who do not want their home to appear unattractive. Home is often an expression of self; displaying medical equipment or institutional-looking steel grab bars can be undesirable. When therapists offer choices for modifications, aesthetics are an important consideration. Presenting clients with a range of options allows them to weigh the costs in relation to their needs, priorities, aesthetic tastes, family goals, and values. Clients should have all of the information possible to assist them in their decision about modifying their home environment.

Visitability as a Universal Design Concept

Most homes have steps at every entrance, interior doorways that are too narrow for passage by someone using a wheelchair, and lack a bathroom on the main floor. These three barriers are the primary design habits that cause people who are disabled to become isolated from their neighbors and extended families and cause people who develop mobility impairments to become unable to reside safely in their own homes. Without intending to do so, the design of homes often forces people with disabilities and older people to be isolated rather than being integral parts of their communities. Fiscally, it costs much more to do home modifications and remove architectural barriers in inaccessible homes than to incorporate basic access features into new construction.

Visitability is an affordable and sustainable design strategy aimed at increasing the number of minimally accessible single-family homes and neighborhoods. The dual goals of visitability are to ensure access by people with mobility impairments to neighbors and family homes and to provide a basic "shell" of access to allow people to remain in their own homes if they develop a disability. Visitability does not offer total access but does allow people with disabilities to enter the first floor of a home without being lifted up and provides access to the rooms and bathrooms on the first floor (Smith, 2003).

Many communities around the globe have incorporated visitability standards that have resulted in a significant number of new homes designed with accessibility features (http://www.concretechange.org). Typically, visitability includes at least one accessible (or "zero-step") entrance into the home (as shown in Figure 60.4), 32-inch clearance doorways on the main level, and at least one half-bathroom on the main floor (Claar & Boan, 2005). Occupational therapists have many exciting opportunities to assist in community development, education and advocacy using the principles of universal design, and specifically visitability (Ringaert, 2003).

How to Make Going to School Achievable

In many Western societies, students with disabilities are entitled to public education in the least restrictive environment (e.g., Individuals with Disabilities Education Act [IDEA] of 1990 and the IDEA amendments of 1997 [P.L. 105-17], Section 504 of the Rehabilitation Act of 1973 [P.L. 93-112], and Ontarians with Disabilities Act [ODA; Government of Ontario, 2001]). The physical accessibility of schools and school playgrounds and access to barrier-free transportation to and from school are important steps toward achieving the integration of students with disabilities. In addition, the ADA requires school districts to provide programs and services that are readily accessible and usable by individuals with disabilities (Abend, 2001), thus enabling students, parents, teachers, and others with disabilities to access schools. The ADA-ABA Accessibility Guidelines (U.S. Access Board, 2004) are based on both adult and child dimensions and anthropometrics and should be applied in renovating or constructing new schools. Occupational therapists can consult about and advocate for architectural accessibility and the use of universal design principles within schools. For example, in Ontario, Canada, occupational therapists can consult with school boards to prepare annual accessibility plans, mandated by the ODA (Government of Ontario, 2001), or to assist in the design and planning of new schools and planning for major renovations to make schools more accessible.

ETHICAL DILEMMA

Should an Occupational Therapist Recommend Expensive Environmental Modifications?

Darrell is a 72-year-old man with post-polio syndrome. He lives with his wife, Edith. They have been married for 50 years. He uses a scooter for mobility. He has weakness and limited range of motion in his upper extremities, likely resulting from obesity and inactivity as well as the late effects of polio. Darrell has demonstrated a change in his cognitive status and has exhibited new behaviors that are not typical of his abilities (losing keys, unable to use the TV remote control). Edith has been Darrell's primary caregiver over the past 20 years. She lifts him, bathes him, helps him dress, prepares meals, and cares for laundry, their pets, and their home. Edith has begun to experience significant pain and dysfunction as a result of her rheumatoid arthritis. She has joint pain, swelling, and stiffness. She recently injured her back transferring Darrell from the bathtub.

Arven, an occupational therapist, received a referral from Darrell's doctor to evaluate Darrell's functional status. Darrell's doctor would like to consider nursing home placement to relieve the stress that Edith is feeling. The doctor also worries about Darrell wandering away, after Edith recently found him scooting along in a nearby park looking at the ducks in a pond.

On evaluation of Darrell, Edith, and their home, Arven discovers that there are many changes that could be made to the home that would relieve the physical strain on Edith. Arven discusses a plan for a bathroom modification that is fairly extensive, with an overhead lift system that will transfer Darrell safely to the toilet and tub. Arven also describes a new alarm system that will alert Edith if Darrell leaves the premises. They discuss the possibility of a new bed, some modifications in the kitchen that will give Darrell greater independence in preparing meals, and a new laundry machine that Darrell can operate from a seated position. All of these changes will relieve Edith of duties and keep Darrell engaged in his daily life. Edith tells Arven that she finally sees a ray of hope in their lives and is thrilled with the possibility of some quality time with her husband. The plan is reviewed, and both Darrell and Edith agree that the modifications will make important and meaningful changes in their lives. Arven sends a report to the physician indicating that the nursing home is not a necessary option and presents his environmental modification plan. Arven is shocked when he receives a call from his supervisor demanding a meeting with Arven to discuss his unethical behavior.

Arven meets with his supervisor and is told that the referring physician will no longer send referrals to the agency. The physician is angry that Arven gave the family hope to stay home and demands to know how Arven can guarantee Darrell's safety, given his functional limitations and likely cognitive changes. The physician is also furious because his patient has called him asking whether there are funds available to make these changes, since the family is on a fixed income and can barely afford the expensive medications that might make a slight change in Darrell's dementia course. The family has asked the doctor which they should spend their limited funds on: the medication or the modifications. Arven's supervisor has also given Arven a message from Edith asking whether he is aware of any available funds to help pay for the modifications. Arven explains to his supervisor that he has some ideas about funding for the project. He admits that he committed to calling the Alzheimer's Association, Darrell's church, and a few other local charitable organizations on Edith's behalf. Arven's supervisor advises him that he has already spent too much time on the case and informs him that looking for funding is not a reimbursable activity. Arven is told that he will not be permitted to look for funding for these clients.

Questions

1. Should Arven have discussed the possibility of expensive modifications when the family could not afford the changes?
2. Should Arven have followed the referral from the physician and focused his attention on how to make the transition to a nursing home as smooth as possible, even though his professional opinion is that Darrell does not need to be there?
3. Does Arven (and his therapy service) have an obligation to find funding for these modifications?
4. How can Arven defend the course of action he has taken with this client?

FIGURE 60.4   Visitability standard: "zero-step" entrance to new home.

Abend's (2001) guide, *Planning and Designing for Students with Disabilities,* provides useful design principles that are applicable to students with various disabling conditions, including physical, sensory, attention and/or learning impairments, and universal design principles. For example, Abend suggests that versatile classroom spaces with a small alcove off a large common classroom area can help to control noise and visual distractions for students with attention deficits. Modular furniture can be combined or separated to support a variety of activities, such as individual and group work, and can include accessible desks and computer workstations to accommodate students who use wheelchairs or who need writing aids such as laptop computers.

Several physical barriers that have been consistently identified by students with disabilities are steep ramps, heavy doors and raised door thresholds at school entrances, a lack of elevators to a second level, and inadequate accessibility on school playgrounds (Hemmingsson & Borell, 2000; Pivik, McComas, & LaFamme, 2002). School cafeterias should have wheelchair-accessible food aisles, food placed within reach of people who use a wheelchair, and accessible seating arrangements. Way-finding within a school can pose problems for many students, including those with visual, cognitive, and perceptual impairments. Clear signage in corridors that provides directions around the school and distinctive color-coding in sections of buildings can assist students and others to find their way around the school.

Occupational Therapy in the Schools with Individual Students

Occupational therapists play a critical role in enabling students with disabilities to succeed in the school environment and to participate in classroom, playground, and extracurricular activities (Mu & Royeen, 2004). A few examples provided below demonstrate how goodness of fit can be achieved by modifying the environment. Further information about school-based practice is provided in Chapters 51 and 64.

For students who use wheelchairs, school accessibility is critical. To facilitate bathroom accessibility, modifications such as installing an electronic door opener, installing grab bars and a raised toilet seat in the toilet stall, and lowering the sink and installing lever-style taps might be necessary. To facilitate group work with peers, the therapist might recommend a round or rectangular table to bring the group together at a level work surface. Classroom materials should be placed within reach of students.

Classroom environments can have high levels of sensory stimuli in terms of noise, visual clutter, and the physical activity of a classroom full of students, which can have a disorganizing effect for children with sensory-processing problems. Occupational therapists assess the classroom environment to identify the sensory features that either facilitate or hinder students' ability to complete schoolwork and recommend rearranging the physical environment to better fit students' sensory-processing needs. For example, sound-absorbing partitions and low lighting can enable some students to focus their attention while working on individual assignments. The therapist might recommend setting up a quiet space in the classroom where a student with autism can use a rocking chair to seek calming sensory input and put on a headset to listen to music or a taped story.

The occupational therapist should become familiar with the conditions and terms for funding environmental modifications and special or adapted furniture or equipment for schools. Some environmental modifications can be made at little cost, while others will involve applying to the school board or a government agency for special funding.

Accessibility at Colleges and Universities

Many colleges and universities have accessibility plans and special services for students, faculty, and staff with disabilities. For example, a college might have accessible student housing options and special services within the libraries to help with accessing books and other educational

materials. Typically, occupational therapists work for the college or university with the role of providing specific services to students and employees or work for a health provider and have a student or college employee as a client. Occupational therapists can also provide consultation regarding the development of accessibility plans and special services, particularly for communal spaces such as libraries, cafeterias, bookstores, and student lounges. For example, the therapist might not only advise about creating accessible spaces, but might also recommend assistive technologies, such as closed-circuit televisions or screen readers for school libraries to support students and faculty with low vision.

When working with students or college employees, occupational therapists can examine their clients' occupational performance challenges in relation to their roles on campus and help clients to access special services. Therapists can use many of the strategies described in this chapter to address access to the home (which would apply to student dormitories and other student housing), access to classrooms and libraries, and participation in campus life in general. Colleges and universities, like other public spaces, are typically subject to the accessibility guidelines that are mandated in their jurisdiction, such as the ADA-ABA Accessibility Guidelines (U.S. Access Board, 2004).

Transportation to campus and around campus can pose challenges for people with physical disabilities. Occupational therapists can assist their clients to develop a transportation plan that might involve such strategies as arranging for accessible transportation to campus or obtaining a parking permit that allows a student to park next to an accessible entrance to a building in which the student has classes.

Interventions in the Workplace

For many people with disabilities, the ability to work is a primary occupational performance goal. However, the opportunity to work is denied to many individuals with disabilities; the rate of unemployment is significantly higher among people with disabilities than among their counterparts who do not have disabilities (U.S. Department of Labor, 2001). The presence of environmental barriers in the workplace influences a person's ability to perform the essential functions of his or her job. For example, steps at the entry to an office building act as a barrier to a person who uses a manual wheelchair for mobility. A person with low vision might have difficulty reading the small print of office signs. With environmental modification, these barriers can be removed, resulting in people with disabilities being able to successfully perform their jobs. Removing barriers by providing adaptive equipment or modification of the physical environment is typically easy and not expensive (Gray, Hollingsworth, & Morgan, 2001). Table 60.4 provides some typical examples of workplace modifications.

TABLE 60.4	EXAMPLES OF ENVIRONMENTAL MODIFICATIONS IN THE WORKPLACE FOR FUNCTIONAL IMPAIRMENTS
Impairment	**Environmental Modifications in the Workplace**
Cognitive impairment:	◆ Minimize distractions in a quiet, private space. ◆ Use the layout of the space to provide structure to the work day. ◆ Provide photographs in addition to words on signs or office name plates.
Fatigue/weakness:	◆ Use the layout of the space to efficiently complete tasks. ◆ Provide parking close to the worksite.
Fine motor impairment:	◆ Implement ergonomic workstation design. ◆ Provide large buttons or controls with lever-type handles and low force requirements to operate.
Gross motor impairment:	◆ Provide an accessible entrance (e.g., add ramp). ◆ Provide accessible parking on an accessible route of travel. ◆ Provide power-assist door openers. ◆ Provide an accessible restroom and break room.
Auditory impairment:	◆ Provide teletypewriter (TTY) with a visual alert system. ◆ Install an emergency alert system with visual or tactile signal. ◆ Encourage full use of visual aids, including films, overhead projectors, diagrams, and chalkboards.
Vision impairment:	◆ Install proper office lighting. ◆ Use high-contrast color on door frames. ◆ Provide large signs with high color contrast.

The ADA and similar human rights legislation in many countries support the individual's right to work by prohibiting discrimination against people with disabilities. In the United States, when people with disabilities can perform the essential functions of a job with accommodations, they are allowed to apply for and maintain a job. Under the ADA, an employer is responsible for providing the reasonable accommodations necessary for a qualified individual to perform the job.

When job accommodations are necessary, the occupational therapist can be invited to lead a team to identify the environmental barriers that influence an employee's ability to work and help to remove these barriers. The team members can include the occupational therapist, the employer, key employees, and the group that is responsible for implementing the environmental changes. The process of making workplace accommodations is similar to that of making home modifications. An occupational performance analysis is conducted, barriers are identified, and solutions are proposed.

Several strategies are useful for workplace modifications. It is possible to consider the use of adaptive equipment such as a telephone headset for a person with limited upper-extremity function (see also Chapter 62) or to modify the functions of the job by eliminating ancillary tasks that are impossible for the individual to perform. The existing job can also be restructured, as in the case of a person with cognitive impairment who had his workstation moved to an enclosed cubicle to minimize disruptions. The physical environment can also be modified to match the functional limitations experienced by an employee, such as installing power-assist doors for an employee who uses a power wheelchair. The Job Accommodation Network website (see http://www.jan.wvu.edu) provides an excellent resource for therapists, employers, and employees with disabilities.

The occupational therapist should consider all aspects of the work experience when making a plan for accommodations. The therapist must consider not only the employee's daily job duties, but also the administrative and practical functions. The therapist must evaluate the employee's ability to park or get from public transportation to the job site, eat lunch, take breaks, visit the human resources office, and receive communication about relevant work issues. The workstation and the worksite must be evaluated. The emergency evacuation plan must be reviewed to ensure that the worker is able to safely evacuate from the worksite in case of emergency.

Changing the physical environment is an expensive prospect, and the plan that the occupational therapist develops should take into account whether the employee's condition is progressive or stable. When a health condition is stable, the modifications that are made should serve the person's needs. In the case of progressive conditions, it is often important to consider a flexible accommodation that can change with time as a condition progresses.

Before starting the job accommodation process, the occupational therapist should have a clear understanding of pertinent legislation, how to apply it, and the limitations of the legislation. For example, under the ADA, workers are permitted "reasonable accommodations" as long as these do not cause "undue hardship" to the employer. A small employer that has a very small profit margin might not be required to pay for an elevator if it would cause the company bankruptcy, but the employer might be required to move the office of an employee with a mobility impairment to the first floor if space was available. Excellent resources are available from the Equal Employment Opportunity Commission (2005) about the ADA in the United States and from the Canadian Employment Programming for Persons with Disabilities (Human Resources and Skills Development Canada, 2005).

It is also important that the job accommodations leave the facility in compliance with regulations regarding accessibility and safety. A modification plan should be reviewed and approved by an individual who is knowledgeable about the regulations to which the facility must adhere. The outcome of the job accommodation should be evaluated, and the continued success of the accommodations should be monitored over time to ensure the best worker-job fit.

The Public Sphere of Occupational Performance: Community-Based Interventions

The public sphere of performance contains spaces in which people visit on a less frequent basis than the work or home environment. Examples of places included in this sphere of performance include government agencies, cultural venues, shopping complexes, and stores. Although people often spend less time in community spaces, they are important environments that serve as links between more private spaces such as work and home, and they also contain critical goods and services necessary for successful participation in community life. Community spheres are important for socialization, recreation, and civic and social engagement. Environments with poor accessibility can negatively affect the community participation of people with disabilities.

Public places are not customized to meet individual needs. Rather, public spaces are typically designed to meet the needs of average individuals and are based on general guidelines such as the ADA-ABA Accessibility Guidelines (U.S. Access Board, 2004) and building codes in Canada. Yet there are still many challenges in achieving accessible communities, as demonstrated in several articles that describe architectural barriers in food stores (McClain & Todd, 1990), restaurants (McClain, Cram, Wood, & Taylor, 1993), physicians' offices (Grabois, Nosek, & Rossi, 1999), and religious institutions (Harris Interactive, Inc.,

2004). We can achieve greater accessibility by working directly with clients, by working with community property owners or consultants, and by working as advocates in the community.

Transportation is a form of functional mobility and represents an important area of occupational performance. People with functional impairments may face challenges when navigating public transportation systems. Iwarsson, Ståhl, & Carlsson (2003) described collaborative work between occupational therapy, traffic planning, and engineering in an initiative to understand the accessibility of transportation systems. They used a travel chain perspective, which involves considering all steps in the process of traveling from the point of origin to the destination. Occupational therapists can also use occupational analyses to examine the steps involved in using public transportation in relation to the functional limitations experienced by people with disabilities with the goal of optimizing the accessibility and usability of these systems.

Another community setting in which occupational therapists can provide input is in sheltered living or long-term care facilities for older adults. Cooper and Day (2003) described a postoccupancy evaluation process involving assessment and recommendations to meet the needs of people with dementia and their caregivers for short-term respite. Their recommendations focused on promoting safety, self-care, way-finding, and quality of life through such strategies as clear signage, temperature control of water to prevent burns, specific products and devices in the bathroom to optimize independence, and the provision of a wandering path and therapeutic garden.

Occupational therapists who recognize the importance the community sphere plays in the participation of their clients with disabilities can also serve as advocates who promote accessible, livable communities. Occupational therapists can bring their knowledge of accessibility standards and theory to community agencies or organizations. Examples of advocacy include ensuring that polling stations are accessible for people with disabilities and preparing an accessibility guide for community restaurants. Although the advocacy role is often voluntary, it is an important service to the community and citizens with disabilities and is often an extension of direct service roles.

In working directly with clients, barrier removal might not always be possible. In some cases, if the environmental support is not part of a mandatory accessibility guideline, it might not be possible to make changes. For example, the elevator exemption in the ADA permits owners of some small businesses to operate on the second floor with no elevator access, making participation for a person with a mobility impairment impossible. It is the occupational therapist's role to understand current legislation and minimum standards and to help the client advocate for change. It is also possible to identify barriers through the assessment process to help clients make decisions about how they could access and use spaces. In this case, understanding the environment is the goal, even though modification might not be possible.

CASE STUDY: *Occupational Therapist Working with a Client Returning Home*

Gary Lau is a 30-year-old man who sustained a closed head injury with diffuse axonal injury as the result of a motor vehicle accident. Before his brain injury, Gary worked full-time as a mechanical engineer. He is married and lives with his wife; they have no children. In the past, he enjoyed participating in social activities with family and friends, playing sports, woodworking, and many outdoor activities. Gary perceives himself to be very independent, a risk taker, and stubborn at times.

The brain injury resulted in both cognitive and physical impairments. Following five months of intensive therapy, Gary was discharged home. Gary is left with some impairments that negatively affect his ability to be independent with his ADLs. The most limiting is Gary's left hemiplegia. He has decreased balance and an unsteady gait, and he uses a quad cane (a cane with four prongs) for walking. He has no voluntary spontaneous movement in his left hand, and he cannot grasp things with that hand. In addition to poor short-term memory, he has limitations in his executive function, including difficulty initiating tasks, poor organization, difficulty sequencing, and poor judgment and safety. He currently has decreased insight; he is aware of his deficits but has poor appreciation of how his deficits affect his occupational performance.

Currently, Gary requires assistance with his ADLs and IADLs. He is independent with most self-care tasks, including dressing, toileting, and grooming (in a seated position). However, he has difficulty with bathtub transfers, and he needs help to wash his legs, feet, and back. He requires assistance with all IADLs, including, laundry, meal preparation, and housekeeping chores.

Katya, who works as a home-care occupational therapist, met Gary and his wife in their 1-½ story bungalow home to assess the home environment and to provide recommendations to maximize Gary's functional independence at home. Katya interviewed the Laus using the

CASE STUDY: *Occupational Therapist Working with a Client Returning Home* *Continued*

Canadian Occupational Performance Measure (Law et al., 1996), and from those results, the Laus identified the following occupational performance goals for Gary: (1) to become independent with bathing and (2) to be able to prepare a simple lunch for himself during the week when his wife returns to work.

Katya chose the Housing Enabler 1.0, a 188 item checklist that provides a reliable, and valid assessment of accessibility (Iwarsson, 2005; Iwarsson & Slaug, 2001), to assess Gary's functional abilities in relation to the physical aspects of the Laus' home environment. Katya first completed the form "Analysis of Personal Component of Accessibility" to identify Gary's impairments before examining these in relation to environmental barriers in his home and its close surroundings (see Figure 60.5). Katya went on to complete the form, "Environmental Component of Accessibility" (http://www.enabler.nu/; selected items are shown in the figure on the W&S Website). She analyzed the assessment findings by looking at Gary's profile of functional limitations in relation to the environmental barriers in the home; an assessment of person-environment fit. This allowed her to generate a list of the greatest accessibility problems for Gary. For example, the carpeted floor throughout the house and the very narrow hallways and door openings made it difficult for Gary to maneuver with his cane throughout the home. In addition, the lighting on the stairway was poor, and the home was cluttered with a lot of furniture, loose scatter rugs on the carpeting, and electrical cords. Katya recommended increasing lighting on the stairway, moving furniture that was creating obstacles, removing the loose rugs, and tapping electrical cords to the floor or walls to create a safer, more accessible environment.

The assessment of the bathroom and the kitchen revealed several barriers. In the bathroom the toilet was a standard height; there was no place to sit in the shower/bath; there were no grab bars located in the shower/bath or by the toilet; the handles to control the water temperature in the bathtub required high force and were extremely difficult to grasp; there was no nonslip bath mat in the bathtub; a very thick carpeted bath mat lay on the floor outside of the bathtub; the bathroom had a very low, small rounded sink with no counter space; and the mirror was located at a height that was useful only for someone in a standing position. Katya then analysed the accessibility of the bathroom in relation to Gary's occupational performance needs, which are described below. This analysis led her to identify a number of intervention strategies.

Occupational Performance	Recommendations/ Intervention to Enable Safety and Independence	Rationale for Intervention
Bathing ◆ Difficulty transferring into and out of bathtub. Gary was using a very unstable towel rack to help him transfer into and out of the bathtub.	◆ Install a bath transfer bench with back. ◆ Install a clamp-on bar on side of the tub and a vertical grab bar on the wall beside the tub. ◆ Put a nonslip bath mat or a rubber mat with suction cups in the bottom of the bathtub. ◆ Add a hand-held shower.	◆ Bench legs go over the side of the bathtub, which allows Gary to slide his legs over and into the bathtub while sitting without having to step in and out. ◆ Allows Gary to sit and shower, this helps to compensate for his impaired balance. Sitting on a shower bench is much safer than standing, and it helps to conserve energy and increases Gary's independence. ◆ Easy to use, portable, and makes transferring into and out of bathtub easier and safer ◆ Much safer and reduces Gary's chance of slipping and falling in a wet bathtub. ◆ Allows Gary to have control over where the water sprays, works well when using a bath bench because it allows him to wash and rinse himself independently.

Kitchen, laundry room, utility kitchen (pp. 131–35, 148)

	A	B1	B2	C	D	E	F	G	H	I	J	K	L	M	N	Notes
Insufficient manoeuvring areas around white goods/storage units (service area less than 1.2 m in front). Insufficient area because of furnishings is rated under C9.		3	3		3	3	1		3				3	4	1	
Wall-mounted cupboards and shelves placed extremely high (lowest shelf more than 0.5 m above the working surface).		3	3		4	3	3	2	4	3	4	3	3	4	3	◆ The kitchen cupboards were installed very high and required standing on a stool to reach items on the top shelf. ◆ When working at the counter, reaching above shoulder height was required to reach greater than 50% of the items. ◆ There were no adjustable shelves within cupboards. ◆ Cupboards were very deep and required extensive reaching and twisting of body to retrieve items in back of cupboard.
No surface at a height suitable for sitting work (0.85 m or higher is only suitable for standing; lower working height is required for sitting). Leg clearance is required at C29.					1		1						3	3	1	◆ The counters were all greater than 0.85 m in height. ◆ The counters were too high to sit and work.
Low working surfaces (i.e. 0.84 m or lower).								3				3			1	◆ Only low working surface available was kitchen table
No working surfaces with leg room (clearance less than 0.65 m height, depth 0.6 m, width 0.8 m, p. 134).					2		2						2	3	2	◆ Only working surface that had leg clearance and was at an appropriate height to sit and work was the kitchen table
Working surfaces too deep (more than 0.6 m).									3	1	4		3	3		
Shelves too deep (i.e. more than 0.3 m). Deeper shelves require pullout shelves/turntable units.									4		4	3	3	3	1	
More than half of apparatus/controls in very high/inaccessible position (>1.2 m above the floor).						2		2	3	1			2	4	1	◆ Inaccessible and unsafe access to electric outlets for use of small kitchen appliances ◆ Required stretching and twisting of body to access outlets located on back wall of the counter, and behind microwave stand

FIGURE 60.5 Housing enabler: Analysis of personal component of accessibility (or person-environment fit) (from Iwarsson & Slaug, 2001. Printed with permission).

Hygiene area (pp. 64–70)

Criterion	Values	Observations
No place to sit in shower/bath.	2	3	3	1	◆ Bathtub with shower (no shower chair and no hand held shower) ◆ No place to sit in shower
No grab bars at shower/bath and/or toilet.	1	1	4	4	4	4	4	1	◆ No grab Bars Installed in bathroom
Controls/operable hardware in hygiene areas refers to permanent functions, e.g. taps, handles of bathroom cupboards etc. (pp. 111–15, 178).		
Illogical controls.	4	2	3	3	3	3	
High force required to activate controls (p. 113)	3	3	1	3	3	1	◆ Handles to control the water temperature in the bathtub required high force to turn on and off, very short-lever arms
Use requires intact fine motor control (pp. 112–13).	1	1	3	1	3	1	◆ Pulling the drain plug out from the bottom of the bathtub and sink
Complex manouvres (more than one operation/movement) and good precision required (p. 113).	2	1	2	1	1	1	
Use requires hands.	3	4	3	4	3	◆ Turning on and off bathtub and sink water faucets ◆ Pulling down handle to flush toilet ◆ Turning on/off light switch ◆ Opening cupboard door below the bathroom sink
Wash-basin placed at a height for use only when standing (top edge 0.81 m above the floor or higher).	3	3	3	◆ Wash basin was at height for use only when standing. Also, it had no leg clearance space thus making it very difficult and uncomfortable to sit and complete grooming activities
Toilet with standard height (0.41 m incl. seat) or lower.	3	3	1	3	3	1	◆ Toilet was mounted onto wall at the standard height
Mirror placed at a height for use only when standing (lower edge more than 0.9 m above the floor, p. 69).	2	3	
Toilet roll holder in inaccessible position (more than 0.4 m from toilet, other height than approx. 0.8 m above the floor, placed on the wall behind toilet, etc., p. 70).	1	1	1	1	2	1	
Storage cupboards, towel hooks, etc. inaccessibly placed (recommended height 0.9–1.2 m above the floor, p. 70).	1	1	2	3	◆ Personal care items for completion of grooming tasks were not easily accessible (located below sink in the cupboard) and thus required reaching very low to retrieve
Slippery floor surface (pp. 70, 96–97).	3	3	3	1	3	3	1	◆ Thick carpeted rug lying on floor outside of bathtub—this will increase risk of tripping and falling

CASE STUDY: *Occupational Therapist Working with a Client Returning Home* *Continued*

Gary presents with decreased safety and independence with meal preparation secondary to both cognitive and physical deficits. On assessing the kitchen environment, Katya could see that some physical features were not a good fit for Gary with his current functional limitations. The kitchen in Gary's home is very small and cluttered, and it has very limited counter space.

Occupational Performance	Recommendations/Intervention to Enable Safety and Independence	Rationale for Intervention
Meal Preparation ◆ Mobility: Gary is ambulating around the kitchen with a quad cane, and he has impaired left hand function; therefore, he finds it difficult to transfer heavier items such as foods and plates.	◆ Recommend that Gary use a four-wheeled walker (rollator) with a tray/basket or a tea trolley. ◆ Consider purchasing lightweight pots, pans, and plates.	◆ Enable him to independently and safely transfer items to and from counter, stove, and refrigerator to the table. ◆ Enable him to safely lift and use while conserving energy.
◆ Cupboards' height of installation is very high, dishes (plates, glasses) are stored on the top shelves. Gary's ability to engage in overhead reaching is limited by decrease balance, unsteady gait, and decreased upper extremity fine and gross motor skills.	◆ Lower the height of the cupboards. ◆ Relocate items in the cupboards so the items that are most frequently used are in easy-to-reach places. ◆ A long-handled reacher can be used for overhead reaching of light items.	◆ Allow Gary to have easy access and promote safe reaching. ◆ Avoid unnecessary bending and reaching. ◆ Reduce risk of falls due to overreaching (loss of balance).
◆ Short-term memory deficits and executive function ◆ Gary sometimes forgets and needs to be reminded to turn off the stove.	◆ Place written sign above stove that reads "TURN OFF STOVE." ◆ Use a timer for reminder; when the timer sounds, that acts as a cue to turn off the stove. ◆ When preparing a meal while home alone, try to prepare something light that does not require use of the stove (e.g., a sandwich).	◆ Utilize compensatory strategies to enhance independence and safety.
◆ Executive function deficits	◆ Arrange the ingredients and place the objects and items that Gary uses most frequently in one area (in cupboard, in the refrigerator). ◆ Label drawers and cupboards so that Gary knows exactly where to look to retrieve the cooking utensils and ingredients that he needs. ◆ Gary and his wife could generate step-by-step instructions for commonly prepared items and place these in clear plastic jackets so that Gary can use an erasable marker to tick off steps as they are completed.	◆ Compensates for short-term memory deficits and increases independence. Katya discussed her recom-

CASE STUDY: *Occupational Therapist Working with a Client Returning Home*   *Continued*

mendations for environmental modifications with Gary and his wife. Although Gary's condition might improve, some of the modifications were considered essential for safety. Gary and his wife followed through with the recommended environmental modifications. Katya met with Gary and his wife and trained them both in the safe use of all the modifications in the home. As a result of this environmentally based intervention, Gary has made several advancements in his occupational performance. Gary has increased independence and improved safety with bathing activities and can

independently prepare a simple meal. He is less reliant on his wife to help him with these activities. Gary reports improved satisfaction and performance scores on the Canadian Occupational Performance Measure, although his personal abilities (cognition, strength, and range of motion) have not changed during this intervention. Gary and his wife are pleased with his increased independence and have expressed their appreciation for the extra time they now have to spend on family activities instead of on self-care.

CASE STUDY: *Occupational Therapy Consultation to a Community Group*

A community center in a small urban community has asked for an occupational therapist to join the design team for the redevelopment that is to occur at the center. The center serves as a focal point for seniors, people with disabilities, single parents, low-income families, new immigrants, and the general public. Programs and activities include a shared meal program, employment preparation classes, arts and crafts programs, evening movies and dance programs, exercise classes, healthy living classes, and counseling.

The present facility is in an old two-story building that has a very steep add-on ramp to the building, one "accessible" toilet stall that is not fully accessible, narrow 32-inch corridors, a lack of windows, and many other issues. The center has obtained a very large foundation grant to build a new facility. The design team will have the opportunity to decide the best location for the new facility and the best design features. Funding has been conditionally provided, given that this facility will be a showcase for universal design.

The design team provides expertise in design, while users of the facility provide firsthand knowledge of their needs and desires for the best functional design. Many designers do not fully understand the functional needs of people with disabilities and value the occupational therapist's knowledge and skills in this area.

Because this is a public building, the occupational therapist will first develop a conceptual analysis of the clients who will use the building, including their age range, their general abilities and functional challenges, and how they use the building. The occupational therapist will use her expertise in interviewing and in research to run focus groups with clientele from the existing facility (the user-experts) to determine their needs and wishes for the new facility. Design team members will attend the focus groups to hear from the user-experts directly. The occupational therapist will combine the information from the user-experts with her knowledge of disability and abilities and access issues and will share the synthesis with the design team. The occupational therapist will work with the design team throughout the design process and assist in site selection, building layout, space requirements, materials, and color selections. For example, site selection should consider where transportation can be most easily accessed. The occupational therapist can help to identify the best dimensional requirements for user groups and assist with specific selection of assistive technologies.

Questions

1. Describe more specific occupational therapy roles and areas of expertise for this case study.
2. What are the specific issues that the occupational therapist will want to ensure are addressed?

COMMENTARY ON THE EVIDENCE

The Effectiveness of Physical Environmental Modifications

Despite the widespread calls from occupational therapists and others for environmental modifications to promote independence and occupational performance in homes, schools, workplaces, and the community at large, evidence demonstrating the effectiveness of environmental modifications is still evolving. Available evidence tends to focus on home modifications related to outcomes of falls prevention, reducing caregiver burden, and optimizing productivity and participation primarily in the home environment.

Falls and Injury Prevention

Two reviews focus on falls prevention interventions for older adults (Gillespie et al., 2003; McClure et al., 2003), and one review addresses home modifications to prevent injuries in children, the general population, and older adults (Lyons et al., 2003). Together, these systematic reviews suggest that home hazard reductions may be most effective with older adults who have a history of falling. There is not yet sufficient evidence to support the reduction of home hazards to prevent injuries. Home hazards can be the single focus of the falls prevention intervention or more commonly as part of a larger, multifactorial intervention.

Reducing Caregiver Burden

Much of the literature about the effectiveness of environmental modifications to reduce caregiver burden focuses on caregivers of people with dementia. The Environmental Skill-Building Program (ESP), described by Gitlin and Corcoran (2005), is a structured intervention that involves working collaboratively with caregivers of people with dementia living in their own homes. The intervention includes education, environmental modifications, and skill training of the caregiver. The environmental focus includes a home hazards assessment and recommendations for equipment such as bathroom devices, lighting modifications, ramps, and intercom and communication systems. Overall, the ESP resulted in improvements for both care recipients and caregivers. For example, the three-month intervention resulted in reduced declines in IADL in the care recipients, while caregivers experienced reduced upset,

and female caregivers reported higher levels of self-efficacy (Gitlin et al., 2001). The six-month study noted reduced caregiver stress and subjective burden and reduced upset behaviors (Gitlin et al., 2003). A twelve-month follow-up demonstrated improved caregiver affect, trends towards maintained skills, and fewer behavioral problems for participants in the intervention group (Gitlin, Hauck, Dennis, & Winter, 2005).

Optimizing Participation and Productivity

There is growing evidence to support the relationship between physical environments and participation in home, community, and work environments in people who have had spinal cord injuries and traumatic brain injuries (Richards et al., 1999; Whiteneck, Gerhardt, et al., 2004; Whiteneck, Meade et al., 2004). Although physical environments are not the only environmental factors that influence participation, such factors as transportation and access to public buildings clearly influence participation and productivity.

There is growing evidence about the effectiveness of home modifications to promote occupational performance. For example, Gitlin, Miller, and Boyce (1999) found that bathroom renovations resulted in significant improvements in bathing, ADL performance, and transfers. Stark (2004) found that self-reported occupational performance scores improved after an intervention that involved home modifications to address environmental barriers in the homes of older adults. Fänge and Iwarsson (2005) found that while overall ADL dependence did not change as a result of home modifications, bathing dependence did improve, as did participants' perceptions of the usability of the home environment.

Barriers to the implementation of home modifications have also been identified. In particular, costs associated with home modifications can be prohibitive for some participants (Pynoos & Nishita, 2003). Lysack and Neufeld (2003) identified that people receiving publicly funded insurance were provided with fewer recommendations for home modifications and assistive devices than were people receiving private insurance. Therapists need to be alert

COMMENTARY ON THE EVIDENCE *Continued*

to these barriers and strategies that might be used to address them. For example, Stearns and colleagues (2000) suggest that home modifications resulted in reduced Medicare expenditures.

Despite some efforts to evaluate the implementation of recommendations for workstation modifications (e.g., Goodman et al., 2005), limited evidence is available that demonstrates the effectiveness of workstation modifications in improving productivity or work performance.

The least amount of evidence seems to be available to demonstrate the effectiveness of making community sites more accessible to people with differing abilities. For example, although principles of universal design have been described, there is less literature that demonstrates the effectiveness of universal design in outcomes such as social, leisure, or community participation. Some evidence is now accumulating about the accessibility of public spaces and strategies are emerging on how best to evaluate accessibility (Meyers et al., 2002; Thapar et al., 2004). The perspective of the users (client centeredness) and the use of theoretical models that include participa-

tion factors (such as the ICF) rather than audits of environmental features provide more meaningful information and are recommended. Because universal design and the ADA are relatively new initiatives, research should be conducted to evaluate the value of improving access for all in homes, workplaces, and the community at large.

Future Research Directions

For occupational therapists who are interested in generating new evidence related to the effectiveness of physical environmental modifications, many areas warrant further research. First, we need to know whether environmental modifications make a difference in areas of performance that are important to our clients. Further, while evidence is accumulating related to home modifications, less evidence is available to support environmental modifications in workplace, school, and community environments. As universal design principles are implemented, there will be opportunities to explore the effects of design on occupational performance and participation.

CONCLUSIONS AND FUTURE CONSIDERATIONS

Physical environments can create barriers or provide the necessary supports toward enabling optimal occupational performance. Occupational therapists have considerable experience and success with interventions to make homes more accessible and supportive of clients' occupational performance. As a profession, we are demonstrating leadership in addressing environmental factors that influence the participation of people with disabilities in their daily pursuits through the services that we provide in schools, communities, and workplace environments. Today, more people with disabilities are able to go to school, return to work, and participate in their communities through efforts made by occupational therapists to reduce environmental barriers and harness environmental resources. To provide this leadership, it is critical that occupational therapists maintain a strong working knowledge about key disability rights legislation, building codes, universal design initiatives, and accessibility guidelines that can

improve the overall participation and empowerment of persons with disabilities.

PROVOCATIVE QUESTIONS

1. Many occupational therapists spend a great deal of time involved in home modifications and the many frustrations that go with them, including lack of funding. Perhaps the occupational therapist could also advocate for visitable housing in the region so that there would be less need for as many home modifications. Is this an occupational therapist's role?

2. Although occupational therapists may be readily able to identify home modifications that promote occupational performance with a client, funding limitations might present significant barriers. How can occupational therapists ensure that they are not impeded in providing the best recommendations for clients because of perceived or real limitations in funding?

3. Universal design principles have been described in the literature, and occupational therapists can provide

insights into their implementation in public buildings and spaces. How can we evaluate the effectiveness of this type of service to justify our involvement?

4. Think about your own personal environmental hierarchical continuum. What are some of your proximal and distal environments? If you were suddenly unable to access these environments independently, how would this affect your life?

5. Think about your current home environment. If you used a manual wheelchair, would you still be able to live in your current home? What new limitations would you face? What if you were using a power wheelchair or a scooter? What adaptations would have to be made? Would you be able to continue independently engaging in your meaningful occupations?

Assistive Technology and Wheeled Mobility

MARY ELLEN BUNING

61

Learning Objectives

After reading this chapter, you will be able to:

1. Explain how the client's goals drive the selection of assistive technology and its use as an enabler of occupation and participation.
2. Describe assistive technology devices on the basis of their ability to help people compensate for challenges to occupational performance.
3. Describe how knowledge of occupational performance helps to identify and optimize the human-technology interface.

ASSISTIVE TECHNOLOGY: TECHNOLOGY TO ENABLE ACTIVITY AND PARTICIPATION

Assistive technology (AT) is a multidisciplinary intervention that helps people develop compensatory techniques to engage in activities that are important to them. Occupational therapists specializing in assistive technology use knowledge from human occupation, kinesiology and biomechanics, perception and learning theory, and skills in activity analysis and energy conservation to help people do the things they want to do. Occupational therapists guide clients in selecting AT solutions and integrating them into daily life. They emphasize activity and participation, not just the technology. Broad knowledge of human occupation is a valuable asset on an AT team.

Although AT is a relatively new area of occupational therapy practice, microprocessor-based technologies are now familiar and useful parts of daily routines and personal productivity. Concepts such as storing and sending data via the Internet, signaling garage doors with radio frequency, and beaming data between infrared ports on a personal digital assistant (PDA) are commonplace today. Technologies are an essential part of daily life and can be used to aid persons with impairments. Even when occupational ther-

apists do not possess AT skills themselves, they should recognize when a client might benefit from AT and make an appropriate referral.

The HAAT Model

An engineer and an occupational therapist created the Human, Activity and Assistive Technology (HAAT) Model to explain and guide evaluation and delivery of AT services (Cook & Polgar, 2008) (Figure 61.1). The HAAT model, based on general systems theory in which change in one element creates a consequence in another, represents performance as an interaction between the person, the person's activities, the AT, and the environment (American Occupational Therapy Association, 2002; Cook & Polgar, 2008).

The client's desire to engage in occupations is often the starting point for an AT evaluation. Context includes the physical attributes of environment, such as temperature and moisture (affecting technology performance), and the social and cultural attributes, which are both external and within the individual (affecting expectations and tolerance for technology). For example, in the school setting, students need to answer questions and work with others in the classroom and want to talk with friends in the cafeteria and after school. Different settings require different types of communication and may require particular product features to meet the client's desire for participation and acceptance. To identify the features that are needed in an AT device, it is important to understand the settings, the occupations, and the person's strengths (intrinsic enablers) and gaps in performance. When the AT device supports performance, it serves as an "extrinsic enabler." For example, a text-to-speech synthesizer added to a computer enables use of the computer by a client with a visual impairment or learning disability. Unimpaired performance skills and capacities (listening and remembering) are enlisted and used in combination with the adapted computer.

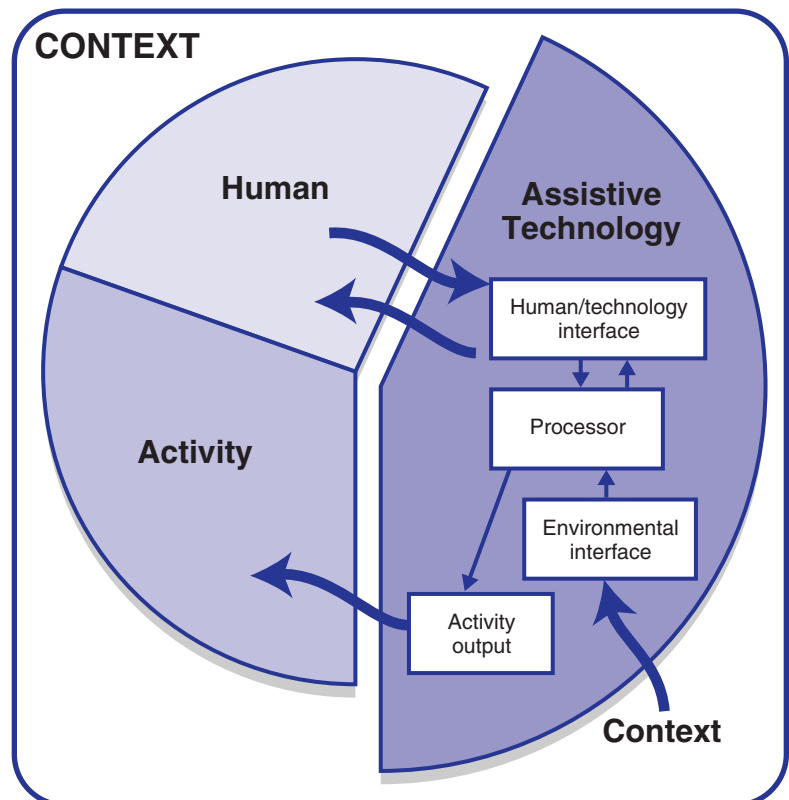
The HAAT Model describes the interaction between the four components of an AT device. The *human-technology interface* is the means by which the client interacts with the device—to either input or receive information or both. A computer keyboard and display are examples of common human-technology interfaces. The *processor* acts on the user input (e.g., pushing a joystick) and follows instructions or a program (e.g., the wheelchair's computer) to produce an activity output (e.g., motor-powered movement in the direction the joystick is pushed). The *activity output* of AT devices ranges from speaking selected words via digitized speech to launching a music CD in response to activation of a switch on a remote controller. Some AT devices have an *environmental interface.* This factor detects external information, interprets it, and delivers it back to the human through the human-technology interface. A page scanner that converts print into computer text for listening via speech synthesizer and an ultrasonic cane that detects obstacles for an individual without vision are examples of environmental interfaces.


FIGURE 61.1 The HAAT model represents all the system factors that must be considered for successful assistive technology intervention.

Client-Centered Intervention

The desire for meaningful occupation facilitates motivation and the potential for successful use of an AT device. The positive experience of using AT to engage in valued occupations often opens the door to considering other forms of AT. For example, the stimulation of attending a baseball game in a new powered wheelchair might naturally lead to the desire to talk about teams or game statistics. This experience could lead a nonspeaking individual to consider using an augmentative or alternative communication (AAC) device to enhance the capacity for participation. The investment of time and effort in learning to use an AT device is returned when the client becomes even more motivated for activity and participation.

Multidisciplinary Teams

Because occupational therapists have broad expertise in human performance and activity analysis, they are involved in many aspects of AT practice. However, occupational therapists are not experts in the areas of hearing, speech and language, special education, or engineering. Multidisciplinary teams with broad expertise lead to client success. For example, a speech therapist will be better prepared to support a person who is learning to communicate with an AAC device when the speech therapist works with an occupational therapist who helps to identify the best selection method and the optimal device placement. The technical skills of engineers are useful in customizing or integrating two or more technical solutions. An interactive multidisciplinary team has greater problem-solving skills for meeting the client's needs. Depending on the client's age and activity and participation needs, the team might include a physical therapist, speech therapist, audiologist, special educator, rehabilitation technology supplier, rehabilitation engineer, and/or vocational rehabilitation counselor.

The AT Evaluation

The occupational therapist's evaluation focuses on the human-technology interface and activity output to support engagement in desired occupations. The occupational therapy evaluation identifies the performance skills and patterns that are needed to efficiently control an AT device and/or to individualize its activity output.

Because clients use AT in various settings, such as school, work environments, home, or community, the evaluation processes vary. Usually, one team member orients the client to the process and interviews the client about his or her activity goals; the settings in which the client will function; and his or her physical, sensory, or learning challenges. This lead role in the evaluation process is ideal for an occupational therapist. In the case of a child or a nonspeaking adult, family members or advocates actively participate in the evaluation. The lead therapist reviews reports from referring specialists, if they are available, looking for history and diagnostic data for prognosis or precautions or summaries of the client's strengths and abilities and then determines whether additional information is needed. The lead therapist identifies the other team members the client should meet. In collaboration with the client, the therapist summarizes the identified needs and outlines a plan for using AT to address them.

The therapist then develops a process for further assessing the client's needs and begins to identify categories of AT solutions. For example, if the client is a fifth grader with dysgraphia who is struggling to develop written language skills, the therapist might think about keyboarding, knowing that this will be an important lifelong strategy for written communication. The options to be considered might range from a desktop computer to an inexpensive portable word processor (Figure 61.2). A client with amyotrophic lateral sclerosis might also be struggling with writing. In this case, the therapist's knowledge of this disease and its rapid progression leads the therapist to consider a device with more features. The client with amyotrophic lateral sclerosis might initially use a keyboard but will soon need another technology interface, such as a single-switch scan to generate text, and eventually a way to convert that text into speech output.

In considering a range of AT options, it is helpful to use a principle called the *hierarchy of access,* which advises using the least technology required to do the job (Schmitt, 1992). Simpler solutions are easier to learn, cost less, and have fewer elements to malfunction, yet create the desired activity output for the client.

The Human-Technology Interface

As adults in a technologically sophisticated world, we are aware of the many means by which humans control devices:

FIGURE 61.2 An AlphaSmart™ is an example of an inexpensive, portable word processor with adaptive features. It beams text to a computer, where it can be printed and saved.

keyboards, dials, two- or three-button mice, slider bars, push buttons, toggle switches, voice menus, touch screens, and more. When these controls are well designed, they fit the hand or finger, provide enough resistance to increase control, and provide feedback that gives knowledge of results to the user. We recognize a well-designed product because it requires minimal effort for successful use. Designing products for easy and effective use by the largest segment of the population is called **universal design** (Center for Universal Design, 1997). For example, a universally designed cell phone would have larger keys and a larger display, making it usable by elderly people and those with some impairment in vision or motor control as well as the typical user.

The human-technology interface, often called the *user interface* (UI), is central to the AT process and serves as a valuable way to categorize AT solutions (Cook & Hussey, 2002). The UI includes the means of input as well as the type of feedback or output to the user.

MODIFICATIONS TO SYSTEM INPUT: DIRECT AND INDIRECT SELECTION. A user who has good motor control can choose from among all options, and no modification is needed. This is called **direct selection**. When the requirements for direct selection are impaired, every effort is made to enable direct selection through the use of performance or **control enhancers** (Cook & Hussey, 2002). These are low-tech or positioning aids that augment or extend motor con-

trol. **Indirect selection** is used only as a last resort because of the inefficiency of waiting for the scan and the high cognitive load. Table 61.1 provides more information on these three types of user interfaces.

Selecting from a scanning array requires less motor control, but it is much more cognitively demanding. Scanning involves anticipating the presentation of an option and activating the switch at precisely the right time to select it, along with the intellectual ability to systematically build a word or sentence or select a path of travel. When scanning is required, occupational therapists should explore methods for increasing efficiency, such as presenting options in order of frequency of use or using word prediction to save keystrokes (Angelo, 1996, 2000). A single switch is placed where the client can activate it with a hand or upper extremity, chin, foot, knee, or eye blink. The occupational therapist identifies the ideal control site on the body, selects a switch type that complements it, and mounts the switch to optimize activation. Switches vary on many parameters. For example, a small, sensitive switch is selected for finger activation by a person with late-stage multiple sclerosis, and a bright, tough switch is selected for hand or foot activation by a preschooler with powerful athetoid movements.

MODIFICATIONS TO SYSTEM INPUT: PROPORTIONAL AND DIGITAL. Another characteristic on which human-technology interfaces vary is the signaling or control

TABLE 61.1   METHODS TO CONTROL ASSISTIVE TECHNOLOGY DEVICES

User Interface	Description	Examples	Requires
Direct selection	The user picks the desired options from a display of all options (the selection set) possible.	◆ Computer keyboard ◆ Phone number pad ◆ Pressing the TV channel number	Stability, reach, control, strength, control of a finger or body segment to accurately select
Control enhancers	An item that facilitates using a part of the body that could make a direct selection if enabled.	◆ Positioning a keyboard on an easel or platform ◆ Forearm or mobile arm supports ◆ Mouth/typing stick	Observing that a body segment has some but not all of the skills needed for direct selection
Indirect selection	The user is given subsets of the entire selection set. The subsets are presented in sequence. The user waits until the desired option is presented and then picks it by activating a switch; also called scanning.	◆ Repeat presses of "channel up" until reaching the desired channel ◆ Alphabet offered in subsets of five letters with branches to numbers and punctuation	◆ A body part with reliable and repeatable movement ◆ An appropriate single switch placed to facilitate accuracy ◆ The cognitive ability to anticipate and activate a switch and plan a sequence of steps

technology that the interface uses. Individuals with good motor control succeed with **proportional controls**. The typical wheelchair joystick is proportional, with speed and direction linked so that the farther the joystick is pushed, the faster the wheelchair moves. Easing up slows the movement. For people without precise motor control, a digital or microprocessor-based controller is used. Speed is preset, and the user chooses only direction.

MODIFICATIONS TO SYSTEM OUTPUT: USING ALTERNATE SENSORS.

When clients have sensory limitations, it is necessary to modify the system *output*. Just as vibration or flashing strobes can replace the sound of doorbells, clock alarms, and fire signals, so text-to-speech or refreshable Braille displays can substitute for reading text on a computer display. AT is a powerful tool for inclusion, employment, and education for people with sensory impairment, such as when text telephones in combination with relay operators enable clients without hearing to telephone anyone.

The Activity Output

Occupational therapists have affinity with AT because the device's activity output enables individuals to engage in occupations. To illustrate, consider the value of alternative computer access that bypasses the keyboard and mouse for an individual with C-4 quadriplegia. The AT solution could be speech recognition or Morse code sent via a sip-and-puff switch or a head-directed mouse paired with an on-screen keyboard. Regardless of the solution that is chosen, AT restores written communication for any purpose across occupational settings. Computer use enables e-mailing friends and family, writing about life in a journal, or writing advertising copy and participating via the office intranet in work projects. Restoration of written communication supports the client in the roles of friend, family member, and employee.

ASSISTIVE TECHNOLOGY SOLUTIONS

There are many AT solutions, and new or updated products arrive continuously. Because AT solutions change frequently, they are discussed here in categories, along with general guidelines for their use.

Posture

The body continuously cocontracts groups of muscles to maintain posture and enable occupational performance. In addition, an individual automatically shifts body position to relieve pressure, rebalance and stabilize, regain comfort, and improve function. Many occupations occur while seated, and sitting is the only option for clients who use wheelchairs.

Assessing Seating Needs

Many practitioners falsely believe that a client with good sitting posture sits with a vertical trunk and 90 degrees of flexion at the hips, knees, and ankles. This is a posture that many people do not tolerate—or not for very long. A client who is forced by the design of a wheelchair or seating system to sit continuously in one position will be uncomfortable and unable to reposition for tasks.

A physical motor assessment allows observing or checking for the following:

- Ability to transfer and sitting balance
- Bilateral symmetry and range of motion through the spine and pelvis:
  - A fixed asymmetry or deformity must be accommodated, whereas a flexible asymmetry should be corrected to prevent worsening.
- Signs of pressure or shear over bony areas of the pelvis
- Muscle tone, the presence of primitive reflexes, and other factors that affect sitting:
  - Decreased range of motion in the hips affects the seat-to-back angle.
  - Shortened hamstrings directly affect the angle of the footrest hanger.

Table 61.2 provides some examples of seating goals.

Seating for Soft Tissue Management

Individuals without sensation or the ability to reposition themselves are at high risk for pressure ulcers. In addition to ischemia, causes of pressure ulcers include **shear** created by sliding, heat and moisture, poor nutrition, and age-related soft tissue changes. Preventing pressure ulcers is much less expensive than treatment; time lost to healing is also a consideration (Allman, Goode, Burst, Bartolucci, & Thomas, 1999). Properly selected pressure-reducing cushions (rather than low-cost foam) reduce the incidence of pressure sores. (Brienza, Karg, Geyer, Kelsey, & Trefler, 2001; Conine, Herschler, Daechsel, Peel, & Pearson, 1994). Cushion features should be matched to a client's risk factors. Adjusting footrests, armrests, and seat angle also redistribute pressures.

Pressure mapping is a technology that is designed to estimate interface pressure created by gravity. A thin mat of pressure sensors connected to a computer is placed between the client and the seating surface. The computer displays pressure data, and a clinician uses these data to estimate pressure ulcers risk (Brienza et al., 2001; Conine et al., 1994). Mapping of data allows comparison among cushions for a particular client. A pressure map does not measure shear, heat, moisture, or postural stability, and these factors must also be considered.

TABLE 61.2 EXAMPLES OF SEATING GOALS		
Structure	**Function**	**Activity and Participation**
Reduce potential for deformity or slow its progression	Increase sitting tolerance for activities	Enable greater participation in the community
Prevent pressure ulcers by dispersing peak pressures over larger areas of soft tissue	Decrease pain, enable use of seated posture, increase comfort and well-being	Support personal productivity in education or employment
Maintain vital organ function	Orient the head for visual input	Maximize independence in transfers and self-care activities

Seating for Pelvic Support

For some clients, stabilizing the pelvis in an optimal alignment is essential for functioning. Cushions provide external support to compensate for weakness or help to offset the force of spasticity or fluctuating tone. A neutral pelvis supports the natural curves in the spine and contributes to upper extremity function. Positioning belts can help to maintain pelvic position. Tilting the seat pan toward the rear also increases pelvic control and diminishes extensor tone. The only option for fixed pelvic and spinal deformities might be a custom-molded system that accommodates the shape of the trunk, distributes pressures, and optimizes orientation in space.

Matching Seating to Client Needs

Seating goals plus the material properties and shape of cushions underlie the selection of wheelchair cushions and seat backs. Sling upholstery, the most common seating, is popular because it collapses. In fact, sling upholstery is such a poor foundation for the pelvis that over time, it leads to postural deformity (Trefler, Hobson, Taylor, Monahan, & Shaw, 1993).

Today, a seat pan and cushion are used. Cushions include flat or contoured foams, air-filled bladders, viscous fluids, contoured plastic honeycombs, custom-contoured foam, and alternating pressure systems. They vary in their ability to distribute pressure, stabilize posture, insulate or conduct heat, and perform over time. Seat backs vary in height, lateral support, accommodation for spinal curves, and orientation to the seat pan. The certified rehabilitation technology supplier (CRTS) is an essential partner for the occupational therapist. The CRTS specializes in knowing available products and their features. When the occupational therapist works in partnership with a CRTS, this enables matching an active client with paraplegia with a very low wheelchair back that permits full arm mobility, torso rotation, and leaning with the upper body and a pressure relieving cushion. Alternatively, a client with significant trunk weakness is matched with the support of a taller, deeply contoured back.

Recline and Tilt-in-Space

Seating can also be modified with a wheelchair frame that enables recline or tilt-in-space, relieve pressure, manages posture, increases comfort, and helps with personal care activities. *Recline* changes the seat-to-back angle and, in powered wheelchairs, is user controlled. Reclining the seat back creates shear, so antishear mechanisms should be used. Recline helps to stretch hip flexors and enables attending to catheters and dressing. *Tilt-in-space* keeps the hip and knee angles constant while tilting the whole body. Reduced gravity makes it easier to reposition. A tilt of 35 degrees or more unweights the ischial tuberosities and facilitates extension in the spine, neck, and shoulders (Sprigle & Sposato, 1997). Individuals with sensation who are unable to shift their weight or change position require tilt-in-space for day-long comfort. Individuals with high-level spinal cord injury, amyotrophic lateral sclerosis, or advanced multiple sclerosis use tilt to manage dependent edema. In addition to a head rest, a tilt-in-space wheelchair usually creates the need for greater support for arms and legs.

Mobility

Many clients need support to accept and integrate wheeled mobility into daily life when ambulation is no longer safe and efficient. Wheelchairs enable many people to achieve occupational competence despite the loss of ambulation (Iezzoni, 1996). There are many factors to consider in choosing between manual and powered mobility, and it is sometimes a difficult decision (Buning, Angelo, & Schmeler, 2001). Skilled users of manual wheelchairs can maneuver in tight spaces and pull their chair into a car. Heavy powered wheelchairs require accessible environments but traverse hills and distances with ease (Figure 61.3). The user can focus on activities and interactions rather than propelling.

Therapists should not insist on manual propulsion just because a client has the ability to push. Long-term manual propulsion appears to be linked to repetitive strain

FIGURE 61.3   A powered wheelchair enables assuming many valued occupations and supports self-reliance but requires a supportive environment with ramps, elevators, and wider doors.

injuries (RSIs) and rotator cuff tears. These injuries abruptly end self-propulsion as well as transfers, lifting, and reaching (Boninger, Baldwin, Cooper, Koontz, & Chan, 2000).

The Human-Technology Interface: Controls

A primary difference in wheelchairs is the means of control. For manual wheelchairs, it is either a passive system in which someone else pushes or an active one in which the individual uses hands or a combination of hands and feet to self-propel. In a powered wheelchair, the motors are directed by a controller, which receives and translates input from the user. The typical controller is a joystick, but alternatives such as head movement or a sip-and-puff switch are available.

Table 61.3 categorizes wheelchair types, features, usability, and environmental requirements.

MANUAL WHEELCHAIRS.   The Centers for Medicare and Medicaid Services (CMS) assigns product codes to all wheelchairs based on their features (Health Care Finance Administration & United Healthcare, 1998). All insurers now use these codes to categorize wheelchair features. Coding decisions are often controversial because they rigidly limit access to wheelchair types on the basis of the ability to transfer or other functional skills, which can impede independent mobility. For example, a standard wheelchair with large rear wheels appears suitable for self-propulsion. However, its weight, limited size options, sling upholstery, and nonadjustable axle position make it a poor choice for self-propulsion.

Axle adjustability is a valuable feature. Alignment of the rear axle directly below the shoulder improves access to the pushrims throughout the push stroke and balances the muscle groups that are used in propulsion (Boninger et al., 2000). This increased efficiency results in fewer strokes for the distance traveled, which reduces the likelihood of RSI. When the axle is in this position, turns are easier, but so is tipping backward. The therapist must offer skills training and provide rear antitippers until the client is skilled. Axle adjustability is essential for long-term users, but few clients currently qualify because of CMS coding restrictions.

The body of scientific evidence favoring light, adjustable-axle manual wheelchairs is growing. Manual wheelchair users experience a 49–73% incidence of carpal tunnel syndrome (Boninger et al., 2000; Boninger, Cooper, Baldwin, Shimada, & Koontz, 1999). These individuals depend on their upper extremities for propulsion, transfers, and ADL. Carpal tunnel syndrome in wheelchair users leads to costly surgery, loss of productivity, and usually to powered mobility and the consequent changes in daily environments and lifestyle (Buning et al., 2001).

Boninger and colleagues (2000) found that rear axle placement relative to shoulder position is correlated with median nerve injury. The study also showed that proper rear axle position improved propulsion biomechanics. On a driving course, users of ultralight wheelchairs reported a significant positive difference in perceived comfort compared to users of standard wheelchairs (DiGiovine et al., 2000). When both types of wheelchairs were stressed to simulate 5 years of typical use, ultralightweight chairs proved to be far more durable and economical (Cooper et al., 1997).

POWERED WHEELCHAIRS.   Motors were first added to wheelchairs in the 1950s and have continuously improved in performance and features since then (Cooper, 1998). People who use powered mobility have moderate to severe upper extremity limitations. Even when clients have some ability to propel short indoor distances, they rarely have sufficient strength and coordination to offset the risk for RSI or to maintain independent mobility over time.

The CMS recently released new codes for powered wheelchairs for Medicare beneficiaries with specific requirements for client functioning, such as ability to transfer, need for postural support, or powered seat functions (Centers for Medicare and Medicaid Services, 2006). Medicare reimbursement is tied to enabling mobility-related activities of daily living (MRADL) and is restricted to in-home use. The codes now require a face-to-face visit with a physician (who may refer the patient out to an occupational therapist) and home visits to determine home accessibility. Table 61.4 summarizes information on scooters and powered wheelchairs at present, though further changes may occur.

TABLE 61.3   TYPES OF WHEELCHAIRS: FEATURES, SUITABLE USES, AND ENVIRONMENTS

WC Type and Examples	Features	Suitable Uses	Suitable Environments
Dependent Mobility ◆ Transport wheelchair ◆ Adaptive stroller	◆ 6–8″ wheels ◆ Sling seat ◆ Lighter than standard wheelchair ◆ Foldable ◆ May or may not have postural supports	◆ Temporary transport ◆ Sick or physically unable to propel ◆ Young children ◆ Cognitively impaired	◆ Hospital corridors ◆ Physician's office ◆ Airport ◆ Traveling ◆ Shopping malls ◆ Not for use as a vehicle seat unless crash tested
Dependent Mobility ◆ Standard wheelchair ◆ Depot chair ◆ Hemi-height wheelchair	◆ 24–26″ rear wheel ◆ Heavy (>36 lb) ◆ Few sizes ◆ No or minimal adjustment ◆ Lower seat option for foot propulsion ◆ Foldable ◆ Sling seat	◆ Short-term use ◆ Able to transfer ◆ Able to reposition self ◆ For hemi-height, use of same side arm and leg	◆ Hospital corridors ◆ Physician's office ◆ Airport ◆ Home ◆ Community outings with pusher ◆ Not for use as a vehicle seat unless crash tested
Dependent Mobility ◆ Tilt-in-space (55-degree tilt) ◆ Recliner (seat back to 180 degrees)	◆ 24–26″ or 10–12″ rear wheel ◆ Long wheel base ◆ Heavy (40–60 lb) ◆ Few sizes ◆ Specialized seating ◆ Not foldable	◆ Long-term use ◆ High postural support needs ◆ Dependent with pressure management ◆ Unable to transfer or reposition self	◆ Home ◆ School ◆ Community outings with pusher ◆ Not for use as a transit seat unless crash tested
Dependent Mobility ◆ Heavy duty (for clients who weigh 250–650 lb)	◆ 24–26″ rear wheel ◆ Heavy (>50 lb) ◆ Width: 24–30″ ◆ Depth: 18–22″ ◆ Double crossbars ◆ Stabilizer bar between seat canes ◆ Heavy tubing	◆ Long-term use ◆ Difficult to propel with arms so often used with foot propulsion ◆ Variable ability to transfer	◆ Inside the home ◆ Inside the office ◆ Hard, smooth surfaces ◆ Becomes dependent mobility in most community travel. ◆ Not for use as a transit seat unless crash tested
Independent Mobility ◆ Lightweight wheelchair	◆ 24–26″ rear wheel ◆ Heavy (26–40 lb) ◆ Two height options: regular and hemi ◆ Two seat depth options. ◆ No axle adjustment ◆ Accepts removable seating/backrest	◆ Long-term use in limited environments ◆ Able to transfer ◆ Able to reposition self	◆ Inside the home ◆ Inside the office ◆ On hard or smooth surfaces. ◆ Reverts to dependent mobility in most community travel. ◆ Not for use as a transit seat unless crash tested
Independent Mobility ◆ Ultralightweight folding frame ◆ Ultralightweight rigid frame	◆ 24–26″ rear wheel; may have quick release hubs ◆ Light (<30 lb, some <20 lb) ◆ Custom sizes for depth and width ◆ Axle position can adjust to shoulder position. ◆ Accepts removable seating/backrest	◆ With appropriate adjustment of axle, appropriate for long-term use in all community environments	◆ With ability to do a "wheelie," all indoor and most community ◆ With knobby tires, usable on packed trails and in snow ◆ Not for use as a transit seat; should transfer to vehicle seat

TABLE 61.4 SCOOTERS AND POWERED WHEELCHAIRS: FEATURES, SUITABLE USES, AND ENVIRONMENTS

Wheelchair Category and Examples	Features	Suitable Use	Suitable Environments
Scooters or Power-Operated Vehicles ◆ Three-wheeled scooters ◆ Four-wheeled scooters	◆ Front- or rear-wheel drive ◆ Steers with a tiller ◆ Large turning radius or three-point turns due to long wheelbase ◆ Disassembles for transport ◆ No options for postural support	◆ Required for MRADL "in the home" ◆ Unable to walk long distances because of pain, low endurance, etc. ◆ Able to transfer safely ◆ Able to maintain postural stability ◆ Home needs open floor plan	◆ Ramped, accessible environments only ◆ Three wheels: for smooth, flat surfaces ◆ Four wheels: for uneven or unpaved surfaces; not indoors ◆ Outdoors: shopping malls, sidewalks, etc. ◆ Not for use as a transit seat; client should transfer ◆ Medicare does not reimburse for four-wheeled scooters
Group I: Limited-Duty or Portable Powered Mobility	◆ Wheelchair size: <24" × 40" ◆ May fold or disassemble ◆ No part >55 lb ◆ Joystick only ◆ Electronics not upgradable ◆ Only "off-the-shelf" seating ◆ Obstacle climb: 20 mm ◆ Min. top speed 3mph	◆ Required for MRADL "in the home" ◆ Unable to propel manual wheelchair ◆ Is required for very light use ◆ Minimum range: 5 miles on a charge ◆ Ramps: 6 degrees	◆ Ramped accessible environments only ◆ Hard, smooth surfaces; climbs only a threshold ◆ Not for use as a seat in transit unless crash tested
Group II: Limited-Duty or Portable Powered Mobility ◆ Front-wheel drive ◆ Mid-wheel drive ◆ Rear-wheel drive	◆ Wheelchair size <34" × 48" ◆ May fold or disassemble ◆ No part >55 lb ◆ Joystick only ◆ Nonupgradable electronics ◆ Expandable electronics only at initial issue ◆ Skin protection and positioning cushions on sling or solid seats ◆ Obstacle climb: 40 mm ◆ Min top speed: 3mph	◆ Required for MRADL "in the home" ◆ Light use but with special seating ◆ Minimum range: 7 miles on a charge ◆ Ramps: 6 degrees	◆ Ramped accessible environments only ◆ Hard, smooth surfaces ◆ Inside the home ◆ Not for use as a seat in transit unless crash tested

TABLE 61.4   SCOOTERS AND POWERED WHEELCHAIRS: FEATURES, SUITABLE USES, AND ENVIRONMENTS   *Continued*

Wheelchair Category and Examples	Features	Suitable Use	Suitable Environments
Group III: Medium-Duty Powered Mobility ◆ Front-wheel drive ◆ Mid-wheel drive ◆ Rear-wheel	◆ WC size <34″ × 48″ ◆ Suspension to dampen vibration ◆ Proportional joystick or alternate input ◆ May upgrade to expandable electronics ◆ Expandable controller at initial issue ◆ Customized seating possible ◆ May include powered seat functions: tilt and recline ◆ Obstacle climb: 60mm ◆ Min top speed: 4.5 mph ◆ Home visit and evaluation by OT/PT/MD/DO	◆ Required for MRADL "in the home" ◆ Neurological or myopathic diagnosis and inability to stand/pivot transfer ◆ Needs postural support and/or pressure relief. ◆ Minimum range: 12 miles ◆ Accommodates a ventilator ◆ Min range: 16 mi. on a charge ◆ Ramps <7.5 degrees	◆ Ramped accessible environments only ◆ Indoor and limited community use on hard surfaces with some uneven surfaces ◆ Not for use as a seat in transit unless crash tested

Group IV: Heavy-Duty Powered Mobility
◆ Front-wheel drive
◆ Mid-wheel drive
◆ Rear-wheel
Also includes
    pushrim-activated
    power-assist wheels
	◆ Need for drive wheel suspension
	◆ Proportional joystick or alternative input
	◆ May upgrade electronics
	◆ Customized seating and powered seat functions
	◆ Obstacle climb: 75 mm
	◆ Min top speed: 6 mph
	◆ Home visit evaluation by OT/PT/MD/DO
		◆ Required for MRADL "in the home" and for community use
		◆ Need for wheel suspension
		◆ Unable to transfer
		◆ Need for postural support and/or pressure relief
		◆ Accommodates a ventilator
		◆ Minimum range: 16 miles
		◆ Ramps ≥9 degrees
			◆ Ramps and accessible environments only
			◆ Indoor and community use on most surfaces
			◆ Available for use as a transit seat as this category must pass crash test
			◆ Medicare does not reimburse for this category of wheelchair.

A powered base with mid-wheel drive is highly maneuverable and turns within its own footprint, making it ideal for small spaces. This is important because payment for a powered wheelchair is based on its necessity for MRADL. If the person is also using a powered chair in the community, the advantages of front- or rear-wheel drive should be considered. Wheelchair users will make significantly different demands on the batteries, motors, and torque offered by a powerbase, so knowledge of contexts and occupations is important.

An individual's need for postural support, pressure management, and comfort will also determine the category of wheelchair that is needed. A range of aftermarket products can customize pelvic position; head, back, and arm support; thigh placement; and foot support. Powered options for tilt-in-space, leg elevation, recline, seat elevation, and sit-to-stand should also be considered. The most commonly used powered wheelchair option is tilt-in-space as it redistributes pressure for individuals unable to transfer or shift weight.

A joystick is the typical control interface for a powered wheelchair and uses proportional control. When a client cannot use a joystick, the therapist, using the concepts presented previously, collaborates with the client and the CRTS to determine alternative control options. Interfaces such as a sip-and-puff straw or directional switches

embedded in a head support allow the client to control direction and move at preset speeds. Powered wheelchair users can also use scanning interfaces in which they choose from the four directions as they are offered sequentially.

The Human Interface for Mobility

A client will not be fully successful with manual or powered mobility unless the client is confident that he or she can control its activity output. The therapist needs to teach mobility skills. Active manual wheelchair users need to learn to do a wheelie so that they can feel comfortable going down ramps, bouncing off a curb, or traveling over soft earth (Kirby, 2005). In dependent mobility systems, the therapist teaches the pusher, who must deal with these same barriers.

The equivalent with a powered wheelchair is programming the controller for the user's ability and environ-ments. Novice users should have driving parameters set conservatively and readjusted when skills improve. Clients who drive in hilly areas should have torque settings adjusted for better climbing performance. Those with progressive impairment should have settings adjusted periodically to compensate for weakness, lost range of motion, or tremors. These modifications show the benefit of having a smart processor as part of an AT solution. The processor modifies input or output as needed in response to changes in skills or the environment.

With powered wheelchairs that have more complex control interfaces, a partnership between the therapist and the CRTS is critical. The therapist conveys the client's needs and output requirements to the CRTS, who is able to recommend products with the needed features and performance attributes. The knowledge and ethics of a CRTS are valuable in ordering the wheelchair, negotiating payment, and later handling product warranty and repairs.

PRACTICE DILEMMA

WHEN *NO* DOESN'T MEAN *NO!*

Debra, a 58-year-old woman, has symptoms with no clear diagnosis. Her neurologist continues to do tests to rule out one diagnosis after another and meanwhile refers Debra to a seating and mobility clinic. Debra comes in using an ill-fitting borrowed manual wheelchair. She has tremors in her upper extremities, significant weakness in her legs, and paresthesias in her feet, and she can walk only a few feet. Tremors make it difficult for her hands to connect with the pushrims on the manual chair and coordinate self-propelling movements.

The occupational therapist interviews Debra and notes her occupations as homemaker, wife, and grandparent. Following a complete assessment, Debra, the occupational therapist, and the CRTS discuss several wheelchair options. After a driving trial, they agree that a small, mid-wheel drive powered wheelchair would maneuver within the dimensions of Debra's home yet have the power to get her out onto the rear deck, where she could watch her grandchildren play. The occupational therapist writes up the evaluation results and includes the CRTS's report from the home visit with a demo chair, the letter of justification, and the specifications for the wheelchair that meet Debra's needs.

Four weeks later, Debra calls saying she that has received a letter of denial from her health plan. The occupational therapist is stunned. Surely, a follow-up phone call will clarify Debra's need for a powered wheelchair. The health plan representative cites Debra's lack of diagnosis and her ability to walk short distances as reasons for denying the powered chair. The representative outlines the appeal process, and the occupational therapist immediately writes a letter of appeal to the health plan with a copy to Debra's neurologist.

Five days later, Debra calls again with more bad news. She has fallen while attempting to get clothes out of her dresser. She lay on the floor for several hours and was discovered only when her daughter stopped at the house. Debra bruised her right arm, fractured a rib, and blackened her right eye. She spent a night in the hospital and is quite distraught.

Questions

1. What ethics should guide this occupational therapist's behavior in this situation?
2. How can clinical findings be used to get the health plan to recognize its responsibility?
3. How will the occupational therapist be reimbursed for the time required for this appeal?

An important context for wheelchairs is transportation. Personal vans with lifts are ideal but are expensive. Other types of transportation include public buses, paratransit, and school buses. At a minimum, the therapist should be aware that wheelchairs to be used as seats in motor vehicles should meet transportation safety standards with crash-tested frames and securement points (RERC on Wheelchair Transportation Safety, 2000) (Figure 61.4).

Communication

Communication is essential for expressing needs; making choices; forming and maintaining relationships; and participating in education, employment, and community life. Communication happens through facial expression and gestures as well as through speech and writing (Beukelman & Mirenda, 1998). Speech-language pathologists who have specialized in AAC are the leaders of an AAC intervention team. They evaluate a client's potential to use an AAC device, which range from line drawings representing basic human needs to computer-based devices that can store and retrieve language (U.S. Society for Augmentative and Alternative Communication, 2005).

The Human-Technology Interface: Selection Methods

The ideal human-technology interface for an AAC device is direct selection. Clients with poor pointing accuracy or limited hand range of motion will need keys that are sized and located to match their capacity. Performance enhancers such as mouth sticks, head pointers, or mobile arm supports may augment residual abilities (Figure 61.5). Some high-end devices allow the use of electronic head pointing, in which sensors within the AAC device detect light from a reflective dot worn on the forehead. This input is equivalent to a key press. Touch screens allow customization of key size and location so that frequently used keys are placed where accuracy and range are better.

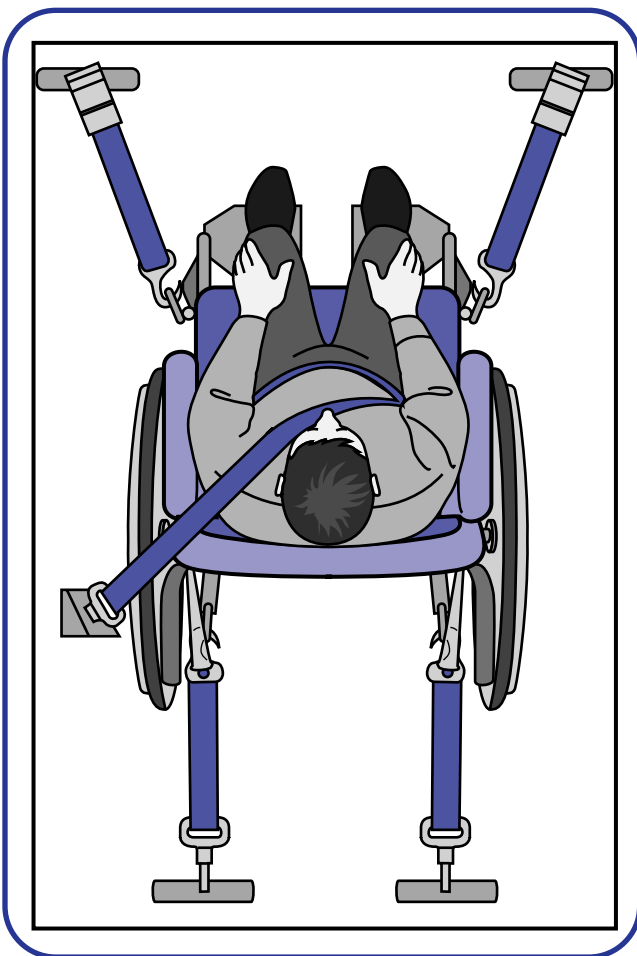
When a client cannot use direct selection methods, indirect selection or scanning methods are used. Users of AAC devices already speak very slowly, and scanning slows the process further. Scanning strategies such as row/column allow the user to first select the row with the desired icon and then move through columns until the icon is reached. Row/column is just one style of scanning array, and users with more skill can use other styles to increase their efficiency. AAC users who rely on scanning use word and icon prediction to decrease switch activations. A client with visual impairment uses a method called **auditory scanning**. The name of the icon or message is quietly announced to the device user, who then activates a switch to select it, which makes the AAC device speak aloud.


FIGURE 61.4   Using best practices in wheelchair securement and occupant restraint creates equivalent safety for individuals who cannot transfer to the motor vehicle seat. Wheelchairs are now available with the transit option.

FIGURE 61.5   A forearm support paired with a polycarbonate keyguard on the keyboard functions as a performance enhancer to reduce effort and increase accuracy.

Visual perceptual skills should be considered in setting up communication boards or choosing the symbol set to represent stored sentences or words. Clients with good tactile and spatial awareness may soon memorize icon location on AAC devices with fixed displays.

The Human-Technology Interface: Mounting for Access and Function

Most AAC users use wheelchairs, so devices are mounted to its frame. Therapists recommend where to mount AAC devices so that they are positioned for optimal visual and motor access. AAC mounts should not obstruct driving, passing through doorways, completing transfers, or functions of the wheelchair, such as tilting. Mealtime is a natural context for communication, so the mounting system should make it possible to both eat and talk.

The Processor and Activity Outputs

It is important to remember that expensive AAC devices are wasted if clients are not expected or allowed to communicate. The people who are the communication partners of AAC users must learn to respect their speaking pace and avoid interrupting, guessing, ignoring, or peering at the display on a user's device. Helping family members, teachers, and personal care attendants to embed communication within occupations is another important role for occupational therapists. Everyone needs to reinforce the effort of learning to use an AAC device.

Manipulation

Another major area of AT intervention is helping people to compensate for hand skill limitations, such as paralysis, weakness, tremor, incoordination, and limited range of motion. These limitations make writing a message, reading a textbook, balancing a checkbook, or turning on the TV difficult or impossible. AT devices called *electronic aids to daily living* (EADLs) and alternative methods for accessing computers assist people with limited hand skills.

The Human-Technology Interface: Selection Methods

The selection methods for EADLs are similar to those that have already been discussed: a variety of direct selection methods and, if these are not possible, indirect selection. Speech recognition is sometimes used when physical limitations prevent controlling items in the environment. After configuring the interface, learning commands, and training the device, the user speaks commands such as "Dial Jack" or "TV on" to get results. Users without speech are often limited to indirect selection methods. Scanning arrays might need to offer pictures to clients who do not read.

Electronic Aids to Daily Living

Managing the telephone, controlling TV and music, exiting the house, and regulating lights and temperature create safety and comfort at home. Because home automation systems enable remote control of these electronic devices, therapists simply adapt the user interface to enable control for people with physical limitations. Previously, EADL devices were called *environmental control units.* The name change spotlights their function: using electronics to perform instrumental ADLs.

Evaluation for EADLs begins with a review of a person's daily environments and the activities and routines that occur in each setting. This information helps to identify the types of devices to be controlled and whether a stationary or portable system is needed. Assessing the person's motor and cognitive abilities helps to identify the requirements of the user interface. Because individuals who use EADLs often have significant physical limitations, it might be important to integrate the EADL with other equipment to make use of limited movement. Flexibility and expandability are important considerations in an EADL system. High-end devices are expensive, so thinking ahead is important when someone is learning how to use one or is faced with a progressive diagnosis (Bain & Leger, 1997; Cook & Hussey, 2002).

As is seen in Table 61.5, EADLs use several means to transmit a signal.

Figure 61.6 shows the two categories of EADLs. Simple EADLs use one signaling technology to control one type of device—the TV, a light, a toy, or a telephone. They succeed when needs are limited or when clients are young and learning. One example is a scanning telephone that enables using a switch to answer the phone or scan through prestored numbers to dial and make calls via speakerphone.

Complex EADLs control multiple devices using two or more signaling technologies. They use one control center to manage several systems: send electrical current to X-10 modules or send infrared (IR) signals to home entertainment appliances or an IR telephone. Wheelchair-mounted complex EADLs often incorporate radio frequency so that users can independently unlock and open doors. EADLs reduce attendant care and enable the satisfaction of safely spending time alone. Using EADLs, clients can call for help or exit the house in an emergency as well as independently manage daily activities.

EADLs can also be controlled through AAC devices, computers, and wheelchairs. High-end AAC devices have IR sending capacity and can be used to directly control any appliance with an IR receiver. The user interface on an AAC device is ideal, since picture symbols are used to represent the output (e.g., lights on, music on). In a similar way, computer software with a graphical user interface can drive hardware that sends several signal transmission technologies. Several manufacturers of high

TABLE 61.5   ELECTRONIC AIDS TO DAILY LIVING: SIGNAL TYPES

Signal Type	Description	Typically Used to Control	Requirements
Infrared (IR)	A light beam from an invisible part of the spectrum	TV, stereo, CD or DVD player	Clear line of sight Unique coded light bursts that are paired with a device function
Radio frequency (RF)	An electromagnetic signal sent from an antenna to a receiver using a very high-frequency radio wave	Garage and entry door openers, alarm systems, remote car entry, etc.	Transmits through solid materials Signal travels distance based on strength of transmitter
X-10	A short RF burst of digital information travels via the house wiring until it meets the coded module or receiver matched to the signal	Devices that plug into wall sockets such as a fan, table radio, or lamp. Also, X-10 units like an alert chime.	Lamps, etc. plug into coded modules that are plugged into electrical outlets. Used to control on/off devices; special modules dim lights and adjust thermostat.

Simple EADLs

Each device uses one type of signaling technology or controls a separate type of appliance.

X-10 Boxes
Controlled by X-10 Controller, TASH Ultra 1 and 4, AAC device

IR Sender
Controlled by large button remote, scanning remote, Relax II, AAC device

Intercom
Controlled by remote or wall unit

Bed
Controlled by remote or switch interface

Telephone
Controlled by computer phone dialer software, switch activated phone, or IR phone dialing device

Complex EADLs

One base unit controls many kinds of appliances.

One unit controls all of these appliances using IR, ultrasound, and RF signaling technologies. Base units offer many access methods: direct selection, voice, and scanning.

Base unit

Examples:
Sicare Pilot, Nemo, MasterVoice, NewAbilities TTK, Proxi, AAC Device computer-based systems, etc.

FIGURE 61.6   Simple and complex EADLs.

end power wheelchairs have just started including this technology within the wheelchair controller.

Computers for Occupation

For people with disabilities, computer input or output can be adapted to accomplish tasks while increasing their access to the broader community and its resources. Computers can significantly enhance self-reliance and quality of life for people with disabilities.

Because clients who could benefit from alternative computer access may have varying abilities and interests, the first step is evaluation to identify goals and begin to narrow the options. A young child with cognitive limitations might need to learn cause and effect with the help of software or develop number concepts through early learning software. A middle-schooler with hemiplegia might need only a one-handed keyboarding application. An adult with spinal cord injury who is preparing for self-employment might want to use desktop publishing software, a spreadsheet to manage accounts, and computer-enabled phone dialing. Each of these activity goals and many more can be reached with knowledge of alternative computer access methods. The next step is to assess a client's performance skills to determine what types of adaptations might be needed.

INPUT MODIFICATIONS.   Computer input modifications can be categorized as a substitute for either the keyboard or the mouse. With the hierarchy of access in mind, it is important to start simple. The computer operating system (OS) control panels offer options that can compensate for mild limitations. For example, the sticky keys option helps a computer user who is typing with one hand or a mouthstick. The sticky keys option enables a user to replace simultaneous keystrokes (e.g., command+alt+delete) with the same keystrokes entered in sequence. All of the accessibility options are fully described on company Websites (Apple Computer Inc., 2005; Microsoft Corporation, 2005). Using a control enhancer such as an easel to reposition the keyboard and using a trackball to increase mouse control are other simple solutions.

Alternatives to the standard keyboard include miniature keyboards that require less range or reach, large keyboards that increase key size and adjust sensitivity to improve accuracy, and keyboards that make one-handed typing more efficient. When keyboard use is not successful, other methods of text entry, such as speech recognition, sending Morse code, pointing a cursor at the keys on an on-screen keyboard, and eye pointing, are considered.

The ability to control cursor movement is important in graphics and design applications, or it may be preferred for moving around a computer desktop. Alternative cursor or mouse control methods include mouse keys (a control panel option), joysticks, and several head-controlled technologies that use either reflected light or ultrasound.

Usually, these head-controlled mice are paired with an on-screen keyboard to allow writing text as well as fluid mouse movement. Keyboard shortcuts by-pass the need for a mouse for many common tasks.

These options are examples of direct selection. Users who do not have the ability to use these methods must revert to indirect selection. It is possible for a client using scanning software that interprets the switch activation to control every aspect of computer use or, with more limited goals, to work within just one application or perform one meaningful task.

THE PROCESSOR: THE COMPUTER'S CENTRAL PROCESSING UNIT.   The power and speed of microprocessors continue to increase, and devices such as modems, CD players, and wireless cards are now standard equipment on computers and give users many options. Many keyboard or mouse alternatives are hardware solutions paired with software for modifying settings or options. Other alternatives, such as the on-screen keyboard, rely only on software. Either way, alternatives must be compatible with the computer's OS and hardware.

THE ACTIVITY OUTPUT: INTEGRATING COMPUTERS INTO DAILY LIVES.   Occupational therapists help clients use computers to engage in activities. To illustrate, a student with significant motor impairment might use a scanning method with a computer at school. This student will need support to master an alphabet scan and then to move beyond just writing. Learning a scan that manages the computer environment will allow shifting between applications and functions, such as searching the Web for a geography assignment in one period and then taking and printing a spelling test in the next. This teaching role is well suited to an occupational therapist focused on integrating AT into school occupations and enabling the student's academic success.

Sensory

People with visual and auditory impairment need modifications to the computer output. AT developers have created excellent solutions in this area. The problem has been getting information and funding to clients who could benefit from using them.

The Human-Technology Interface: System Outputs

When using computers, individuals with low vision need enlarged print on the display or hard copy. Enlargement gives access to any information that can be acquired through a computer. The accessibility options within the OS control panel permit basic screen enlargement for someone who is an occasional user or one with minimal vision loss. Screen enlargement applications add many

features that increase usability for individuals with greater needs.

Individuals without vision need substitutes for moving around desktops, icons, and menus. When you cannot see, pointing with a mouse is irrelevant. Impressive software enables navigating within and between documents and controlling functions such as saving or printing by using keys on the number pad. This software offers access to the text within word-processed documents or e-mails by either a speech synthesizer or a refreshable Braille display. Text can be sent to a Braille printer if hard copy is needed. Technology is also capable of scanning a page of text printed on paper, recognizing the image as letters and numbers, and converting the image into digital text using a process called optical character recognition (OCR). Once in digital format, text can be saved in large print, listened to via computer speech synthesizer, or converted to Braille. OCR creates access to printed materials any time the individual wants it, not just when a sighted reader is available.

Computer users with hearing impairment need captioning on multimedia software and visual alerts such as a blinking title bar rather than auditory signals such as a beep. The ability to communicate with hearing friends and colleagues via e-mail or cell phones with text messaging or short messaging service opens new possibilities for interaction. Video phones that enable direct communication in American Sign Language with other signers or relay operators are quickly changing telecommunication modes for individuals who are deaf.

The Human-Technology Interface: Activity Outputs

Closed-circuit television technology enlarges any item for individuals with low vision. Systems use a camera and flat-panel display to magnify whatever is under the camera—a greeting card, a household bill, or a crochet hook. Full-sized systems can be used only on a desktop, but small handheld models are easy to carry into the community for shopping.

Many commercially available products support independent living. These range from kitchen timers, alarm clocks, and telephones with large numbers for people with low vision to vibrating or flashing alerts for alarm clocks, doorbells, and fire alarms for people with hearing impairment. It is easy to get information about and purchase these items from the Internet.

Cognition

AT can be very useful for clients with cognitive impairments because the AT processor performs the missing skill. Many of the issues that affect the user interface are relevant to this area of AT. For example, when the human-technology interface is modified with icons and spoken

FIGURE 61.7   The PocketCompass™ offers pictures and stored speech as cognitive supports for sequencing activities. PDAs can also remind, report location, and support decisions.

menus, the same process that enables an individual with blindness to hear text also assists a person with a severe learning disability.

Mainstream technologies such as the PDA, pager, global positioning system, cellular telephone, and digital voice recorder are being modified and incorporated into AT devices for use by individuals with cognitive impairment (RERC on Cognitive Assistive Technology, 2006). For example, software written for a PDA allows customization of photos and digitized speech to depict the steps of a morning grooming routine or catching a bus (Figure 61.7). Repeating reminders can alert a person that it is time to take medications. Cellular phone with voice commands such as "call home" make it simpler to use the phone and have two-way communication with family or job coaches. Cell phone cameras can help with recall, and digital voice recorders can substitute for writing memos. Using mainstream technologies in this way can provide new options for safety, discrete assistance for remembering, and a means of remote supervision.

CUSTOMIZING AND INTEGRATING AT SOLUTIONS

Occupational therapy practice uses teaching and an understanding of the learning process to help clients make changes. This knowledge helps therapists in following up with clients as the clients learn to use an AT device and integrate it into meaningful routines and activities. Awareness of the interaction between individual and device and

between an individual and the environment or context enables occupational therapists to modify aspects of AT devices. This ability to notice changes in social and physical settings where AT devices are used helps to solidify their use and usefulness.

When clients have significant levels of impairment, it is often necessary to combine AT solutions, as in a person with both low vision and motor impairment who wants to use a computer. It is very common for the same person who uses a powered wheelchair to also need an AAC device and want to control entertainment devices or doorways in his or her environment.

It is increasingly common for AT devices to work well with each other because of improved standards in OS design and control electronics. Technical support from manufacturers or rehabilitation technology suppliers is often helpful if conflicts do arise. The iterative process of product design with feedback from informed users and therapists has helped to improve AT devices. In reality, AT devices have very small markets, and the economies associated with mass-market products do not apply here. Therefore, this cycle of improvement is often slower than is desired.

PAYING FOR AT SOLUTIONS

Third-party payment for AT is essential, since the majority of individuals with disability survive on small incomes and AT devices tend to be proportionally expensive. Although funding systems have become more responsive, there is continued resistance to paying for AT devices. More studies are needed to demonstrate the outcomes or the long-term economic benefits to society that accrue when AT devices enable better education, improve or create skills for employment, and reduce the costs of dependent care. There are also the individual benefits of participation, expanded social networks, and improved emotional and mental health.

Occupational therapists will always have an important role in documenting the need for AT devices. Their skill set enables them to make a correlation between deficits in occupational performance and the features of AT devices that enable occupation and participation. The ability to use this logic in written letters of justification is effective in getting funding for AT devices. Photos and videos of clients accomplishing their goals during trial use have often strengthened these letters.

When attempting to identify a source of funding for AT devices and services, think about a client's age or occupations and the associated programs and resources. For example, a toddler might expect funding assistance as part of an early intervention program, whereas an adult seeking employment should look to vocational rehabilitation. It is important to remember the goals of the potential payment source in writing letters of justification. Schools want to know about the educational benefit of an AT device, and Medicaid wants to know about its medical necessity. Remember that a funding denial does not mean *no;* rather, it means that you must strengthen the case or ask for a higher level of review.

CONCLUSION

This chapter provides an introduction to the use of assistive technology. Even experts must constantly update their skills through continuing education, AT-oriented conferences, and advanced education. Often, a powerful motivator for learning more about AT is meeting a client who could really benefit from AT intervention. Either refer your client to an AT expert or work collaboratively with your client to gather information and learn more. With the use of OT concepts, the foundation that you have gained in this chapter, persistence, and your own experience with twenty-first century technologies will help you to incorporate AT in your practice.

CASE STUDY: *Making a Computer Work for Ted*

Ted, a 25-year-old man, uses a computer to e-mail and browse the Web. Significant health problems (rheumatoid arthritis, liver disease, and glaucoma) kept him at home when his high school peers left for college. His health is stable, and he wants to pursue his interest in art through an online course in art theory. His visual acuity is poor, and he leans in close to the display to see. His vocational rehabilitation counselor has referred him for assessment.

Following an intake interview, the occupational therapist shows Ted how to reduce the resolution on the display, which has the effect of magnifying everything on the display. She also shows him the magnifier option among the OS accessibility options. Using these together, Ted can see more detail at the location of the mouse or text cursor. There are screen enlargement applications that provide features such as text tracking and text-to-speech, but Ted says that he is not interested. He says that he will return for more powerful solutions if his vision worsens.

1. How does the therapist's approach demonstrate hierarchy of access?
2. Do you agree with the therapist's approach?

From Disability Rights to Empowered Consciousness

62

JOY HAMMEL, JIM CHARLTON, ROBIN JONES, JESSICA M. KRAMER, AND TOM WILSON

Learning Objectives

After reading this chapter, you will be able to:

1. Compare and contrast different models of framing disability, key terms within each model, and implications of each model for occupational therapy practitioners and for disabled people.
2. Describe the disability rights movement in the United States and its history as an example of a social movement's framing of the disability experience from within.
3. Describe the sociopolitical and social justice issues that disabled people as a minority group face in the effort to realize rights and improve participation opportunities and access in society.
4. Critically reflect on your practice as an occupational therapist, how you "treat" disability, and key points in the process of reflecting and incorporating sociopolitical, economic, and cultural perspectives into your practice.
5. Develop innovative strategies to collaborate with disability communities on systems change and community and empowered consciousness building.

INTRODUCTION

How you think about and construct disability significantly influences how you experience disability in your own life as well as how you "treat" disability and disabled people as an occupational therapy practitioner and as a member of society. Notice that we put the term *treat* in quotation marks.

BOX
62.1

INITIAL LEARNING ACTIVITY

Take out a piece of paper, and jot down what you think about when you hear the words *disability* and *independence*. What do these words mean to you? How are they defined and constructed in society (e.g., by the public or in the media)? How does the profession of occupational therapy view disability and independence?

Practitioners frequently use the term *treatment* to designate what therapists do to, or do in collaboration with, clients during therapeutic sessions. However, the term *treat* can also refer to how people are viewed and treated as a social group in society.

This chapter focuses on this sociological framing of treatment by exposing you to different models and framings of disability and the disability experience using a critical theory stance. Critical theory involves stepping back to critically reflect on how disability is constructed in society and your role as a professional in that construction. The chapter also introduces you to a sociological framing of the political, economic, social, and cultural issues that influence the disability experience of individuals and that of disabled people[1] as a collective minority group. Specifically, a critical theory framework will challenge you to reflect on every aspect of your evaluation and intervention as an occupational therapist to determine whether they authentically reflect the insider experiences, needs, priorities, issues, and goals of people with disabilities and what is most meaningful and relevant to them and to people with disabilities as a minority group.

COMPARING AND CONTRASTING MODELS OF DISABILITY

Individuals do not exist or operate in isolation from their social worlds, their communities, and the broader society with its expectations, norms, cultural beliefs, and socio-

---

[1]Although the term *people with disabilities* often appears in the literature as recommended people-first language, *disabled people* and other "disability-centered" terms are increasingly preferred and used by many activists and scholars who promote positive disability identity as an act of resistance against disability oppression (e.g., the focus is not on the deficit in the individual but on the society that imposes disability on disabled people as a collective minority group).

political and economic realities. Nor do occupational therapists operate in isolation from their own beliefs or from the values and economic interests of the systems within which they work and the broader society in which they live. Yet we often try to achieve this isolation within the therapeutic context; that is, we try to focus in on individual rehabilitation goals, impairment remediation, or functional return without fully considering the holistic needs and desires of the individual as influenced by society.

We can look to different models and conceptual framings of disability to better understand this social phenomena and to critically examine how rehabilitation professionals such as occupational therapists have situated themselves in relation to disability and to disabled people.

From a historical perspective, some of the earliest documented societal framings of disability are situated within religious and cultural constructions (for detailed history accounts, see Longmore & Umansky, 2001; Oliver, 1990, 1996). Although different religious sects and cultures treat disability differently, one of the most important influences in defining disability has been that of Western Christianity and the *moral model* of disability. In the moral model, disability is seen as a moral marking. In most cases, the mark is seen as a negative one—one that designates a sinner or an evil or unclean presence within the person. Historically, the mark was used to validate the separation of that person from the rest of society lest the evil spread or to justify the need to cleanse the person from the evil spirit, a type of early cure. At the same time, however, the moral model asserted the responsibility of the religious community to have pity on the less fortunate and to take care of them, thus extending into the *charity model.* Together, these beliefs led to the formation of institutions, asylums, sanitariums, and segregated communities to isolate yet take care of people with disabilities.

The charity model was also reified by Western-influenced societies, such as the United States and United Kingdom, and in turn extended beyond religion into a societal practice within the *welfare model*. In this model, society assumes responsibility over the welfare of the less fortunate, who are otherwise deemed not to be capable of supporting themselves (Oliver, 1990, 1996). Using a welfare model, groups of people, including people with diverse disabilities and those labeled as *sick, feeble, poor, criminals,* and *the underclass* were often grouped, housed, and "treated" together, separate from the rest of society.

Although they were framed within a charity model, conditions in these institutions were often less than charitable, and since these individuals were not deemed to be a valid part of the productive workforce, financial supports were often limited and were cut back even more during times of societal depression. This trend toward a *political economic and materialist framing* of disability focuses on labor economics and on surplus or deficit in the labor market to define and "treat" disability (Hahn,

1985; Oliver, 1990, 1996). In our capitalist society in the United States, the ability to work or not and the simultaneous value of independence have been central forces in defining and socially constructing disability and the treatment of disabled people.

Historically, as science and technology came to the fore and continued to progress within industrialized societies, we began to see the formulations of a more scientific approach to disability in the field of professionalized medicine (Foucault, 1973; Mechanic, 1974; Oliver, 1996). The scientific focus was based on a positivist framing that there are certain universal truths or facts that can be identified and proven. In this case, those truths relate to disability in the tenet that one can identify what is wrong, how it came to be wrong, and therefore how to treat and/or cure that wrong. In some branches of medicine, these tenets applied to treating physical ailments, conditions, and impairments. In psychology, similar tenets were applied to diagnosing and treating illnesses of the mind, such as psychiatric and cognitive conditions.

However, given the difficulties involved in trying to objectively explain social and psychological behaviors, other psychologists began to qualitatively examine how people interacted in the moment and how actions were shaped by and given meaning via social interactions with other people in everyday contexts (Blumer, 1969; Goffman, 1963). Concepts such as stigma, learned helplessness, self-efficacy, and social learning emerged, tying together the individual with the immediate social environment in an *ecological framing* (Bronfenbrenner, 1979). Sociologists and anthropologists challenged the focus on the individual, however, and began to focus on cultural and societal constructions of disability, pointing to the political, economic, and cultural influences of the society on individuals and groups of people in society. Concepts such as oppression, marginalization, and alienation were used to describe disabled people as a minority group. The *social model of disability* (Oliver, 1990, 1996) asserts that oppression occurs because of the political economy of societies that exclude disabled people and prevent them from moving out of welfare systems to the productive workforce, thus invalidating them as full citizens. The *minority group model of disability* (Hahn, 1985; Longmore, 1995) acknowledges the societal oppression of disabled people but, like other minority group social movements (e.g., by race, ethnicity, gender, or sexual identity), equally emphasizes the strengths, power, and pride of the group. Thus, the minority group model introduces concepts such as disability identity, culture, community, and pride as ways to reframe and own disability "from within." Feminist scholars further tie the individual and the society together via the slogan "The personal is political and the political is personal," pointing to the need to recognize how the personal experience of disability and gender intersect and, in turn, are heavily influenced by and constructed by societal beliefs, norms, and ideologies (Morris, 1992; Thomas, 1999). It is within these soci-

ological and cultural framings that disabled people as a social group and as insiders to the disability experience continue to assume control and power over reframing disability from an insider perspective according to a critical theory stance.

Although it is beyond the scope of this chapter to comprehensively review the history of medicine, rehabilitation, disability, and sociology, this brief history leads us to a contemporary critical analysis of disability models as shown in Table 62.1 that you can use to inform your everyday practice. The table presents three key models of disability: the medical model, the rehabilitation model, and the closely related social and minority group models, which are ascribed to and framed from within disability-led groups and social movements.

What is important to note is the location and construction of disability, moving from:

- A deficit or dysfunction within the individual to treat or cure within the medical model
- To a negative interaction of the person with his or her immediate environment within a rehabilitation model, pointing to the need to remediate, compensate, or normalize the individual
- To a societally constructed and imposed phenomena that can be addressed only through social and societal change within the social model
- To a collective social movement of empowered consciousness from within (e.g., disability culture and art, community building, identity, and pride) within a minority group cultural model.

Also note the shifts in power across the models, from the expert, professionally driven medical model to the professional-client relationship of the rehabilitation model (which can vary from professional-led to client-centered) to the disability constituency–led movements of social change and critical consciousness within the social and minority group models. Depending on which model you situate yourself within, terms such as *independence, participation,* and *empowerment* can take on different meanings as well. For example, *independence* can be defined as the individual ability to safely perform activities by oneself (as we frequently ascribe to in rehabilitation) or as a rights-based framing of freedom of choice, access, and opportunity in society, and autonomy in managing one's life decisions (as framed in a minority group model). It is important for occupational therapists to be aware of and responsive to the disability rights movement's conceptualizations and underlying philosophy of independent living as something that is not about the individual's impairment so much as about the individual's right to societal opportunities and the need to create environments and to change systems, rather than individuals, to support those rights. For example, an occupational therapist might focus exclusively on increasing a client's functional independence, that is, the client's ability to perform activities independently.

TABLE 62.1   COMPARISON OF DISABILITY AND INDEPENDENCE CONSTRUCTIONS

	Medical Model	Rehabilitation Model	Minority Group/ Social Model
What is disability?	Disability is deficiency or abnormality.	Disability is loss or inability to functionally perform everyday activities independently or in a socially expected way (e.g., timely, safely, efficiently).	Disability is difference. (Some would argue for saying that *impairment* is difference, while *disability* occurs only when societally imposed barriers limit people.)
How is disability constructed?	Being disabled is negative.	Being disabled is negative and something to be overcome or to accept/ adjust or adapt to its negative consequences within one's life.	Being disabled is neutral; negative constructions occur when society imposes barriers and oppresses participation; positive constructions occur when the personal and social world own difference and support and validate people.
Where is disability located?	Disability is in the individual body.	Disability is in the individual or in the interaction between the individual and the immediate environment.	Disability derives from the interaction between the individual and society. Disability is located in societal structures and practices that oppress.
What is the mechanism for change?	The remedy for disability-related problems is cure or normalization.	The mechanism for change for disability-related problems is to rehabilitate or remediate to normal and/or to become as physically/ cognitively independent in everyday activities as possible.	The mechanism for change is changing the interaction between the individual and society.
Examples of change strategies	Surgery, medication, medical technology and intervention	Individual remediation and person/environment compensation or adaptation	Systems and social action change; collective activism; disability identity, pride and culture
Who/what are the agents of change?	The agent of remedy is the professional.	The agent of change is the professional in collaboration with the individual client and/or people in client's immediate social world (e.g., client-centered approach).	The agent of change can be the individual; an advocate or ally; any person or group of people that changes the interaction; the community; the society's sociopolitical structure and systems; and art, culture, and media.
What is independence?	Individual physical, cognitive, and mental ability to perform and capacity to make decisions	Individual physical and cognitive ability to perform everyday activities safely and in a reasonable amount of time	Freedom to do what you want to do, when, where, and with whom you want; choice; power over life decisions; control over everyday life and resources to support it

Source: Adapted by Joy Hammel & Access Living based on Gill (1999); Linton (1998); Longmore (1995); Oliver (1996); Rioux (1997).

If you assume a social or minority group model instead, disabled people would argue that *independence* to them means the freedom to make choices and to be in control of decisions, regardless of whether they can perform an activity by themselves. So as an occupational therapist, you might consider spending equal time collaborating with the consumer on whether he or she might want to use a personal attendant and how to access and get funding for this supportive resource to remain "independent."

THE DISABILITY RIGHTS HISTORY AND MOVEMENT: FROM RIGHTS TO EMPOWERED CONSCIOUSNESS

To better understand and apply these models, it is important to situate them within the history of the disability rights movement internationally. The history that follows represents a synthesis of accounts documented by disabled people with and about disabled people who were a part of this history (for detailed histories, see Charlton, 1998; Longmore, 1995; Longmore & Umansky, 2001).

The Organization of Empowerment

Out of the different and often hard realities of everyday life, organizations of people with disabilities have appeared in virtually every country in the world. Most of these organizations embrace the principles of empowerment and human rights, independence and integration, and self-help and self-determination, and these organizations form the core of the international disability rights movement. In a few places, people with disabilities have been politically active for many decades, but in most places, the disability rights movement is a recent phenomenon. Today, most activists locate the beginning of what constitutes the contemporary disability rights movement in the early 1970s.

Trying to pin any social movement down to a given period is complicated, but two periods stand out. It was during the early 1970s that people with disabilities in the United States and Europe, influenced by and directly involved in the civil rights, antiwar, and student movements, began to organize on disability-related issues. The year 1972 is associated with the founding of the Berkeley Center for Independent Living (CIL). It was also about then that the Boston Self-Help Center became interested in independent living as an alternative kind of organization. The independent living movement has been the linchpin of the disability rights movement (DRM) in the United States, and its leaders have had an influence on activists and leaders elsewhere. For example, the first disability rights–oriented group in Europe was established in England when Vic Finkelstein, Paul Hunt, and others initiated the Union of Physically Impaired Against Segregation in 1975. As activists in the United States and Europe began to take up major disability-related issues, the DRM began

to develop and grow. Early on, these issues included the inaccessibility of public transportation; the lack of accessible, affordable housing; the institutionalizing of poor, young people with severe disabilities in nursing homes because of the prohibitive cost of personal assistance; the struggle for inclusion of students with disabilities in regular classrooms; and efforts to change the way in which the public relates to, perceives, and understands disability. The first center, Berkeley CIL, began in 1973, but most CILs in the United States were set up in the early 1980s. There are now more than 350 in the United States. CILs are the most important organizations within the U.S. DRM for two reasons. First, most of the early disability rights leaders were identified with CILs, and the philosophy of independent living formed much of the basic philosophical underpinning of the larger DRM. Second, CILs were and still are cornerstones of the DRM because of the sheer numbers of paid staff. These centers have extensive resources. Out of the work of early activists, legislation and legal mandates concerning the "handicapped" appeared. This happened in North America and northern Europe and to a lesser extent in the Third World. The most important legislation in North America was the Rehabilitation Act of 1973.[2]

The first half of the 1980s were also crucial. The year 1981 was designated the International Year of Disabled Persons (IYDP) by the United Nations. The significance of this was not lost on most disability rights activists in the United States. The year 1981 was very important to the DRM on the international front. In many cases, it was the first time efforts had been made to involve people with disabilities in disability-related projects and programs. Indeed, a crucial event had taken place earlier than the IYDP, in late June 1980, when there was a split in Rehabilitation International (RI), the most significant disability-related international body. RI was a large membership organization composed primarily of rehabilitation professionals. Through efforts of people from Sweden and Canada, RI for the first time made an attempt to bring people with disabilities to its conference in Singapore.

---

[2]It took a month-long sit-in and office takeover at the San Francisco office of the U.S. Department of Health, Education, and Welfare to force Secretary Joseph Califano to mandate enforcement of the act. There are a number of interesting accounts of this action. "More than 150 people took over the federal building and remained for twenty-eight days. Ed Roberts left his new office as Director of the California Department of Rehabilitation to join the protest. Judy Heumann crossed the Bay from Berkeley to become one of the leaders of the takeover. Early in action, Heumann, in a statement reminiscent of freedom fighters of all ages, declared that 'we will no longer allow the government to oppress disabled individuals. . . . We will accept no more discussion of segregation.' . . . The Black Panthers and the Gray Panthers brought in food donated by Safeway and assisted with personal care needs. The siege remains the longest takeover of a federal building by any group in American history" (Brown, 1992, pp. 57–58).

The largely token effort backfired. The few hundred participants who had disabilities demanded that RI mandate that 50% of its delegate assembly be composed of people with disabilities. This motion was overwhelmingly defeated by a vote of 61 to 37, a vote that probably represented the sentiments of the 3,000 other delegates at the convention. Those with disabilities and a few supporters led a split in RI, the outcome of which was the formation of Disabled Peoples' International (DPI).[3] DPI has seen impressive growth in the last 25 years. There are affiliated groups in dozens of countries and an international headquarters in Winnipeg, Canada.[4]

The early 1980s was also a time when many of the leading disability rights organizations were founded, such as the National Council of Disabled Persons Zimbabwe, the Organization of the Revolutionary Disabled in Nicaragua, the Self Help Association of Paraplegics (Soweto) (SHAP), the Program of Rehabilitation Organized by Disabled Youth of Western Mexico (PROJIMO), DPI-Thailand, the Southern Africa Federation of the Disabled (SAFOD), and the American Disabled for Accessible Public Transportation (now known as ADAPT). At the same time, different disability constituency groups began to form and further assert their voice and their rights, including groups such as People First and Self Advocates Becoming Empowered (SABE), representing people with intellectual disabilities, and groups such as MindFreedom and Mad-Nation, representing people with psychiatric disabilities. From many disparate beginnings and places, networks began to form, and the disability movement, as owned and framed from within, began to go public.

Many of these organizations started as a response to the simple need for survival, and their goals were limited to economic self-help and self-sufficiency. Others started as political groups that wanted to mobilize people with disabilities in their communities, cities, countries, or regions. These groups and purposes have gradually merged. All seek to link their work with the struggle for self-determination and human rights. With few exceptions, this is their common denominator. All the organizations within the DRM have a few basic things in common. Most important, they are organizations that are controlled by people with disabilities. Each, in its own way and in its own circumstances, confronts the everyday realities of disability oppression. Another crucial similarity is that each embraces the general philosophical principle that people with disabilities must have their own voice and have control in their lives.

Empowered Consciousness

The emergence of disabled people's organizations, the concomitant promotion of independence and empowerment, and the recognition of the centrality and imperative of speaking for themselves spawned a whole new generation of disabled people who rejected the paternalistic, medical model notions regarding disability. As hundreds of thousands or even millions of disabled people worldwide have come to understand that the "problems" of disability have little to do with them and much to do with how society is organized, large numbers of political activists with disabilities have come forward.

Out of similar and divergent experiences, people with disabilities have acquired a consciousness about themselves and the world around them. This new understanding has affected their aspirations and responsibilities. They have come to a raised consciousness of themselves not only as people with disabilities, but also as oppressed people. Moreover, they have become political activists because their raised consciousness has become empowered. (See Figure 62.1 for images of collective activism and empowered consciousness.) They no longer think of disability as a medical condition; instead, they see it as a human condition. They are no longer interested in the "welfare of the handicapped"; they are interested in the human rights of disabled people. They have joined a social movement to free people with disabilities from political, economic, and cultural oppression (Charlton, 1998).

For political activists, consciousness that resists the emasculation of the self by the dominant ideology, that is, raised consciousness, has been transformed into a consciousness of active opposition: empowered consciousness.[5] Empowered consciousness means acting collectively to empower an entire social group. This can mean educating people, creating disturbances, confronting institutions, and seeking group power in churches, schools, communities, and institutions. Empowered consciousness insists on the active, collective contestation for control over the necessities of life: housing, school, personal and family relationships, respect, independence, and more. People with empowered consciousness might still see only part of the larger world, but they understand that they can and should influence it. This does not mean that they insist on being leaders. It does mean that they want to empower others, especially other people who are experiencing disability. These people see the connections between themselves and others and begin to recognize a level of universality that was obscured in their consciousness. They begin to speak of "we" instead of "I" or "they." Some of these activists

---

[3]Diane Driedger's book *The Last Civil Rights Movement: Disabled Peoples' International* (1989, especially pp. 28–57) is a good history of the split and the subsequent formation of DPI.
[4]RI remains much larger and more influential than DPI. In recent years, RI has added people with disabilities to its executive committee, but it is still dominated by rehabilitation "professionals" (doctors, therapists, social workers, psychologists, etc.). Since the split, a number of disability rights activists have worked with both RI and DPI. RI is headquartered in New York City.

[5]Whenever and wherever this transformation occurs, it produces recognition of the self on both the personal and political levels. This transformation has been particularly important to feminist and multicultural studies. See Charles Taylor's "The Politics of Recognition" (Goldberg, 1994, 81–85).
FIGURE 62.1 Collective disability activism took disability public during the fight to pass the Americans with Disabilities Act (left) and continues to do so in the ongoing movement to mandate and fund community-based living options with supports (right). (Copyright Tom Olin, Photographer.)

are motivated by personal experience (poverty, harassment, institutionalization, a personal loss, rape, indignity, etc.). Others are motivated by something they have learned by being exposed to injustice and oppression in school or out of an outraged sense of social injustice. Most people are politically active for a combination of these and other reasons. A consciousness of empowerment is growing among people with disabilities. (See Figure 62.2 for symbols of this empowered consciousness created from within.)

Empowered consciousness is, in Cheryl Marie Wade's words, being passed around on notes, and it has to do with being proud of self and having a culture that fortifies and spreads that feeling:

> Disability culture. Say, what? Aren't disabled people just isolated victims of nature or circumstance? Yes and no. True, we are far too often isolated. Locked

away in the pits, closets, and institutions of enlightened societies everywhere. But there is a growing consciousness among us. . . . Because there is always an underground. Notes get passed among survivors. And the notes we are passing these days say, "There's power in difference. Power. Pass the word." Culture. It's about passing the word. And disability culture is passing the word that there's a new definition of disability and it includes power. (Wade, 1994)

LEGISLATIVE AND SOCIAL POLICY INITIATIVES EXPERIENCED BY DISABLED PEOPLE

The history of the disability rights movement has culminated in several key pieces of legislation that reify the values and rights of the movement. It is critical that occu-

FIGURE 62.2 Symbols of disability identity, power, and pride. (Sources, from left to right: ADAPT, 2006; Triano, 2007; MadPride, 2007).

pational therapists be informed about this legislation and stay abreast of changes to it in reauthorizations, as this information is essential to advocacy. Table 62.2 summarizes many of the primary social policies and legislation within the United States that influence the rights, choices, and control of disabled people. They correspond to major areas of societal participation (e.g., transportation, work) that also represent ongoing areas of disability activism to further increase societal opportunities. Following is a brief overview of these policies, legislation, and systems:

- **Rehabilitation Act of 1973, Section 504:** A federal act that prohibits discrimination on the basis of disability in programs conducted by federal agencies, in programs that receive federal financial assistance, in federal employment, and in the employment practices of federal contractors. Section 504 states that "no qualified individual with a disability in the United States shall be excluded from, denied the benefits of, or be subjected to discrimination under" any program or activity that either receives federal financial assistance or is conducted by any executive agency or the U.S. Postal Service. Each federal agency has its own set of Section 504 regulations that apply to its own programs. Agencies that provide federal financial assistance also have Section 504 regulations covering entities that receive federal aid. Requirements common to these regulations include reasonable accommodation for employees with disabilities, program accessibility, effective communication with people who have hearing or vision disabilities, and accessible new construction and alterations.

- **Individuals with Disabilities Education Act (IDEA):** A federal program that provides funds to states and local education agencies (school districts) to support education for children with disabilities ages 3 to 21 years and supports early intervention services for children from birth to age 3 years. IDEA provides guidelines and protections for children to ensure their right to a free and appropriate public education. The principle of the law is that children with disabilities should not be denied the opportunities that are offered to everyone else; everyone gets access to public education, and therefore children with disabilities should have the same access. School

districts are obligated to prepare and implement an Individualized Education Program (IEP) for each disabled child that is designed to meet the child's unique needs.

- **Americans with Disabilities Act of 1990 (ADA):** A comprehensive federal civil rights law that provides protections to individuals with disabilities similar to those provided to individuals on the basis of race, color, sex, national origin, age, and religion. It guarantees equal opportunity for individuals with disabilities in public accommodations, employment, transportation, state and local government services, and telecommunications. There are five titles under the ADA:

  Title I: Employment. Prohibits discrimination in all aspects of the employment process including recruitment, hiring, retention, and benefits of employment. Private employers with 15 or more employees and public employers with one or more employees are covered.

  Title II: State and Local Government. Prohibits discrimination in all programs and services offered to the public and requires that all facilities where programs and services are delivered be readily accessible to and usable by people with disabilities, including transportation.

  Title III: Places of Public Accommodation. Prohibits discrimination in the delivery of goods and services by places of public accommodation, including architectural accessibility and effective communication.

  Title IV: Telecommunications. Requires access to the telecommunication services provided by private telecommunication companies (e.g., relay services).

  Title V: Miscellaneous. Provisions for nondiscrimination in areas including insurance, retaliation based on exercising rights under the statute, availability of attorney fees, and more.

- **Help America Vote Act (HAVA):** A federal law that was enacted in 2002 to reform elections management and voter registration nationwide. The following issues are covered by HAVA:

  1. The proper operation and maintenance of voting systems and technology

TABLE 62.2   IMPORTANT POLICIES AND LEGISLATION CORRESPONDING TO MAJOR AREAS OF SOCIETAL PARTICIPATION AND OCCUPATIONAL THERAPY PRACTICE

	Section 504	I.D.E.A.	ADA	HAVA	Medicaid/ Medicare
Transportation	Requires transportation systems owned/operated by entities that receive federal financial assistance to be accessible	Requires appropriate transportation services to be provided to students with disabilities	Requires all public and the majority of private transportation systems to be accessible to individuals with disabilities		Provision of transportation for medically related services
Employment	Prohibits discrimination against qualified individuals with disabilities in all aspects of employment		Prohibits discrimination against qualified individuals with disabilities by private employers of 15 or more employees and public employers with 1 or more employees		
Education	Requires entities that receive federal financial assistance to ensure equal access through architectural accessibility and provision of reasonable accommodations in K–12 and post-secondary education	Requires provision of a free appropriate public education for children with disabilities in the least restrictive environment	Prohibits discrimination by public and private educational entities including architectural accessibility, provision of reasonable accommodations. And effective communication		
Voting	Requires entities that receive federal financial assistance to ensure equal access, including architectural accessibility, provision of reasonable accommodations, and effective communication		Requires nondiscrimination in voting as a program of state and local government	Requires equal access to voting facilities and the voting process	

TABLE 62.2   IMPORTANT POLICIES AND LEGISLATION CORRESPONDING TO MAJOR AREAS OF SOCIETAL PARTICIPATION AND OCCUPATIONAL THERAPY PRACTICE   *Continued*

	Section 504	I.D.E.A.	ADA	HAVA	Medicaid/ Medicare
Housing	Requires entities that receive federal financial assistance to ensure nondiscrimination in housing, including construction of accessible housing units and reasonable modification of policy and procedure		Requires transient housing (i.e., hotels/motels, dormitories, social service housing) to be constructed in accordance with the ADA accessibility guidelines, reasonable modification of policy and procedure, and effective communication		Provision of institutional care and/or use of available (state by state) Medicaid Waiver Program to finance community based placement. May be used by states to meet their nonsegregation obligations under the Americans with Disabilities Act
Health care	Nondiscrimination in the provision of medical services offered by entities receiving federal financial assistance, including architectural accessibility, reasonable accommodations, and effective communication		Nondiscrimination in the provision of medical services, including architectural accessibility, reasonable accommodations, and effective communication		Financial support of basic medical services (dental, skilled nursing services, etc.).
Community Participation	Nondiscrimination in programs and services offered by entities receiving federal financial assistance including architectural accessibility, modification of policy and procedure, and effective communication		Nondiscrimination in access to goods and services offered by public and private entities, including architectural accessibility, modification of policy and procedure, and effective communication		Community Based Waiver Program can be used to support non-medical services that enhance quality of life (e.g., environmental modifications)

2. The rights of voters to cast provisional ballots, the proper processing and counting of those ballots, and how provisional voters can determine whether their votes were counted and, if not, why not

3. The nondiscriminatory application of HAVA's identification requirement for certain voters who register by mail

4. Identifying and assisting voters with disabilities, including psychiatric disabilities, in order that such voters can participate fully in the voting process independently and privately

5. The rights of minority language voters to receive language assistance at the polling place

◆ **Medicare:** A federal health insurance program for people age 65 years or older. Certain people younger than age 65 can qualify for Medicare too, including those who have disabilities and those who have permanent kidney failure or amyotrophic lateral sclerosis (Lou Gehrig's disease). The program helps with the cost of health care, but it does not cover all medical expenses or the cost of most long-term care. Medicare is financed by a portion of the payroll taxes paid by workers and their employers. It also is financed in part by monthly premiums deducted from Social Security checks. The Centers for Medicare & Medicaid Services (CMS) is the agency in charge of the Medicare program. Medicare has four parts:

1. Hospital insurance (Part A), which helps to pay for inpatient care in a hospital or skilled nursing facility (following a hospital stay), some home health care, and hospice care

2. Medical insurance (Part B), which helps to pay for doctors' services and many other medical services and supplies that are not covered by hospital insurance

3. Medicare Advantage (Part C), formerly known as Medicare + Choice plans, which is available in many areas. People with Medicare Parts A and B can choose to receive all of their health care services through one of these provider organizations under Part C.

4. Prescription drug coverage (Part D), which helps to pay for medications doctors prescribe for treatment

◆ **Medicaid:** A federal/state entitlement program established under Title XIX of the Social Security Act to pay for medical assistance for certain individuals and families with low incomes and resources. It is a cooperative venture funded jointly by the federal and state governments to assist states in furnishing medical assistance to eligible needy individuals. Medicaid is the largest source of funding for medical and health-related services for America's poorest people, including people with disabilities. Within broad national guidelines established by federal statutes, regulations, and policies, each state establishes its own eligibility standards; determines the type, amount, duration, and scope of services; sets the rate of payment for services; and administers its own program. Medicaid policies for eligibility, services, and payment are complex and vary considerably, even among states of similar size or geographic proximity. Thus, a person who is eligible for Medicaid in one state might not be eligible in another state, and the services that one state provides can differ considerably in amount, duration, or scope from services that are provided in a similar or neighboring state. In addition, state legislatures may change Medicaid eligibility, services, and/or reimbursement during the year. The Social Security Act authorizes multiple waiver and demonstration authorities to allow states flexibility in operating Medicaid programs. Each authority has a distinct purpose and distinct requirements. The waiver that is most commonly used by people with disabilities is the Home and Community-Based Services Waiver. This program allows for the waiver of Medicaid provisions to allow long-term care services to be delivered in community settings. This program is the Medicaid alternative to providing comprehensive long-term services in institutional settings.

Despite the existence of this disability and civil rights legislation, the DRM continues to face many important social policy issues and challenges to advancing the equality of disabled people. The level of sheer desperation in parts of the disability community continues to be astounding. More than 1.8 million people with disabilities remain isolated in nursing homes and institutions. The minimal income supports available for people living on Social Security condemn people with disabilities to abject poverty. Sheltered workshops remain an established system to address unemployment among disabled people at wages much lower than the already low minimum wage. Transportation is difficult for many disabled people, given that there are few lift-equipped over-the-road buses in the nation's bus fleet. In many cities, para-transit systems are consistently late, require advance notice to book, have increasingly limited budgets, and suffer frequent service cutbacks; in rural areas, such systems often are not available at all. According to the National Council on Disability (NCD), other social policy areas that have high priority among disabled people include access to high-quality health care, education, work, telecommunications and assistive technologies, voting rights, parenting rights, euthanasia/assisted suicide, and sexual identity and freedom (NCD, 2006a & b). Every single day people with disabilities face social policy issues. To illustrate what the DRM is doing to address ongoing isolation, discrimination, and impoverishment, this section will focus on one key social policy example: that of community living rights that cut across policies of long-term care, housing, access to services, and provision of community-based supports.

Long-term care (LTC) is an area of rapidly evolving change in concept, policy, and practice. As recently as 50 years ago, home care was mostly seen as a family responsibility with state-run institutions filling in where families were unable or unwilling to respond. Although "Homes for the Feeble Minded" "County Farms," and

"Institutions for Mental Disease" were at first seen as reform, it was not very long before journalists and whistle-blowers were exposing the abuse and neglect that were common in these places. Despite this exposure, they continue to exist in various forms or are being replaced by other institutions such as nursing homes and intermediate-care facilities.

In 1965, Medicare and Medicaid were created, and the social policy for providing LTC changed. While the state-operated institutions continued to be funded, the private nursing home industry began to also widely expand as large sums of Medicaid dollars became available to place lower-income people into a system that had been previously used by private pay middle- and upper-class citizens. The medical system also played a role in convincing families that all parties were better off when disabled family members were placed in institutions, such as nursing homes, citing benefits of health care access, safety, and socialization. Existing research on nursing homes has documented abuse, neglect, crime, and rapid declines of quality of life and health that would challenge these assertions (DePoy & Werrbach, 1996; Henderson, 1995; NCD, 2003, 2005a, 2006b; Wright, Grofein, & Owens, 2000). At the same time, emerging research on community-based alternatives has pointed to the high meaning of aging in place in the community and the positive outcomes of home and community-based waiver programs that provide supports to live in community settings on emotional and physical health and well being (CMS, 2007a; NCD, 2003, 2005a, 2005b, 2006a, 2006b). Despite this research, the struggle to rebalance LTC toward community-based alternatives continues, in large part because of the strength of the multi-billion-dollar nursing home and institutional industry and its political lobbies.

Some of the first steps for effecting a paradigm shift in LTC involved advocating for the creation of new consumer-directed models and use of nonprofessionalized personal assistant services. The many forms of alternatives to institutional care are known as home and community-based services. Critical steps in making this change in LTC social policy included the following:

1. The establishment of the Berkeley CIL with its experimentation with personal assistant services that resulted in the funding in 1980 of a national network of independent living centers as a base to build a broad advocacy campaign and recreate community-based alternatives.
2. The formation of People First, a national organization for and controlled by people with intellectual disabilities that was instrumental in filing court challenges to the forced institutionalization of their people.
3. The book and film (based on the book) *One Flew Over the Cuckoos Nest* and other literature, art, and films that promoted the liberation of people in LTC institutions in the public media, which also resulted in changes in public attitudes about disabled people.

4. The passage of the Americans with Disabilities Act, which defined unwanted institutionalization as a violation of the civil rights of people with disabilities.
5. The national campaign by ADAPT, a national disability rights organization, to pass legislation called MiCASSA (Medicaid Community Attendant Services And Supports Act), which called for mandated funding of home and community-based services at least as strong as the mandate to fund nursing homes and institutions. If passed, MiCASSA would allocate significant amounts of money to help people move from institutions to home and community settings and allow people real choice in where they would receive their long-term care.
6. The *Olmstead* decision, a Supreme Court case interpreting the Americans with Disabilities Act, which asserted that people with disabilities have a right to live in the most integrated setting that is appropriate to their needs. This decision has ignited activists and led to widespread systems change.

The rally across the street from the Supreme Court at the time the *Olmstead* case was being argued was one of the largest DRM rallies ever held in Washington, D.C. Strikingly, this activism resulted in many states changing their opinions to side with the DRM on *Olmstead* least restrictive placement rights. However, the political systems in many states are still skewed toward an institutional bias; approximately 70% of LTC spending nationally still goes to segregated institutional settings such as nursing homes, state mental hospitals, nursing homes specific to people with psychiatric disabilities, and intermediate-care facilities specific to people with intellectual disabilities (CMS, 2007a; NCD, 2003, 2005a, 2005b, 2006a, 2006b). Despite this institutional bias, many important steps were taken at the federal level to support *Olmstead* implementation under the umbrella policy and executive directive of the New Freedom Initiative. These actions included the following:

1. The CMS sent policy letters to all state Medicaid directors elaborating on what the states should be doing to be in compliance with *Olmstead* and to rebalance LTC financing toward community-based options.
2. CMS System Change Grants allowed states to apply for grant money that could be used to create home and community alternatives to segregated settings, to strengthen existing home and community infrastructure, and to experiment with consumer-directed programs to support community living. Some states have used the grants well and developed models that other states could learn from (see CMS, 2007b).
3. In 2006, CMS appropriated $1.75 billion to establish Money Follows the Person (MFP) Demonstration Projects. The MFP concept is one of the operative principles of the federally proposed MiCASSA legislation, which calls for consumer-directed management and

choice in supports with the money that would otherwise have been spent on institutional placement to "follow the person" to the community. Since MFP was implemented in Texas, more than 10,000 people have left nursing homes to live in the community with supports; this represents strong evidence for systems change (CMS, 2007a).

Now the battle for home and community-based LTC is specifically focused at the state level, in which policies and outcomes vary widely across the country. There are a few states such as Tennessee that still have almost no home and community-based service programs. They can be contrasted with other states such as Oregon, Washington, and New Mexico that spend more than 50% of their LTC dollars on home and community-based services, including access to occupational therapy, assistive technology, and environmental modifications.

LTC is an issue that the DRM is winning, albeit slowly. The DRM is also closely collaborating to apply the same philosophy of least restrictive, community-based living and consumer direction with senior citizens. Activists face a government that is trying to drop its responsibility to fund LTC for people who do not have resources to purchase it in the private marketplace. Cuts to Medicaid—and therefore to states—are likely to further hinder progress. Nursing homes, other private providers, and unions will intensify their efforts to hold onto the lion's share of the funding. Change will require greater political empowerment by disabled people and senior citizens as a coalition to counter this political power.

Ongoing policy issues still include the need to build stronger home and community-based infrastructure as baby boomers age. There is an increasing need to provide enough affordable, accessible housing that supports aging in place and can meet the demand that comes with increasing numbers of people moving out of institutions. New models of services that support consumer control and meet the needs of people with cognitive and psychiatric disabilities also require creative exploration, demonstration, and study. Occupational therapists can play key roles in these policy initiatives, as allies in the activism movement, and as contributors in the design, implementation, and evaluation of new community living environments and programs in collaboration with the disability and aging communities.

HOW MODELS OF DISABILITY, HISTORY, AND POLICY INFLUENCE INTERVENTION

Now that you have learned about disability models, disability rights history, key legislation, and some of the major social policy issues that affect disabled people as a minority group, the next step is one of praxis, that is, reflecting back on what you have learned and applying it to your everyday practice. Following are some key concerns and strategies to consider in trying to integrate social and minority group model approaches throughout the process of occupational therapy assessment and intervention.

◆ **The environment and contextual reasoning:** Throughout the assessment and intervention process, critically reflect on how the social, political, economic, and cultural environments are influencing an individual's choice, control, motivation, and self-efficacy. Embed environmental questions and discussions into your assessment, including asking whether a person has access to economic resources to engage in certain activities, whether the person is given opportunities and supports to engage in these activities, or whether the person is aware of supports such as waivers, vouchers, home services, adapted transportation, and assistive technology. Can you equally emphasize contextual reasoning, rather than focusing solely on your "clinical reasoning" during intervention; that is, can you collaboratively plan, strategize, and negotiate how the environment and the systems within it influence a person's occupational choice and control?

◆ **Consumer direction:** To what extent are you supporting consumer direction throughout the rehabilitation process and in key decision making beyond it? As a profession, we consistently voice our commitment to client-centered practice. However, research has shown that in reality, this often does not happen, and the therapist instead leads the therapy process (Bowen, 1996; C. Brown & Bowen, 1998). In contrast, the policy trend within the disability and senior activism communities is to move away from professional-directed services and to promote consumer-directed choice and control with supports to do so. What are you doing as an occupational therapist to promote not only client-centeredness, but also consumer direction? For example, can you incorporate time into your intervention so that the consumer can practice directing his or her own care, such as directing a personal attendant in how to support and communicate with him or her, practicing how to communicate with a rehabilitation counselor to justify the need for supports to live in the community, and applying for and managing a menu of community-based supports across different systems (e.g., medical, medication, housing, attendant care, home modifications). These are all occupational performance activities that disabled people have identified as critical to community living.

◆ **Risk with dignity:** A large part of occupational therapy involves determination of safety, as in safe performance of everyday activities. For example, a person might be deemed too unsafe to go back home and instead recommended for nursing home placement. In contrast,

disabled people are bringing to the fore the concept of risk with dignity, that is, being able to take risks as the rest of society does and focusing on providing environmental supports to minimize the risk. What can you do as an occupational therapist to strategize environmental supports that would enable a person to live in the community or the least restrictive setting of his or her choice? Can you anticipate potential safety risks and work to problem-solve these in the natural home and community contexts? For example, in a home-based environmental intervention program for older adults with Alzheimer's disease and their spouses, the occupational therapist did a full home audit; collaborated with the consumer/caregiver to identify any potential safety issues; and used a problem worksheet to list the issues, assign next steps to work on between occupational therapy visits, and revisit the situation to see what worked or did not work (see examples from Corcoran & Gitlin, 1992; Gitlin, Corcoran, Winter, Boyce, & Hauck, 2001). Such a program could support people to stay in their homes and communities of highest meaning for as long as possible. Another way to do this is to work with the consumer to advocate for needed supports for personal safety and security, such as personal attendants, community safety check-ins, environment modifications, and assistive technology such as intercoms and emergency call systems.

♦ **Disability identity:** How are you framing disability in every interaction with disabled people? Do you talk about people as diagnostic labels (e.g., refer to people as *paras, quads, stroke, LD, TBI,* and the like) or as deficits (e.g., *your bad arm* or *affected arm*) versus respecting the individual's personhood and dignity? Do you treat disability as a negative deficit within the person that needs to be remediated, compensated for, or normalized? Can you instead frame disability as difference, as a different way of being and of doing that is significantly influenced by the environment? Can you link consumers with other disabled people who have been through a similar disability experience who can serve as positive role models and mentors on how to own difference and maintain a high quality of life? For example, can you link someone who is new to disability with disability advocates and peer-mentoring activities at a local CIL or start a peer-mentoring program at your own facility by inviting prior clients back to serve as mentors to new clients? Some community programs have also started intergenerational groups in which adults with disabilities mentor youths with disabilities or disabled youths mentor older adults who become disabled later in life.

♦ **Social interdependence:** How are you framing "success" in the rehabilitation process? Are you focusing on functional independence, that is, cognitive and physical ability to perform activities by oneself? Many

disabled people, and feminist scholars as well, would challenge this emphasis on individual independence. Instead, they point to the importance of social interdependence, that is, relying on each other and on other people and, in turn, giving back and supporting others within reciprocal relationships (Magasi & Hammel, 2004; Morris, 1992). This concept of interdependence and how to support it is critical for many disabled people. For example, during therapy, are you talking with consumers about prioritizing energies and options to use other supports and people, such as family, personal attendants, and homemakers? Are you strategizing with consumers about how to assertively ask for support without feeling helpless or dependent? Are you offering consumers information about options for support in the community, such as where to look for qualified personal attendants; how to hire, fire, and train them; and systems to fund them in the home, such as home and community-based waiver programs and CIL attendant pools?

♦ **Social participation, support, networking, and capital:** The concept of social interdependence extends to many other areas of social participation. Active engagement and participation in social relationships and membership in any social community are increasingly being identified as positively contributing to emotional and physical health outcomes and well-being (Barlow & Harrison, 1996; Barlow & Williams, 1999; Fawcett et al., 1994; Hernandez, 2005; Magasi & Hammel, 2004). Yet we often spend little if any time on these social issues within therapy, assuming that people will work on them after therapy or that it is not our role to do so. However, we also know that many disabled people are socially isolated and report that they are not participating in social opportunities as much as the rest of society is (National Organization on Disability/Harris, 2004). Strategizing ways to "be a part of," to express and strategize social and intimate relationships, and to develop a social network to meet different needs, such as emotional, instrumental, and thriving needs (Magasi & Hammel, 2004), is a valid focus for occupational therapy, given our emphasis on meaningful engagement as well as research pointing to the benefits of this social engagement. As an occupational therapist, you can help to facilitate this social network development by using assessments such as a role inventory or a social network map so that people can identify what their network looks like now versus what they want it to be and then working with consumers to link to community groups and organizations in which they can begin to create, or re-create, their networks of choice. For example, a consumer might identify the importance of participation in a religious community, and you as an occupational therapist could support the consumer in exploring how to do this and how to work with that community to make

it a supportive environment for people with disabilities. As another example, you might invite in peer mentors during therapy sessions so that clients can meet other people with disabilities and determine whether they might want to establish a social network with the disability community.

◆ **Your role and power as a professional:** Are you aware of your own power as a professional therapist? Many therapists would reply that they work within a system that dictates what they can do and that they really do not have much power themselves. However, when you reflect on it, you have a great deal of power as a rehabilitation professional. You have power in determining whether a person is qualified to receive therapy services and the type and extent of therapy the person will receive, what goals are focused on in therapy and how therapy time is spent, discharge and transition planning and whether people are aware of and referred to follow-up services, information access and awareness of options and choices people have and how to advocate for needed supports, whether assistive technology is recommended and funding of it, and so on. You can passively abdicate your power, or you can use it creatively to be an advocacy ally with disabled people throughout and beyond the rehabilitation context.

◆ **Advocacy as a life role and the development of an advocacy network:** It is critical that occupational therapists recognize the importance of advocacy as a life role and work collaboratively with consumers to develop advocacy skills (including how to access information and systems to advocate for supports). An equally important occupational skill is the development of an advocacy network of support that people can count on when they need it or when self-advocacy is too tiring or not enough to address the bigger societal barriers they are facing. For example, you might work with a consumer to identify a primary personal attendant who will support the consumer in his or her everyday activities as well as several emergency backup strategies (e.g., signing up for an attendant pool at a local CIL or having the phone number of an attendant service if the person's attendant does not show that day). Just connecting a person with community advocacy groups, such as CILs, the Americans with Disabilities Act centers, and Protection and Advocacy or Ombudsman programs (available across the country), can offer the person an important source of support on which he or she can call when it is needed rather than having to try to find them during a crises or emergency. These groups can also link consumers to civil rights and legal assistance if needed, which can be particularly critical for someone who is living alone or in an institution.

◆ **Peer mentoring, support, and advocacy:** Recognizing your limitations and role as an occupational therapist is also important. Are you serving as a liaison or ally in linking consumers with other disabled people who can share their experiences and strategies or with disability-led community groups such as CILs that offer peer counseling and mentoring? Increasingly, research is showing the positive benefits of peer mentoring and social learning in supporting emotional and physical health, well-being, community living management, and advocacy skills (Balcazar et al., 1991; Barlow & Harrison, 1996; Barlow & Williams, 1999; Garcia, Kramer, Kramer, & Hammel, 2007; Hernandez, 2005; Lorig, Ritter, & Plant, 2005).

◆ **Collective and empowered consciousness:** One of the most powerful ways to develop self-advocacy is to become involved in collective activism; this is relevant for disabled people and for occupational therapy as a profession. The disability rights community offers many opportunities for social action on behalf of disabled people as a minority group. Do not assume that you need to already have self-advocacy skills to participate in these actions; instead, participation in such collective activism can lead to the development of self-advocacy. Above and beyond fighting for rights, however, comes the added benefit of empowered consciousness when one becomes a part of a shared community that is creating disability identity, culture, community, and pride. Exposing people, including yourself, to this social movement and to the culture and art that are produced within it can be a transformative experience and, in turn, can build community and power from within.

INCORPORATING DISABILITY EXPERIENCE INTO PRACTICE, RESEARCH, AND ADVOCACY: EXAMPLES FROM PARTICIPATORY ACTION RESEARCH

In this final section, we focus on opportunities to promote empowered consciousness via participatory action research. The disability community's history of interaction with researchers has led the community to distrust or be wary of the research process because of mistreatment, continued perpetuation of concepts of incompetence, or irrelevance of research findings and outcomes to their everyday lives (Kitchen, 2000; Zarb, 1992). As a result, the disability community has called for participatory and emancipatory research that is conducted by people with disabilities and that empowers people with disabilities (Zarb, 1992).

One way in which researchers and practitioners can engage in research that is more empowering is to collaborate with disabled people and disability-led community groups in participatory action research (PAR). PAR is an approach rather than a specific design or set of methods (Tewey, 1997). It involves a dynamic collaboration

This is a story about a PAR project that was a collaboration between the Chicago chapter of People First, the staff of El Valor of Chicago (a local community agency offering services to people with intellectual disabilities), the Rehabilitation Research and Training Center on Aging with Developmental Disability (with Joy Hammel as principal investigator), and Edurne Garcia, John Kramer, and Jessica Kramer, doctoral students in the Disability Studies Program at the University of Illinois at Chicago. People First, run by people with disabilities, is an international movement that promotes the self-advocacy of people with disabilities. The mission of People First of Illinois is as follows:

> To work together for justice by helping each other take charge of their lives and fight discrimination. It teaches us how to make decisions about choices that affect our lives so we can achieve our independence. The way we learn to become self-advocates is by supporting one another, and helping each other gain confidence in ourselves to speak out for what we believe. (http://www.peoplefirstofillinois.org/)

The Issue

Community agency staff members, who were people without disabilities who provided support to the Chicago chapter of People First as supporters, expressed concerns that people with intellectual disabilities in the group were not leading it or realizing self-advocacy and community advocacy empowerment goals within the group and the larger community. Group members also wanted to become more involved in advocacy and community participation activities.

The Community-Building Process

Disability studies and occupational therapy practitioners and researchers approached People First as a group to do a PAR project together to work on these goals of raising the critical awareness of the group in the broader community and developing the empowered consciousness of the group itself. The focus was placed on transferring power from agency staff to group members with intellectual disabilities. This focus is aligned with the concept of empowerment as defined by Fawcett and colleagues (1994) as a process by which people gain some control over valued events, outcomes, and resources of importance.

Participatory Strategies

A number of participatory strategies were used to recognize and tap into the wisdom and experience of the members with intellectual disabilities and to locate members in positions of power within the group. Rather than imposing preset therapeutic goals, the researchers observed and participated in several People First meetings to evaluate the group dynamics and identify existing strengths and concerns within the group. The People First members then engaged in a participatory focus group discussion that sought to better articulate why they liked being People First members, how they made decisions in the group, and what activities they would like to do as a group. To facili-

tate the participation of members, various strategies were used, including the use of a circular room arrangement in which participants face each other (with staff positioned outside the circle), round-robin questioning in which each person in the circle takes a turn in offering his or her perspectives, passing a microphone to designate who has the floor, the use of a timer, and the inclusion of many pictures to support the generation of ideas and concrete action plans.

Actions and Lessons Learned

This group discussion resulted in two main actions. First, the members identified that many decisions and actions were carried out by staff supporters rather than members. Second, the members identified that they would like their community to know about People First and that they wanted to publish a newspaper as a first step toward this goal. Many participatory strategies were introduced to support these actions. For example, the group used pictures and questions (such as "what do we want" and "what do we need to do") to create a picture-based logic model, or visual process guide, to guide the newsletter creation (see Figure 62.3). (Additional examples of logic models and how to use them in occupational therapy can be found in the work of Letts and colleagues 1999.) Group members took turns generating names and ideas for the newsletter, and voted by placing a sticker next to their favorite name. They used the same strategies to break down tasks and to select positions (see Figure 62.4).

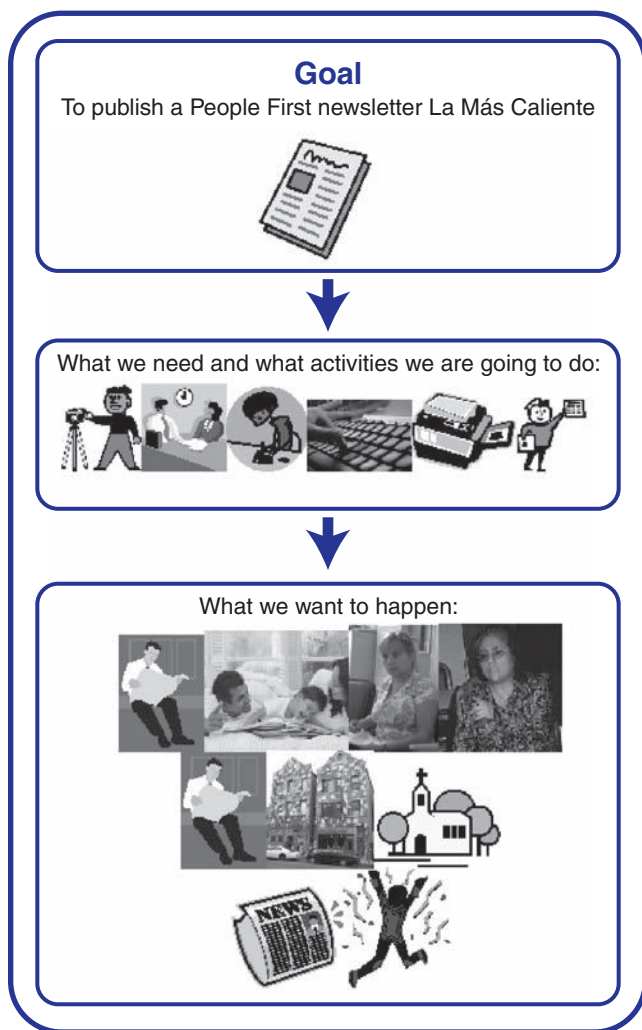
Members then started to apply these strategies at every group meeting, slowly assuming control on a wider basis. To facilitate the group's reflection and growing empowerment, a group evaluation checklist was developed. Members determined who had carried out each task during each meeting. The members decided that each of them would pick one task they could assume control over and then used the group checklist after every meeting to check their progress. These strategies supported not only self-advocacy, but also group determination and power. Self-advocacy did not need to be taught on an individual basis or required as a prerequisite to group participation but could be learned and built on via a social group approach, with the added benefits of increased community activism and group-empowered consciousness. The other lesson that the group members learned was that there are many ways to participate and that functional independence was not the goal so much as "being a part of" and being a valued member of the group. To support this active participation, information needed to be offered in multiple accessible formats that could be used and owned by people with intellectual disabilities, and the professionals needed to step back, reflect on their power, and scaffold the empowerment of group members. (For more information on the project and resources developed, see Garcia et al., 2007.) Many of the participatory strategies that are featured in this example could also be applied in community-based OT practice and collaborations.


FIGURE 62.3 Picture-based logic model developed by People First group members to define their social group, membership in it, and actions they most want to do and direct.

FIGURE 62.4 Examples of action research strategies to promote access to information, decision making, and control within the People First group and empowerment activities. Top: Flipchart of tasks for newsletter with picture voting on who will take lead on each task. Bottom: Use of picture-based meeting agendas developed by participants so that they can run their own meetings.

between researchers, community partners, disabled constituents, and key stakeholders using an agenda that is driven by social issues that have been identified from within the community. PAR can result in shared knowledge that the community can use as evidence to effect social action change and to build community and empowered consciousness from within (Reason & Bradbury, 2001). It is research that is done by and with disabled people rather than for them or on their behalf. Given this applied, community-driven focus, PAR can be a useful framework for occupational therapy collaborative programming (Taylor, Braveman, & Hammel, 2004) as well as a basis for collaborating on systems change to improve participation opportunities in society. The case study provides one example of a collaborative PAR project that focused on disability rights, social justice, and empowered consciousness building with a disability community.

SUMMARY

This chapter has focused on exposing you to different ways in which you can rethink disability, specifically focusing on the perspectives, insights, and experiences of disabled people and disability advocacy organizations. Many of these perspectives may challenge you as an occupational therapist to critically examine your own power and influence as a health care professional. By understanding the history and philosophy of the disability rights movement and the sociopolitical and social justice issues that disabled people experience as a collective social group, you can begin to reframe your own practice as an occupational therapist to focus on these environmental barriers

BOX 62.2

SUMMATIVE LEARNING ACTIVITY

Take out a piece of paper again, and reflect back on your replies to the questions at the start of this chapter. How would you change your responses? How would you change your actions as an individual, as a member of society, and as an occupational therapist?

and incorporate these visions of independence, participation, citizenship, and disability identity, culture, and community building. Occupational therapists can play a critical role in shaping a person's disability experience. By serving as a facilitator and a liaison to disability groups and organizations, you can link disabled people to critical social networking and community-building opportunities. By allying with disability groups and organizations and using participatory action strategies to do so, you can also work to effect change in policies and systems to improve societal opportunities and rights.

Therapists in Action: Examples of Expert Practice

> " The true expert, then, is someone who knows something of what lies beneath the surface of his or her practice, and spends time and effort not just understanding it but developing it further, and who can then talk about it more publicly too. "
>
> *Della Fish & Colin Coles*

School-Based Practice: Enabling Participation

MARY MUHLENHAUPT

Learning Objectives

After reading this chapter, you will be able to:

1. Discuss issues that occupational therapists consider to define a student's education needs and develop program plans.
2. Formulate reflective questions that are designed to contribute information to support a student's participation in the curriculum.

INTRODUCTION

Because occupational therapy services in schools are designed to enable students to participate in, and benefit from, a curriculum that prepares them for further education, employment, and independent living (Individuals With Disabilities Education Improvement Act, 2004), my practice in the schools focuses on the following:

1. The *student*—his or her motivations, interests, and functional performance in learner, friend, and player roles
2. The *curriculum*—its activities, materials, and instructional approaches
3. The *settings and situations* in which the student's school performance is expected or desired—both the human (adults and peers) and non-human environment (including physical, sensory, temporal, cultural, and legal aspects)

My work activity varies during any day. One morning begins with an impromptu meeting to discuss a teacher's concerns about one of her students. Then I go outside to the playground to complete part of an evaluation of a student who has just moved into the district. I then drive to the high school building to meet a student during her lunch period in the cafeteria. Together, we are working on ways in which she can gain independence to purchase her meal, eat at the table with her friends, and clean up

after herself, all within the allotted lunch schedule. She travels around the school using an electric wheelchair and communicates with a Dynamo®, an augmentative system. Later, I implement an afternoon language arts activity with a kindergarten teacher. I focus on specific writing and drawing tasks that reinforce the phonics elements the teacher introduces. By coleading this activity, I am implementing a whole-school approach that is designed to enrich available opportunities, reduce learning challenges, and prevent failure (Gartner & Lipsky, 2002).

Throughout my school-based practice, I use occupational therapy theory and knowledge about how children develop and learn, professional reasoning and evidence, and ethical and practice standards. In addition, education philosophies, federal and state education law and regulation, state and district learning standards and curriculum, and the culture and resources of the local district influence what I do each day. I will describe my work with Davey, an 8-year-old boy, to illustrate how an occupational therapist works in a school-based setting.

REFERRAL

Davey was referred for an evaluation by the district's Child Study Team (CST). As a result of previous recommendations I had made to the district administration to streamline the evaluation process and verify educationally relevant concerns, Davey's teacher, Ms. Ray, completed a questionnaire when she initiated the evaluation request to the CST (Box 63.1).

The referral information gave me an idea of Davey's teacher's expectations as well as the challenges he was having in school, so my evaluation already had a necessary direction. A telephone interview with Davey's mother gave me an opportunity to learn her perspectives and priorities (Box 63.2). Knowing about Davey's performance over time, how he functioned in less structured and small-group or solitary situations, how he managed certain tasks at home, and what his parents, who know him best, saw as his strengths and needs would help me to individualize my evaluation.

OCCUPATIONAL PROFILE

Davey is an 8-year-old student in a third grade general education program at his neighborhood public school. He likes school, especially gym and recess. His academic strengths are in math and science. His reading skills are below grade-level expectations. His written work is often incomplete and difficult to read, and homework assignments are completed inconsistently. During classroom free choice time, he chooses games on the computer. He stumbles into things in the classroom, hurries, and trips and falls in the cafeteria and on the playground. He is distracted during many classroom routines, and Ms. Ray frequently gives him verbal reminders to refocus him back to his assignments.

Davey lives with his parents, who see him as a bright boy who needs to develop his self-control and motor coordination in order to complete his schoolwork with higher levels of independence. He needs continued prompting from his mother to stay at the kitchen table and complete his homework. He fidgets and drums with his pencil or goes off to play in the family room. Davey does not seem

---

BOX 63.1

TEACHER QUESTIONNAIRE FOR SCHOOL-BASED OCCUPATIONAL THERAPY REFERRAL

1. What is the focus of your classroom curriculum?
General education, 3rd grade. Instructional approaches, methods, and materials have moved from the tactile-kinesthetic approaches that were emphasized in the primary grades. More emphasis on listening and following series of directions. Independent work and cooperative group work periods, initiating requests for assistance when needed.

2. How is this student managing within that curriculum?
Davey is a bright student who is very active. His written work is sloppy. Behavior difficulties interfere during parts of the day, especially when he needs to work quietly or in a small group. He pokes peers, talks about unrelated topics, asks for permission to sharpen his pencil, go to the boys'

room, etc. He is distractible and needs reminders to focus and complete assignments. Sometimes he needs extra time to settle down after "free choice" time or recess.

3. What has been tried to increase this student's participation in the curriculum? What have been the results?
Extra attention from the teacher, verbal reminders and cues, his desk is moved near to mine so I can keep an eye on him. More time in a quiet area of classroom (such as the book corner) after recess. Tried a sticker chart to motivate him to pay attention. None of these things are obviously successful. He goes to the resource room to support language arts and reading curriculum.

EXAMPLES OF PARENT INTERVIEW QUESTIONS FOR THE OCCUPATIONAL THERAPY EVALUATION

- ◆ What would you like to see Davey accomplish this year at school?
- ◆ What about Davey's performance in school and during schoolwork is of most concern to you?
- ◆ What does Davey enjoy doing at home or during free time?

to need much sleep; he has a difficult time falling asleep and wakes early each morning. He recently joined the soccer team in his community, something that his parents hope will encourage his motor skills while giving him a chance to run around and "blow off some steam."

EVALUATION PROCESS

Federal regulations determine that a school-based therapy evaluation needs to generate information that the team can use to understand the student's educational needs and plan an individualized program (IDEIA, 2004). The occupational therapist is focused on increasing competence in the student role and enabling the child to benefit from instructional activities (Muhlenhaupt, 2003). Davey was enrolled in the third grade general curriculum, a program that was already familiar to me. My next step was to learn more about the specific environments and situations in which Davey needed to participate and how he used the supports that were available to him. Several strategies accomplished this purpose:

- ◆ My direct observation of Davey's participation (both quiet, independent work and movement opportunities; solitary and group activity)
  – In the classroom during seatwork assignments (15 minutes in the classroom, beginning when the teacher gave the group instructions)
  – On the playground (15 minutes that included speaking with the recess aide about Davey's general activity during recess)
- ◆ Interview with the reading teacher to understand more about what her instruction included and how Davey functioned in the smaller group and quieter environment of the resource room
- ◆ Review of the amount and quality of Davey's finished written work completed in different settings
  – Ms. Ray provided sample homework assignments and spelling tests that Davey had completed prior to the

evaluation dates, along with samples that were representative of average work by other students in class.
- ◆ Review of Davey's educational file (social, developmental history)

While I was in the classroom for my initial observation, I asked Ms. Ray to rate Davey's performance during that time and to continue to do so during several classroom seatwork periods over the next few days, using a form I developed (see a completed form in Box 63.3). The data that Mrs. Ray recorded over nine different class periods confirmed variation in Davey's performance, his best performance being during math lessons, with lower ratings in language arts activity. When I looked further and examined these ratings against the daily class schedule, I noted that lower performance was common during classes that were held in the afternoon hours. I kept this reporting in my file and recorded the average rating over all periods (2 points) for use as a baseline against which to measure change once specific intervention strategies to enable Davey's participation were put into place.

DAVEY'S PERFORMANCE DURING ROUTINE SEATWORK ACTIVITIES

4: Completed entire task in time period, no help/reminders needed

3: Worked entire period, in seat, verbal reminders/ redirection only

2: Worked entire period, but out of seat, verbal reminders and redirected to seat and task—completed assignment

1: Worked part of period, out of seat, continued redirected to task—assignment incomplete

0: Refused to work, no product turned in

Date	Class period/task	Rating
9/12	Morning board copying	2
9/12	Reading book, answering questions on paper	1
9/13	Social studies: coloring maps	3
9/14	Science: lab activity with partner	3
9/14	Language arts workbook pages	1
9/14	Spelling test	2
9/15	Math worksheets	4
9/18	Math: puzzles and sets	4
9/18	Language arts: "write a story"	1

Referral concerns did not identify any performance limitations related to fine motor difficulties in school or at home, and my observations of his work in the classroom did not lead me to suspect fine motor difficulties were a factor in his performance. Therefore, standardized measures to rate Davey's fine motor functions according to those of his peers were not indicated in this evaluation.

ANALYSIS OF OCCUPATIONAL PERFORMANCE

On the basis of the procedures I had completed to this point, I concluded that Davey understood his teacher's directions and knew what he was supposed to do in the classroom. He had the essential perceptual and motor skills needed for performance. He did not have cognitive challenges or any apparent psychosocial factors that interfered with completing the assigned work or assuming expected levels of responsibility throughout the day. Aspects of the physical environment—his desk and chair size, the writing tools and paper he used—were appropriate. I suspected that more information about his sensory processing would help me to identify whether the behavior that affected his school performance could be attributed to his unique responses to sensory information. I selected both the Sensory Profile (Dunn, 1999) and the Sensory Profile School Companion (Dunn, 2006) to provide more information.

I also scheduled an assessment period outside of the classroom so that I could observe Davey's engagement in play and learning activities. I had him participate in table-top activities and noted how he used materials, organized his work space, approached tasks, and reacted when help was needed, along with his general attention and activity level over a period of sedentary work. Then outside, I encouraged him to explore on the playground and watched his pace and choice of activity. These procedures also gave me an opportunity to implement some trial interventions. I was able to see how he responded and therefore consider some specific modifications or accommodations that might support him throughout the routines of the school day.

PROGRAM PLANNING

When compared to those of other children without disabilities, Davey's Sensory Profile results indicated definite differences in vestibular and touch systems and multisensory processing of touch, body position, and movement. Davey looked for opportunities to experience movement and touch stimuli in many situations in the classroom and across the school day. He fidgeted in his seat, and he tapped on his desk with his pencils, rulers, hands, and fingers. He left his desk and chair frequently and without permission during classroom seatwork periods and chose multiple different movement activities on the playground. When interpreted from a sensory-processing perspective

(see Chapters 59 and 60), Davey's behavior suggested that he had a high response threshold for sensory information, particularly in movement and touch systems, with difficulty modulating his responses to this type of sensory information. His preference for touch- and movement-related sensory information and the apparent challenge he faced in matching his responses to environmental demands in different situations had particular significance for Davey. Now in third grade, he faced classroom routines that incorporated less active movement and an expectation for increased focus and independent work, compared to the primary grades. Because of the difficulty of balancing this sensory information, his system became overwhelmed. I saw Davey's behavior patterns as a means to help him cope when he faced situations that challenged his sensory preferences (Dunn, 1999). This perspective helped me to explain Davey's "distractible" behavior, fidgeting, and increased activity that interfered with his listening to directions and completing a variety of assignments and tasks during the day (see Box 63.4).

THE INDIVIDUALIZED EDUCATION PROGRAM TEAM PROCESS

Collecting all of this information about Davey's strengths and needs and using occupational therapy theory and principles to develop a program plan to increase his participation made up only part of my process. As a school-based

---

BOX 63.4   INITIAL HYPOTHESIS TO GUIDE DAVEY'S INTERVENTION

If:
Davey's fidgeting, out-of-seat behavior, illegible penmanship, and difficulty completing assignments

Is due to:
His nervous system's unique pattern of response to sensation and difficulty modulating between too much, sufficient, or insufficient responsiveness to touch and movement sensory experiences

Then:
Considering the touch- and movement-related sensory information/events/opportunities throughout the school day and implementing specific environmental accommodations will provide sensory experiences that match his nervous system's needs and will promote optimal levels of arousal, attention, and self-regulation for effective participation in school tasks.

therapist, I then needed to convey my findings to the Individualized Education Program (IEP) team for their consideration and decision making. Recognizing that team-generated goals are the foundation for a student's school-based support services (Giangreco, 2000), the IEP team reviewed my evaluation results in relation to Davey's educational goals. The group agreed that an occupational therapy service offered new and specific strategies to support Davey's participation in the curriculum. (Box 63.5 highlights some of the information from Davey's IEP.)

In accordance with accountability requirements that are part of the IEP process (Turnbull, 2005), we targeted educational outcomes and agreed on the need to collect data in the classroom to determine whether or not Davey's behavior changed once this intervention was implemented. In keeping with IDEA provisions to support a student through a program plan that is "only as special as necessary" (Giangreco, 2000), the team acknowledged that the occupational therapist's presence in the context of Davey's school routine would not be required for an extended period over the school year. That was reflected in the way in which occupational therapy was listed in Davey's IEP: "OT services, 2 hours/month during the first marking period and 1 hour/month during the 2nd marking period" was recorded in the "Related Services" section.

IMPLEMENTING INTERVENTION

Sensory integration theory (Lane, 2002) influenced my recommendation for the availability of specific types of sensory experiences within Davey's school and homework routines. I drew on evidence suggesting that information about a child's sensory profile can be most appropriately used to design activities and environments that match the child's sensory needs rather than to guide interventions to change the child to meet the demands of specific environments (Dunn, 1999; Williams & Shellenberger, 1994).

Helping Davey to stay in his seat, sit still, and get his work done was a priority. I believed that his need for movement contributed to his distractibility and out-of-seat behavior during the language arts curriculum, which was a challenge for him, and during the long afternoon block of in-classroom activity. As a part of my school-based service, one of my visits (sessions) was a scheduled meeting with Ms. Ray to help her understand how the sequence of different activities in the school day and the demands within those activities influenced Davey's attention and activity level. Together, we identified specific tasks that incorporated movement yet fit logically within the classroom routine, such as the job of "paper passer" or "office messenger" for her to use when Davey needed a movement break. We developed a simple three-point rating scale that she used over the next week to test out whether she was more satisfied with his in-seat behavior once he took advantage of these naturally occurring movement breaks (see Box 63.6).

Until now, throughout the day, Ms. Ray had been giving Davey repeated cues and using discipline in response to his inappropriate behavior. My goal was to help him to monitor and adjust his own behavior in a variety of situations. I had some previous positive experiences with several students who had similar needs when I used the Alert Program™ (Williams & Shellenberger, 1994) (see Box 63.7). I spoke to Ms. Ray and to Davey's mother about the program, explaining the absence of published

---

BOX 63.5

SELECTED INFORMATION FROM DAVEY'S IEP

◆ Present level of academic achievement and functional performance: Mathematics at grade level. Reading at 2.0 grade level. Cognitive and motor skills at age level. He finds reasons to get out of his seat and move around the room, needs reminders to attend to, and extra time to complete, written work; written seatwork rated at 50% legible, 60% completion rate.

◆ IEP annual goal that occupational therapy service supported: Language arts curriculum: Davey will write paragraphs (90% legible) that include a variety of sentence types; appropriate use of the eight parts of speech; and accurate spelling, capitalization, and punctuation to complete required third grade class assignments and homework.

◆ Specially designed instruction: Small-group instruction in structured reading program, inclusion of second grade level reading materials for classroom use, incentives to encourage work completion and legible written production.

BOX 63.6

TEACHER'S RATING SCALE FOLLOWING INTERVENTION IMPLEMENTATION

+1: Student performance/participation meets classroom expectations.

0: Student performance/participation has improved but does not yet meet classroom expectations.

−1: Student performance/participation is unchanged and does not yet meet classroom expectations.

BOX 63.7

ALERT PROGRAM™

The Alert Program™ uses an engine analogy to teach children, their teachers, and their parents ways to change how alert one feels. Individuals learn to choose strategies that help to adjust behavior when they feel their "engine" is in either low or high gear, obtaining a "just-right" engine level (alert, attentive, and ready to learn).

</td></tr>
</table>

evidence regarding the effectiveness of this approach and offering my opinion that was based on experiences with several other students. We agreed to give it a try.

During my occupational therapy sessions, I met with Davey and explained that I would show him some things he could do that would help him to follow the school rules and do his best work. I taught him some basic strategies of the Alert Program™, and we considered when he would use them. For several different days over the next three weeks, Ms. Ray again rated Davey's classroom behavior and his work completion according to the same data sheet she had used previously (see Box 63.3). The data yielded positive ratings when compared to baseline (the data that Ms. Ray had recorded during my evaluation), and that led me to recommend that Davey continue to use the Alert strategies on a regular basis. At that point, I asked Ms. Ray to record the data only once each week so that we could monitor Davey's performance. I told her to increase her data collection only if Davey's behavior and performance deteriorated. I also arranged with her for me to lead a lesson in the classroom so that she and all of the students could learn about these strategies. Davey took an active role in teaching his friends the different types of things that helped him do his best work in school. He told his friends some of the things he learned to do when "a class is going too slow and you just can't wait for recess" or when "so much is going on that it's hard to pay attention to Ms. Ray." This was an opportunity for peers to recognize Davey and learn from him. It also gave him the experience of advocating for his own needs. For Davey, this afforded a needed "self-esteem boost."

As another example of occupational therapy directed to school performance, once intervention started, Ms. Ray raised concern about Davey's protests to her when it was time to go to art. Mr. Tomkins, the art teacher, reported that Davey often refused to try projects once he arrived in the classroom. I scheduled a visit in the art room while Davey's class was in session. While there, I considered modifications or support that Davey could use during activities that overwhelmed him, such as those with multisensory touch and smell sensations. I considered whether changes in aspects of the environment, or the demands of art room tasks and activities would enable Davey's success. On the basis of the environment and activity analysis, I recommended that rubber gloves be available for Davey to use in the art studio. With the gloves on, Davey was able to sit at the table with his peers and mold cold, wet clay.

SUMMARY

My occupational therapy intervention to support Davey's school performance was grounded in sensory integration theory. My service was directed toward adapting his environment through scheduling, task or activity supports, and modifications so that activities and environments matched Davey's sensory needs and interests and the challenging sensory aspects of his daily experiences had a less prominent influence on his performance. I used my understanding about the interaction between the student, what he or she wants and needs to do, and the influence of the situations and settings in which school performance is expected. The evaluation and intervention approaches that I used were specifically targeted to enable Davey to engage in activities and routines across the campus. As a result, he participated in, and benefited from, the third grade curriculum.

There's No Place Like Home: Occupational Therapy Services for People Who Are Homeless

WINIFRED SCHULTZ-KROHN

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the change in the homeless population over the past 30 years.
2. Discuss the factors contributing to homelessness.
3. Identify the role of occupational therapy for those who are homeless.
4. Identify the evidence to support occupational therapy services for those who are homeless.

Occupational therapy practitioners can serve as change agents and provide valuable services to people who are homeless (Finlayson, Baker, Rodman, & Herzberg, 2002). My introduction to working with people who are homeless came when three occupational therapy students approached me, a faculty member, to mentor their senior honors project. They were interested in providing family-centered occupational therapy intervention at a homeless shelter for families. My experiences in working with those students and the families at the shelter served as the foundation for developing an occupational therapy internship program at the shelter

PRACTICE DILEMMA

MEETING THE NEEDS OF A FAMILY WHO IS HOMELESS

Dan, age 32, was employed as a janitor in a business complex for seven years. Five months ago, Dan was laid off from his janitorial position. Dan has a GED but no additional training or education and has been unable to find work. His wife Rita, age 30, works part time at a convenience store and makes minimum wage. Their daughter Emma, age 9, has asthma and regularly uses an inhaler. Their son Jacob, age 12, has a learning disability. Medical insurance was covered through Dan's job, and the extended medical coverage will end next month.

The family used to live in a studio apartment, but the rent increased, and they were no longer able to afford the apartment. They moved in with relatives a year ago. While Dan was still employed, the two families shared the costs of housing and lived in this doubled-up situation. After Dan lost his job, the relatives could not support both families. Dan's family sought housing in a homeless shelter. A shelter for women and children accepted Rita and Emma but not Dan or Jacob. Dan and Jacob searched for another shelter while Rita and Emma remained at the women's shelter.

Unfortunately, this situation is not fictitious.

and several collaborative research projects. This chapter describes occupational therapy intervention for this underserved population.

WHO ARE THE HOMELESS?

The demographics of the homeless population in the United States have changed dramatically over the past 30 years (Turner, 2004). In the past, those without a home were often single, middle-aged men with substance abuse problems (Rossi, 1990). Single men now make up only 41% of the homeless population, and homeless families, the fastest-growing segment of the homeless population, constitute 41% of the group (Turner, 2004). Single women are 13% of the homeless population, and unaccompanied youths are 5%. For adults, homelessness often presents as a series of exits and returns to being homeless (Dworsky & Piliavin, 2000). The majority of those without a home have a history of employment instability and previous episodes

of homelessness or living "doubled up," a situation in which several individuals or families are living together in housing that was designed for a smaller number of occupants. Female-headed families experienced less time being homeless and had fewer episodes of homelessness compared to both single men and single women.

WHY DOES HOMELESSNESS OCCUR?

The causes of homelessness are complex and can be conceptualized in three categories (Glasser & Bridgeman, 1999):

◆ **Personal deficits:** Substance abuse, mental health problems, and family violence are associated with an increased susceptibility to becoming homeless but are not definite predictors of who will become homeless.
◆ **External factors:** Low-paying jobs, insufficient affordable housing, and patterns of discrimination can contribute to homelessness but do not fully explain the extent or diversity in the homeless population.
◆ **Ecological perspective:** Personal deficits and the external factors of societal and cultural conditions may interact, leading to homelessness (Toro, Trickett, Wall, & Salem, 1991).

HOMELESSNESS IS MORE THAN LOSS OF A HOME

People who are homeless experience more than a loss of physical shelter; they experience disenfranchisement from the community (DeOllos, 1997; Toro et al., 1991). Occupational therapy intervention supports community connections by fostering social participation and is guided by two principles (Schultz-Krohn, 2004):

1. Creating an affirming environment that validates skill development can support participation in occupations (Rebeiro, 2001).
2. Participation in occupation can buffer the negative effects of stress and loss (McColl, 2002).

A shelter is not considered an affirming environment; therefore, occupational therapy practitioners focus on facilitating positive experiences for and with clients. For example, we designed an occupational therapy group for parents to help their children cope with the stress of living in a shelter. We discussed the importance of providing time for relaxing and taught stress management methods such as infant massage and relaxation techniques. Parents suggested that playing games could be used to reduce their children's level of stress. The opportunity for parents to share ideas and have those ideas endorsed within the group created a supportive environment. Parents then

selected an activity that they deemed most appropriate for their children. At the next parent group, many parents shared additional relaxation ideas with each other and supported one another. The affirming and supportive environment diminished the stressful experience of living at the shelter, and parents reported having fun with their respective families.

Adults Who Are Homeless

Occupational therapy can help adults who are homeless to enhance personal attributes such as job-seeking skills and foster the living skills they need to remain housed (Davis & Kutter, 1998). A focus on instrumental activities of daily living, particularly budgeting and careful monitoring of funds, should be fostered with adults who are homeless. Although adults who are homeless might attend classes on budgeting, occupational therapy intervention helps clients to translate budgeting skills into habits (Rogers, 2000). The formation of habits enables people to focus their energy and effort on other pressing issues, such as job or housing searches. Sally, a mother who was homeless and living in a family shelter, had a habit of buying candy for her children at the store even though the shelter provided free afternoon snacks. The shelter expected Sally to save money for rent, but she had very limited funds. The occupational therapist accompanied Sally and her children to the store and provided cueing to help Sally apply budgeting skills in context. Conflicting habits, such as trying to budget funds yet buying candy, were identified and addressed through instruction and discussion and by practicing positive habits in context. When the occupational therapist accompanied Sally to the store, Sally practiced reminding her children that she could give them a snack when they returned to the shelter. The therapist supported and encouraged Sally to practice the skill of budgeting in the context where this new skill was challenged.

Adults with Mental Health Problems Who Are Homeless

People without a home often experience severe disruptions of self-esteem, self-worth, and self-efficacy (Buckner, Bassuk, & Zima 1993). Homelessness can produce depression, stress, and anxiety in parents, children, and single adults (Buckner et al., 1993; Davis & Kutter, 1998; Zima et al., 1999). Homelessness has been identified as a factor in producing mental health problems, but those who have severe and persistent mental illness, such as schizophrenia, are also at greater risk for becoming homeless. Men and women with chronic mental illnesses have a 25–50% chance of becoming homeless, particularly when there is a discontinuity of mental health support (Susser et al., 1997).

Susser and associates (1997) documented that homeless men with mental health problems who received intervention to establish networks of community support had fewer nights of homelessness than did those receiving standard mental health services. Over the course of the 18 months, the men who developed social supports maintained stability in housing and demonstrated a progressive decrease in episodes of homelessness. These findings highlight the value of community-based social ties in mitigating the risk of recurrent episodes of homelessness for men with mental illness. Promoting community connections and engagement in community activities by fostering habits related to community interaction is congruent with the occupational therapy goal of promoting healthy habits.

Kavanagh and Fares (1995) describe occupational therapy services for a woman who had depression, several episodes of homelessness, and a history of sexual abuse. Occupational therapy intervention focused on developing roles and habits that supported participation in the community. On the basis of the woman's interests and an activity analysis, the occupational therapist identified crafts that the woman could successfully complete. Previously fearful of participating in community activities, the woman was now able to attend a community fair and sell her crafts, reflecting her sense of self-efficacy—a belief that she could be successful.

Parents Who Are Homeless

Parents who are unable to provide a home for their children often experience stress, a sense of failure, loss of parental roles, and a decrease in overall family function (Thrasher & Mowbray, 1995). Living in an emergency shelter provides a family with needed housing but might not provide an environment in which a parent can exercise parental roles (Schultz-Krohn, 2004). When a family is faced with being homeless, the "structure and cohesion are severely tested by unremitting stressors and by pressing needs for basic survival" (Buckner et al., 1993, p. 385). A person's sense of self-efficacy and identity is threatened by being homeless. These combined stressors can significantly affect family functioning.

Shelter rules supersede parental authority and have been criticized as undermining the parental role of director and authority figure within the family structure. The need to perform basic child-care roles is often eliminated within the shelter (Schultz-Krohn, 2004). Meals are provided without parental input, chores are assigned by shelter staff without consulting parents, and daily routines are determined by the shelter schedule. During my study of the meaning of family routines in a homeless shelter, parents reported diminished parental authority and explained how the rules compromised their role as a parent. One parent explained, "It's not so much the rules, it's just the way it makes you feel, that you're under somebody, and you're not really the parent" (Schultz-Krohn, 2004, p. 537).

Stress, disintegration of parental roles, and conflict are related to a diminished sense of well-being in children (Vandewater & Lansford, 1998). Children who are homeless are more likely to display signs of depression,

ETHICAL DILEMMA

Maintaining Confidentiality: What Are the Risks?

You are providing occupational therapy services at a homeless shelter designed for families. A 27-year-old mother has just been reunited with her two children after completing a substance abuse program. Her children, ages 5 and 7, were both in foster care for the past year due to parental neglect. This woman, diagnosed with depression and substance abuse, has a history of being physically and sexually abused by multiple partners and receives no child support for either child. She completed her substance abuse program two months ago and became employed one month ago as a clerk at a department store. She is re-

ceiving occupational therapy services to improve parenting skills, financial management, and decision-making skills. During an occupational therapy session, she reports that she went out for drinks with the other employees at work. The shelter requires that no alcohol or drugs be used while living at the shelter. Child Protective Services also stipulates that use of alcohol or drugs will result in the children being removed from the mother. She asks you not to tell anyone, and she promises that she will not go out drinking again. What do you do?

developmental delays, and physical health concerns when compared to children who live in low-income housing (Bassuk & Rosenberg, 1990). Killeen's (1993) research documents that children who felt that they performed well in the area deemed important by the parent rated their self-esteem at a higher level. Thus, helping parents to develop habits to provide specific praise for their children can support both parents and children.

To diminish the negative effects of homelessness, we developed interventions to support the interaction between parents and children. Parents were concerned about the lack of leisure and recreational activities they could engage in with their children. We acknowledged the parents' expertise and authority and explicitly identified parents as the directors of family activities. Those skills were built upon to support family interaction by providing an assortment of board games, toys, and activities that parents could use with their children. We discussed developmental play skills, and then the parents selected the toys, games, or activities that they deemed most appropriate for their children. The parents then identified the specific skill that would be praised when playing with their children. The parental skill of praising and supporting their children was fostered in the context of playtime. Follow-up sessions found parents engaging in more activities with their children and requesting additional toys, games, and activities to enhance parent-child interaction. By providing parents with guidance on how to identify behaviors they deemed important, how to provide systematic praise to their children, and how to choose activities that offer their children success, parents were better prepared to foster self-esteem and a positive self-concept in their children. The occupational therapy intervention helped parents to refine their skills of respond-

ing to and controlling their children. Intervention supported the parental role, fostered positive parent-child interactions, and provided appropriate play and leisure activities for children of various ages.

Children Who Are Homeless

Occupational therapy intervention for children and adolescents may focus on fostering socioemotional developmental skills and other school-related skills (Drake, 1992; Zima, Bussing, Forness, & Benjamin, 1997). Children and adolescents who are homeless often experience disruptions in school attendance, frequent changes in schools, and a loss of school friendships, resulting in depression and anxiety manifested by poor frustration tolerance, limited decision-making skills, and poor task persistency (Zima et al., 1997, 1999). To address these needs, we provided intervention at the shelter to foster the children's engagement in activities and occupations with peers to enhance the skills needed to form and maintain friendships. For example, the environment was structured to support decision-making skills and cooperation with peers by offering a choice of cooperative activities, such as playing a board game or working on a collaborative craft project. The therapist and children discussed how a decision could be made fairly and with respect for everyone's feelings. Some children took on the role of explaining the group structure and rules to new members of the group, thereby demonstrating their sense of confidence. The structured and supported teaching, role modeling, and group facilitation provided by the occupational therapist promoted the children's acquisition and application of cooperative decision-making skills and peer relationships.

SUMMARY

Although the shelter where intervention was provided allows families to stay no longer than three months, during that brief period of time, families benefited from occupational therapy interventions designed to foster healthy habits and routines. Interventions were designed to meet the specific needs of individual clients, the parent-child dyad, and the family system. The use of affirming environments, support, and systematic encouragement facilitated self-efficacy and helped clients to develop important skills to fulfill their roles. Their skills were then practiced in various contexts to help clients develop better habits.

Many of the parents who participated in occupational therapy interventions at the shelter appreciated of the use of an affirming environment. Parents commented, "You make us feel good instead of like we don't know anything" and "You seem to really want us to succeed." Creating an environment that acknowledges a client's current skills and systematically supports the development of new skills is a foundation of occupational therapy practice. People who are homeless often face negative and demeaning situations, and occupational therapy can offer an alternative to these negative situations.

A Woodworker's Hand Injury: Restoring a Life

KAREN GARREN

65

It was a shock to hear that the father-in-law of a woman who worked in our building had cut his hand badly in a table saw. When he actually walked into the clinic, it was one of those moments when I could feel my heart sink. Don is a fine woodworker who built spectacular and complex crown moldings and built-ins in very upscale homes. He had indeed put his left hand through a table saw at work ten days earlier. I had just gotten a call from the hand surgeon upstairs telling me that he was sending Don down to be seen immediately for splinting and to start therapy. This doctor had not done the surgery; Don had been rushed to a hospital near where he worked some distance away and was operated on there by a plastic surgeon. The operative report was not available, but from what the doctor was able to ascertain, Don had lacerated his hand through his proximal palm and severed both flexor tendons to his long and ring fingers, amputated his small finger at the metacarpal phalangeal joint (MP), and lacerated the nerves to all his fingers. The doctor was not sure about the involvement to Don's thumb and index fingers. Don had arrived in his office bandaged and protected only by a wrist support with the fingers free to move at the proximal interphalangeal joints (PIPs). This was not good. I brought Don in immediately and told him not to move anything. He said that the doctor had just told him that but that the only thing he had been told at discharge from the hospital was to follow up in a week. He thought wiggling his fingers was good, since they were not immobilized.

There are critical elements to consider in dealing with a patient who has recently undergone reconstructive surgery of tendons and nerves. The first and foremost concern is to protect the repair and then ask questions. I knew enough history from the brief discussion with the referring surgeon to know that I needed to get Don into a protective splint as quickly as possible to reduce the tension on the tendon and nerve repairs and to stop any active motion of the repaired tendons (Culp & Taras, 2002; Duran & Houser, 1975). I also needed to assess the wound to determine the integument condition and, since no operative report was available, to visually assess the exact anatomical level of injury. At the same time, I needed to reassure Don that his zeal to get his fingers moving had probably not ruptured the repairs, since he assured me that he could wiggle them. I do not deceive patients, but informing Don of all of the possible ramifications at that point would only have distressed him, and I needed him to be focused on where we were

going and what he was going to need to do. Once Don's hand was bandaged in a dry dressing and he was safely tucked into a dorsal blocking splint that positioned his wrist in 30 degrees of flexion, his MPs in 70 degrees of flexion, and his PIPs and distal phalangeal joints (DIPs) in as much extension as he could actively produce (the ideal is full extension, but he was already contracted, and applying any force could compromise the repairs), I could safely continue his evaluation. During this process, I was monitoring his reactions to the situation. It can be an extremely emotional time, and patients often have not even looked at their wounds. I keep ammonia capsules and facial tissues readily available. Don seemed to be coping by focusing on the process and asking questions.

The evaluation consisted of the following:

Subjective Examination

- Age, hand dominance
- Date and mechanism of injury
- Functional capability/work status
- Activities of daily living (ADL) status/help status
- Chief complaints: pain, loss of function, sensory changes, sleep problems
- Rehabilitation expectations/goals
- Medical management
- Awareness of pathology/precautions/contraindications/physician orders

Don was 58 years old at the time of the accident, right–handed, and married. He worked full time as a woodworker and loved his job. He wanted to return to his occupation as soon as it was possible to do so; he needed to be able to lift and carry wood supplies, hold tools and hardware, and stabilize wood with his left hand. He was unable to use his left hand for any self-care; however, over the previous week, he had become sufficiently proficient with his right hand alone to manage to dress, feed, bathe, and even drive himself. His wife managed the meals and household tasks. Initially, his chief complaints were loss of function, inability to move his hand, and numbness in all of his fingers. Don could not describe exactly how the accident had happened except that he was cutting wood on the table saw and it caught, pulling his hand down on the blade. This is a familiar story. The blade spins at an incredible speed, and when things go wrong, it is too fast to actually see or react. A table saw blade does not cut like a knife but consists of teeth that are a series of angled chisels that are an eight of an inch wide or more. It leaves a fairly wide slot when it cuts wood. The same happened to Don's hand. The blade had amputated his small finger and continued across his proximal palm in zone 3. When the tendons and nerves were cut, the result was that several millimeters of tissue were missing, as well as skin and thenar and hypothenar muscle. It follows that when the ends of the tendons and nerves were sutured together, the result was shortening of the structure, creating additional tension on the repair.

Objective Examination

- Integument
- Range of motion (ROM)
- Sensation
- Edema

To evaluate Don's hand, I needed to keep in mind the protocol that I would use to guide his physical recovery. There are multiple protocols to choose from, with extensive research supporting advantages and disadvantages. Pettengill (2005) has written a historical perspective on the research of tendon rehabilitation, with a comparison of the most recent early active motion protocols. My input is usually taken into consideration; however, it is the doctor who decides which protocol he or she wants to follow. The doctor who made this referral does not like to use any of the early active motion protocols because he thinks that research has shown that there a greater risk of rupture. In Don's case, it was not an option because his was not a clean and simple wound, we were not starting therapy three days after surgery, and we had no knowledge of what suturing technique had been used to repair the tendons. In fact, we were beginning at the tenth day, which is when research has demonstrated that the tendon tissue actually softens and is at the highest risk of rupture. The doctor was concerned about the amount of trauma and the significant amount of scarring and wanted to minimize adhesions, so I used the modified Duran protocol (Duran & Houser, 1975) to begin early passive flexion with restricted active extension of the fingers but held any active motion until the sixth week. With his wrist and MPs splinted in flexion and his interphalangeal joints (IPs) in extension, I taught Don to passively flex his fingers into his palm and actively extend his fingers as far as the splint would allow. This allowed a few millimeters of tendon excursion with minimal resistance on the repair and has been shown by research to reduce tendon adhesions. His hand was moderately swollen, and he was not able to fully flex his fingers to his palm. Don had multiple system trauma involving not only the tendons but also nerves, muscle, palmar fascia, and skin. I tested his sensation with the Semmes-Weinstein monofilaments (Bell-Krotoski, 2002) because I was not sure whether all the digital nerve branches were severed. The test revealed loss of protective sensation or complete numbness in the median and ulnar nerves to his index, long, and ring fingers.

Setting goals for Don's therapy ultimately centered on what Don wanted to accomplish. The doctor always pushes for a perfect physical outcome, and usually the patient is in agreement; however, returning the patient to his or her previous job is not automatically a goal. I often do not set a return-to-work goal in the initial evaluation when there is a traumatic injury, because it can be too early to determine what the patient wants and what the potential might be in terms of ability, time, and opportunity. Woodworking was Don's passion, not just his job. He had

built something for each of his grandchildren, and he was anxious to build a rocking horse for his new grandchild.

For the next five weeks, the goals for Don were to understand the pathology, precautions, and home exercise program to increase his passive finger flexion; facilitate wound healing; and remodel scar to ensure necessary restoration of strength to the tendon tissues while safely allowing mobility through the adjacent tissues (Pettengill, 2002). The splint would not come off until the sixth week after surgery, so there could be no functional use of his hand. Don was diligent in his exercises and quickly recovered full passive finger flexion. The sutures were removed at 21 days with full skin closure. It was not until four weeks after his surgery that we finally got a copy of his original operative report revealing that there had been repair to his palmar arch, flexor pollicis longus to his thumb, and flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) to his index finger, which had been only partially lacerated. The additional information helped me to anticipate what limitations there might be when the splint came off.

Don's treatment initially consisted of manual ROM, dressing changes, and, when the sutures were removed, moist heat, low-intensity ultrasound, and manual scar massage to increase the soft tissue extensibility and remodel the scar. His treatment was a team effort with Erin Leary (the other hand therapist in the clinic), Don, and me. This partnership required mutual attentiveness in order for Don's feelings, needs, and desires to become part of the common understanding between Don, Erin, and myself (Crepeau, 1991; Rosendahl & Ross, 1982; Tickle-Degnen, 2001).

Six weeks after surgery was the next major hurdle for Don. The splint came off, and he was allowed to move his fingers. It was hard to prepare Don for the disappointment that he felt when his fingers did not actively flex into a fist. His hope was beyond realistic expectation, but Don just wanted to move forward and do whatever it took to be able to use his hand again. He still had no sensation in his fingers.

ton his pants, hold a washcloth to bathe, and eventually hold tools to return to work. This required heat modalities; low-intensity 3-megahertz (3-MHz) ultrasound (Michlovitz, 2005); and manual therapy to facilitate healing, increase soft tissue mobility, and remodel scar. We used occupational coaching (Clark, Ennevor, & Richardson, 1996) to teach Don the skills and strategies he needed for attaining the mutually-agreed-upon goals, and we created a therapeutic alliance in which we worked in the presence of one another. Erin and I served a supportive function while guiding Don in an occupation-based intervention (Tickle-Degnen, 2001). We taught Don sensory loss precautions so that he would not accidentally burn or cut himself. His home program was expanded to include paraffin and a mini-vibrator for scar remodeling and desensitization; however, he discovered that his hot tub water jets worked perfectly. Exercise and functional activities were initiated to increase his active motion and encourage grasp and pinch for pulling on clothes, holding utensils, and washing himself. He began desensitization for the scar and nerve hypersensitivity in his palm with particle immersion and vibration (Barber, 1990).

For the next six weeks, Don used the dexerciser, Chinese balls, pegboards, paper wadding, page turning, manipulating buttons, and pinching out beads in putty to regain active motion of his fingers. Experience guided the choice of these activities to promote tendon excursion through the very dense scar tissue in his palm and to train Don to begin to use his hand for light resistive functional activities. With this guided experience of how much pinch and grip force was safe, Don confidently began to try to use his hand safely at home for daily tasks. At ten weeks, the tendons had healed sufficiently to add resistance using the hand gripper to pick up checkers and the BTE (work simulator/exercise machine) to increase the force against the scar adhesions that limited tendon excursion. Sensation had begun to return in his distal palm, but his fingers remained numb.

AROM			
6 Weeks	**MP**	**PIP**	**DIP**
Index	0/60	−30/60	−10/30
Long	0/55	−30/45	−10/10
Ring	0/30	−35/45	−5/5
Thumb	−10/35		0/25
Wrist	25/60		

AROM			
10 Weeks	**MP**	**PIP**	**DIP**
Index	0/80	−20/100	−10/65
Long	0/80	−35/92	−15/45
Ring	0/30	−35/70	0/25
Thumb	−10/50		−20/75
Wrist	55/70		

His goals were to increase the active range of motion (AROM) of his fingers and wrist to pull up his pants, but-

His thumb index and long fingers progressed to full active flexion, but his ring finger had only 90 degrees of total motion. The loss of his small finger and severe limitation in

active flexion of his ring finger due to adhesion of the FDP in his palm resulted in the syndrome of quadriga described by Verdan (1960), causing incomplete terminal flexion of his long and index fingers during grip. Don could not functionally grip a steering wheel or hold tools for work simulation. He was able to pinch and grip sufficiently to pull on clothes and bathe; however, buttoning and holding screws, boards, or nails were impaired by the sensory deficit.

At 12 weeks, the hand surgeon who had referred Don decided to take him back to surgery for a tenolysis or possible tendon repair, depending on what he found when he opened Don's hand, so we discharged him to a home exercise program until he returned from surgery.

Surgery revealed that the ulnar digital nerve to Don's ring finger was ruptured with a 2-cm defect between the proximal and distal ends. The proximal end of the digital nerve that had previously gone to his amputated small finger was in the immediate vicinity, so the surgeon connected that to the distal end of the ring finger ulnar digital nerve. On evaluation of the flexor tendons to the ring finger, it was discovered that both not only were extremely scarred down, but also were attached only by pseudotendons. After tenolysis of both tendons, it was decided to leave the FDS alone and excise the pseudotendon to the FDP. A primary repair to the FDP was successfully performed with minimal loss of tendon excursion.

Don was referred to therapy one week after surgery for evaluation and initiation of treatment. His original splint was modified to free his index finger and thumb, and his dressings were changed. Don was familiar with the Duran protocol and started passively ranging his long and ring fingers immediately. He required only one follow-up visit after the evaluation to achieve full passive range of motion (PROM) and was discharged to a home program until he came out of the splint to begin AROM. The biggest difference in the course of rehabilitation this time was that Don returned to work in a supervisory capacity as soon as the sutures were removed.

The doctor again decided to hold all active motion until the sixth week after surgery. Even though Don was ready this time for his finger not to move immediately, by the end of the first week of therapy, he was extremely frustrated and disappointed by the lack of progress. By the third week of therapy (nine weeks postoperative), Don was finally beginning to find it easier to do his self-care. Lack of sensation in the fingertips continued to be a problem, but Don was beginning to compensate. As patients progress through the healing process and therapy, they become more cognizant of their own physical and emotional capacity to return to previous occupations or accomplish their goals. Erin's and my goal at this juncture was to help Don begin to identify the problems that interfered with reentering or performing his occupation and to begin to plan possible solutions with him. Clark and colleagues (1996) identified this process as evoking insights in occupational storymaking. We chose many of the same activi-

ties to gain grip and pinch; however, we geared them as much as possible toward work using the nut and bolt board, pegs to simulate nails, and grasping of various-sized objects. Don had already learned how to use his hand safely for self-care tasks after the first surgery and expressed his desire to concentrate specifically on tasks that would restore function related to work,

At the tenth week, a dynamic PIP extension splint was added to reduce the flexion contracture in his ring finger and to mobilize the tendon distally through the scar adhesions (Pettengill, 2005). Don work relentlessly at home, gripping putty in an attempt to force the tendon through the thick scar, but there was still no appreciable difference in flexion, and Don was devastated. At 12 weeks, the repair site had developed enough tendon tissue growth through the anastomosis to almost eliminate the possibility of rupture. On the basis of our experience, we decided to use iontophoresis with dexamethasone to reduce the inflammation and adhesions around the healing tendon. Within one week, Don had increased his ring finger flexion and was able to flex to his central palm.

AROM			
12 Weeks (second surgery)	**MP**	**PIP**	**DIP**
Ring	WNL	−25/90	0/50

Don's therapeutic activities expanded to gripping tools and swinging a hammer into a pillow for controlled grip even though he was not left-handed. He began to notice a significant decrease in hypersensitivity in his palm and reported that he was picking up small pieces of wood at work with some success. At 15 weeks, he returned to full duty but was in a position to modify his activities when needed, lifting Sheetrock with his wrist instead of his fingers. At 18 weeks, he was discharged with 42 pounds of grip, 19 pounds of lateral pinch, and 12 pounds of three-point pinch; he was able to do his job and was working at home on his grandchild's rocking horse.

Over years of practice, I have learned to incorporate methods such as physical agent modalities, manual therapy techniques, and wound care into hand therapy. However, occupational therapy methods and philosophy have always been the foundation of my therapeutic approach. Helping clients to achieve occupational goals requires more than tissue healing and joint mobility. I have learned that recovery is a fabric woven from psychological, spiritual, and physical pain. Hand therapy is about restoring meaning in client's lives as well as restoring tissue function.

It has been a couple of years since Don left therapy, but he recently stopped by to drop off a *Fine Homebuild-*

"Mrs. W.": A Woman with Dementia

CORALIE "CORKY" GLANTZ

Throughout my career, I have worked with patients who have a wide variety of diagnoses. However, it is the people with dementia who have influenced me the most, personally and professionally. The work I have done with this patient population has enabled me to enhance my service delivery not only clinically but also as an educator and, more important, as an advocate. In every clinician's life, there are cases that are hard to forget. One case in particular that stands out in my mind is the work I did with a woman diagnosed with Alzheimer's disease. For this case study, she will be referred to as Mrs. W.

As you read my thoughts and memories about Mrs. W., you will recognize that a number of occupational therapy theorists and frames of reference have shaped my responses. First, I use the work of Mary Law (1998) and her colleagues in Canada for their well-developed materials on client-centered practice. Second, both the Person-Environment-Occupation Model (Law et al., 1996) and the Ecology of Human Performance (Dunn, Brown, & McGuigan, 1994) shape my emphasis on considering the person's engagement in occupations in specific contexts that either enable or handicap the person with dementia. In addition, I use research that supports the use of these frames of reference and practice models as well as the person-environment fit and quality of life for people with dementia, especially the works of Corcoran and Gitlin (1997); Davis, Hoppes, and Chesbro (2005); Dooley and Hinojosa (2004); Edelman, Fulton, and Kuhn (2004); Josephsson, Backman, Borell, Nygard, and Bernspang (1995); Nygard and Ohman (2002); Orange and Colton-Hudson (1998); and Painter (1997).

Mrs. W. was an attractive, beautifully dressed and groomed woman in her seventies who had lived her entire life in the Chicago area, although she had traveled extensively throughout the world. She had been married to the man who was described as her true love for 21 years when he suffered a heart attack and died suddenly at age 49. She remained single for the next 18 years before she married again to a doctor; her daughter described it as "a marriage of convenience." Her second husband died after 10 years of their marriage.

Mrs. W. had two children with her first husband, a boy and a girl who were 2.5 years apart in age. Her son died at age 54 of acute leukemia. The daughter married and had two children. She lived close to her mother and was quite attentive and devoted. The majority of information for the history

portion of the initial evaluation was provided by Mrs. W.'s daughter. Mrs. W. was a very social person with an extensive list of close friends. She was a very giving person. Before her second marriage, she moved in with the son of her future husband in order to take care of three children after the son's wife was killed in an auto accident. Mrs. W.'s daughter indicated that Mrs. W. always made herself available to help whenever ever anyone was in need, especially her family and friends.

Mrs. W. was a wife and mother first and a homemaker second. She had not worked outside of the home since she was married. However, her time was filled with volunteer work and good deeds. Her hobbies and leisure activities included swimming and other sports; her daughter reported that Mrs. W. was an excellent athlete. It was also reported that she enjoyed reading, dancing, shopping, and some arts and crafts, including drawing and knitting. Her daughter also indicated that Mrs. W. had always loved children and spent a considerable amount of time with her grandchildren and taking care of other people's children.

I came to know Mrs. W. when she was residing in a small group home for people with dementia. Before that, she had lived in her own home, then an apartment, then a retirement home. Her daughter had instigated the moves. She felt that her mother's home was too large for her to handle and encouraged the move to the apartment. The apartment was closer to the daughter and also had a swimming pool in which her mother could swim every day. After a few years in the apartment, her daughter was concerned about her mother's memory difficulties and her safety. At this time, Mrs. W. could no longer manage her bills and her checkbook. Her daughter took her to a clinic, and her mother was diagnosed with Alzheimer's disease. Mrs. W. was aware of the diagnosis. Her daughter visited a retirement home with her mother and encouraged her to consider moving. Her mother agreed. The daughter indicated that the years when her mother lived in the retirement home went well until the other residents started to ostracize her. A number of uncomfortable situations occurred, for example, when she was playing bingo and she could not remember the numbers that were called. As a result, the other residents verbally expressed their annoyance with her. She gradually stopped participating in the activities at the retirement home and was concerned only with getting to her meals on time. She would get ready and wait hours before the dinner hour. Her daughter also reported that she would cut their excursions short because she wanted to go back to the retirement home so that she would not miss her meal. While they were on a trip together, the daughter realized that her mother was not always safe in her behavior. On one trip, her mother attempted to take a shower with scalding hot water. This and other incidents helped the daughter to make the decision to move her mother to a dementia-specific facility.

Mrs. W. was referred to occupational therapy by her physician, who had received a request by Mrs. W.'s daughter, who was concerned about her mother's decline. It was at this time that I met Mrs. W. in the small group home for people with dementia. She was socially appropriate for the initial evaluation and was able to do most of her own activities of daily living (ADLs) and some instrumental activities of daily living (IADLs) with cueing. She demonstrated difficulty with word finding, had delayed processing abilities, and had moderate immediate and short-term memory loss. She was aware of her surroundings and showed signs of sadness and depression related to her progressing disease. Her roles had changed considerably. She no longer was the helper of her friends and family, socialite, or active athlete. Her performance skills had changed; she could no longer take care of her own financial matters, take care of her home, or write letters and cards to her friends. Her motor skills were good; however, she did not have the opportunities to use them. She was able to verbalize her basic needs; however, her word-finding skills had notably declined in the past two months as reported by her daughter. Her processing skills were decreased, including her temporal organization, attention to tasks, ability to make adaptations, and ability to accommodate the method of task completion in response to a problem. Communication and interaction skills were significantly reduced, causing Mrs. W. a great deal of distress, since this was of major importance in her life.

On further evaluation, I recognized that the environment and the manner in which activities were presented caused Mrs. W. a great deal of stress. Because of her social appearance, staff often thought that she was capable of many activities that were too demanding for her. Her environment was not familiar and was quite cluttered. This caused her to have difficulty finding her way around the facility and finding things in her room. These problems appeared to complicate her daily functioning and to add to her depression, which was manifested by her starting to withdraw from the daily activities at the home. She appeared aware of the changes occurring in her life and showed signs of frustration, and as her frustrations mounted, she started to exhibit challenging behaviors. The staff reported that there were times when she would scratch them and try to bite. On further exploration, I found that the reported challenging behavior of scratching and attempted biting occurred when a male orderly was attempting to help her bathe.

I spoke with Mrs. W. and her daughter about their goals. We discussed the many strengths that Mrs. W. had and how we could use those strengths to help her to improve her situation and her quality of life in the facility. Strengths that were identified included her social awareness and enjoyment of being with other people, her love of music and dancing, her desire to be helpful and useful, her motivation to be independent, her desire to look good, caring about her clothes and jewelry, her good physical abilities, and her strong family relationships. Mrs. W. and her daughter identified their goals as (1) improving her

ability to communicate with family, friends, and staff; (2) increasing her independence in ADLs and IADLs with minimum and appropriate assistance; (3) establishing a role of usefulness within the facility; (4) finding meaningful occupations that were within her abilities and did not cause frustration; and (5) participating in regular physical activity. Following are the goals as restated to make them client centered and measurable:

1. Mrs. W. will communicate her needs and thoughts to family, friends, and staff through a combination of words, gestures, and movements at least one time daily for five days.
2. Mrs. W. will increase her independence in ADLs and IADLs with minimum and appropriate assistance.
   a. She will choose her clothing and put on her own underwear and blouse and skirt or dress in the proper order with one verbal cue three mornings in succession.
   b. She will put on appropriate makeup and jewelry independently three days in one week.
   c. She will make her own bed and put clothes in the hamper or away in the closet three days in one week with minimum verbal cueing.
   d. She will safely shower independently after being escorted to the shower by a female aide two times in one week.
3. Mrs. W. will participate in helpful facility household chores of her choice two times a week for two weeks in succession.
4. Mrs. W. will participate in meaningful occupations that are within her abilities and do not cause frustration.
   a. She will have the opportunity to go shopping one time a week.
   b. She will have success in completing a craft or activity of her choice that has been broken down into appropriate steps.
5. Mrs. W. will participate in a teacher/leader role in a physical activity three times a week for three weeks.

To develop my intervention plan, I synthesized the information I had obtained from Mrs. W.'s occupational profile and the analysis of her occupational performance to focus on the specific areas of occupation and on their internal (personal and spiritual), external (physical setting, social, and virtual), and cultural contexts (American Occupational Therapy Association, 2002) that needed to be addressed. My intervention focused on the goals identified by Mrs. W. and her daughter. After analyzing Mrs. W.'s problems, strengths, and goals, I decided to focus my interventions on her ADLs and IADLs and the context in which they were being done, on her performance skills and performance patterns in relation to her roles within the facility and with her family, and on her nonverbal communication skills with family and staff of the facility.

Because Mrs. W.'s engagement in the occupation of self-care was being limited by the clutter in her room, I worked with Mrs. W., her daughter, and the facility staff in removing the clutter and organizing the room so that the necessary objects were placed within eye line of the task to be done and in the correct order. Dresser drawers were marked with line drawings and one-word descriptions of what was in them. and the clothes that she was to put on each day were hung on one hanger in the order in which she should put them on. The closet was cleared of all but a couple of favorite outfits. Jewelry was minimized to the pieces she could independently take on and off.

We also worked on grooming and bathing skills. Although Mrs. W. had to be escorted to the shower room, we worked on her being able to safely take a shower in privacy with the shower curtain closed. She was to be escorted to the shower only by a female caregiver. Because grooming, including putting on makeup, was important to her, we set up a dressing table with a seat and mirror and her necessary makeup and hair products. This setup was familiar to her, and it pleased her. Her caregiver was instructed on how to cue Mrs. W. only when necessary. In doing this, we were able to reestablish the performance skills and performance patterns in a morning routine that had been familiar to her in the past. We did have to modify the daily routine of the facility to support her cognitive abilities. We did this by allowing increased morning grooming time to compensate for her slowed processing abilities and permitting her to have a late light breakfast.

IADLs and home care had been a prevalent occupation in Mrs. W.'s life. I worked on these skills with Mrs. W. while I instructed staff in how to break the tasks down to manageable steps. Mrs. W. was then able to make her bed and clean her own room. She was also able to participate in useful tasks in the facility, such as cooking activities, setting the tables, dusting, and folding towels and linen. She was encouraged to help the staff and other residents.

Engagement in the occupation of dancing and other physical activities was another goal that we addressed. I worked with the activity director to establish a dancing class in which Mrs. W. could be not only a participant but also a leader/teacher. Mrs. W. had a wonderful sense of rhythm and retained the ability to do many dance steps. This became one of Mrs. W.'s primary roles in the facility community, and she was recognized for her abilities and for helping others to participate in an enjoyable occupation.

The final and most difficult goal that we needed to tackle dealt with communication. Because Mrs. W.'s verbal communication skills continued to decline, I referred her to speech therapy and began working with the staff and Mrs. W. on her nonverbal communication. I was surprised to find that many of the staff members did not recognize nonverbal signs of communication. Mrs. W. had exhibited very distinct and consistent signs for her most common needs, such as rubbing her stomach or a specific body part if she had pain, grimacing when she had to go to the washroom, closing her eyes or looking at the floor when she was bored or was displeased with what was happening, turning

her head away when she did not want to do something, and smiling when she was pleased or wanted to do something.

A great deal of my intervention utilized therapeutic use of self (Punwar & Peloquin, 2000) and therapeutic use of occupations and activities through occupation-based activity, purposeful activity, and preparatory activity, consistent with the Occupational Therapy Practice Framework (AOTA, 2002). We collaboratively addressed all the goals set by Mrs. W., her daughter, and myself. Her participation and independence in her ADL and IADL function improved, her active engagement in occupation increased, she established roles of usefulness within the facility, and she participated in physical activities on a regular basis.

In the process of developing Mrs. W.'s occupational profile, synthesizing the information, and developing a treatment plan, I used my knowledge, critical reasoning, interpersonal abilities, performance skills, and ethical reasoning (AOTA, 2005):

◆ Knowledge included the integration of relevant evidence and literature on treatment of people with dementia. This included knowledge of the impact of occupational roles, habits, and routines on the day-to-day performance and well-being of older adults; the importance of involving family and caregivers; the aging process and its impact on visual, perceptual, sensory, and physical systems; normative life events, including life transitions and their impact on the older adult's occupational performance, health, and well-being; and team-building theory and teamwork models.

◆ The judgments and decisions I made in developing a treatment plan and in treating Mrs. W. required me to use deductive and inductive reasoning. I had to analyze Mrs. W.'s current occupational performance and how it was influenced by the context of living in the facility. Problem solving was then used to develop appropriate roles for Mrs. W. that would use her strengths (social awareness, enjoyment of being with other people, and love of music and dancing) to satisfy her need to be useful and helpful and her need for more physical exercise. Mrs. W. successfully became a leader/teacher in the facility's weekly dance program and appeared to thoroughly enjoy this new role.

◆ Interpersonal abilities were used in development of my professional relationships with the facility staff, Mrs. W.'s daughter, and Mrs. W. We were able to develop and sustain a team relationship to meet Mrs. W.'s goals. I received feedback from them and communicated instruction and suggestions to them regarding task segmentation, room organization, altering facility schedule to allow time for grooming activities, and nonverbal communication techniques.

◆ The therapeutic performance skills that I used were grounded in the core of occupational therapy; the therapeutic use of self, the therapeutic use of occupations and activities, the consultation process with family and

staff, and the education process used in training staff to bring about the desired changes in Mrs. W.'s quality of life in the facility.

◆ Ethical reasoning was used in dealing with Mrs. W.'s grooming and bathing issues. I had to consider staff's concerns about Mrs. W.'s safety versus her rights, dignity, and desire to have privacy while taking her shower. There was also a safety issue with her mirror and makeup items and her right and desire to use these items. Mrs. W. has not presented with a challenging behavior since the changes in her bathing and grooming have occurred.

I discharged Mrs. W. from therapy after seeing her three times a week for three weeks. I had evaluated how multiple events, life transitions, and contexts had affected Mrs. W.'s occupational roles and determined optimal occupational therapy interventions, which facilitated positive outcomes in occupational performance and participation in her community within the facility.

I was called back into the facility to see Mrs. W. two years later. She had adjusted well to the facility life and was an active participant in the facility community. However, her daughter once again recognized a marked decline in her ADL abilities, her memory, and her ability to follow verbal instructions and an increase in challenging behaviors. Mrs. W.'s daughter realized that this was part of the disease progression; however, she requested occupational therapy to evaluate and determine whether anything would help to maintain her mother's abilities for a while. The physician agreed and ordered occupational therapy evaluation and two weeks of treatment. Once again, I was able to work with Mrs. W., her daughter, and the facility staff. We were able to make some adjustments in her room environment to give more cues. For example, the door of her bathroom was changed to a curtain, and receptacles that she had used as a toilet, such as the wastepaper basket, were removed. The staff were also instructed on backward chaining so that Mrs. W. still could participate in self-care activities that we altered to decrease memory demands so that she could still achieve success. We increased the use of demonstration and hand-over-hand instructions and the use of line drawings for identification of items and places, and we explored antecedents to her challenging behaviors and instructed staff to avoid the antecedents.

Mrs. W. remained an active participant in her ADLs and in some of the facility activities until about two weeks before her death. Her daughter informed me that the staff had continued to follow my suggestions and thereby had avoided precipitating Mrs. W.'s challenging behaviors. Mrs. W.'s daughter expressed her thanks and felt that occupational therapy had made a tremendous difference in her mother's transition into the facility, had helped her to make the adjustment to the facility, and thereby had improved the quality of the last years of her life.

I have learned so much from working with older adults and especially with people with dementia. Too often, I observe staff that see diseases or disabilities and do not see the person. Older adults, including people with dementia, have many strengths and abilities. They are people with wonderful knowledge and experiences, and they are people who have lived many years and have so much to give to those around them. Because I believe that they are often misunderstood, I have become active in educating staff, families, and community groups in understanding dementia. There are many ways in which therapists can help to advocate for the people and populations with whom they work. Over the years that I have been working with older adults and people with dementia, I have been involved with legislation, participating in local, state, and federal panels and consultant groups; holding workshops for facility staff and for therapists; doing presentations for local, state, and national conferences and organizations; presenting to families and seniors; and writing articles and manuals. I volunteered to do in-services and presentations. I suggested to the facilities where I was working that I would do a presentations for families and their community. I volunteered to be part of panels, and I contacted the people involved with doing the draft legislation or the studies. Being an advocate does take time, and your time is not necessarily reimbursed. However, it can bring you countless rewards. It can help you to market yourself and your profession as having knowledge in the practice area. Advocacy can also make a tremendous difference for people or populations. I pursued and participated, and I still pursue and participate. We are all busy, but we make time for what we consider important. I consider advocacy important. It has been important to me personally and professionally, and I have learned so much from doing it. It has also helped to build my practice by establishing my credibility as knowledgeable in the area of practice.

From the feedback I received from Mrs. W.'s daughter, occupational therapy enhanced the quality of Mrs. W.'s life. My experiences with Mrs. W. and other people with dementia have enhanced both my personal life and my professional outlook. These people have given me a greater understanding of how the quality of a person's life can be improved throughout the life course with appropriate intervention. I have also learned that my knowledge base can improve the quality of life for many elderly patients, not only through direct intervention but also through education of fellow clinicians and caregivers and through advocacy work. I encourage clinicians to develop a professional niche, continually increase your knowledge base, and put that knowledge base to work.

MANAGING PRACTICE

" In turbulent times, an enterprise has to be managed *both* to withstand sudden blows and to avail itself of sudden unexpected opportunities. This means that, in turbulent times, the fundamentals have to be managed and managed well. "

Peter F. Drucker

Management of Occupational Therapy Services

BRENT BRAVEMAN

Learning Objectives

After reading this chapter, you will be able to:

1. Explain the relationship and differences between administrators, managers, and supervisors in oversight of work activities in organizations.
2. Identify and give examples of the common roles, functions, and responsibilities of managers.
3. Identify and explain the areas of knowledge and skills necessary for a manager to demonstrate competency.

MANAGERS, ADMINISTRATORS, AND SUPERVISORS

One may assume a variety of professional roles over the course of a career as a practitioner. One such role is that of an *occupational therapy manager.* Management as a function of organizations and the process of managing has been the focus of considerable theory, research, publication, and other scholarly forms addressed by investigators and practitioners in a variety of fields. Consequently, many resources to guide managers in their jobs are readily available on the Internet, in bookstores, and through educational courses offered at colleges and universities or at continuing education events, such as professional conferences.

Learning to be an effective occupational therapy manager is a complicated and time-intensive process that is far beyond the scope of any single chapter or text. Therefore, this chapter will focus on helping the reader to become familiar with what an occupational therapy manager *is* and what an occupational therapy manager *does.* Chapter 69 provides a complementary discussion that focuses on supervision and the roles and functions that occupational therapy supervisors perform.

CHRISTOPHER MANAGES PRODUCTIVITY

Christopher is a new manager of an occupational therapy department in a moderate-sized community hospital who supervises eight occupational therapists and two occupational therapy assistants. His staff provides services to clients and patients across the life course who have a wide range of diagnoses, conditions, and challenges to occupational participation. Like many hospitals, the one in which Christopher is employed is facing financial challenges due to lower rates of reimbursement from the state Medicaid system, increased discounts on care provided to patients participating in managed care, and ongoing losses due to noncompensated care.

As a midlevel manager, Christopher has come under increasing pressure to raise the rates of productivity in his department and to provide less intensive service to patients such as those with Medicare for whom the hospital receives a set rate of reimbursement while achieving the same outcomes. He recognizes the challenges faced by the organization and is honestly committed to doing what he can to ensure the provision of quality care while maximizing reimbursement and minimizing costs. However, Christopher has become quite frustrated by limitations that he perceives as obstacles to making changes to have positive outcomes. There is a wide variation in the performance level of his staff, and he feels that one staff member in particular is unable to meet basic requirements for productivity despite numerous supervisory interventions. Further, Christopher questions this staff member's level of clinical competence and is concerned about patient safety. Yet Christopher has received little support from his boss or from human resources to move toward terminating this employee's

employment and has even, because of hospital policy, felt pressured to give the employee a recent raise that Christopher did not feel accurately reflected the employee's performance.

Christopher is also experiencing other frustrations, including the lack of a comprehensive set of policies and procedures to guide the work of the staff he supervises and the lack of any formal mechanism by which he can assess and document the level of competence of his staff. He is concerned that he does not have all the knowledge and skills he needs to manage the department's budget successfully. Finally, he recognizes that some of the processes and systems that are used in his department seem inefficient, frequently result in errors and rework, and lead to confusion among his staff, but he is unsure how to address these problems in an organized and strategic manner.

Questions

As you read this chapter, consider Christopher's situation and ask yourself the following questions:

1. Does Christopher appear to have the necessary authority required to manage his department and to be held responsible for the outcomes?
2. What types of managerial knowledge and skills does Christopher need to develop to help him confront the challenges he is facing?
3. How might Christopher consider the traditionally identified management functions of planning, organizing, directing, and controlling to begin to logically confront the challenges described?

Understanding the roles and functions of an occupational therapy manager requires that one consider the role of the manager in relation to administrators and supervisors. Table 67.1 provides definitions of **administration**, **management**, and **supervision**. An administrator may be defined as a member of a *governing body,* such as a Board of Directors of an organization; the top officials, such as the President or Chief Executive Officer of an organization; or that official's leadership team. Together, administrators are responsible for the overall welfare of the organization. Administrators may supervise others but often are only indirectly responsible for the oversight of the work of the organization. They frequently delegate authority for

much of the day-to-day coordination of organizational functioning to managers.

Managers are responsible for oversight of work units, such as occupational therapy departments, and of their contributions to the organization's mission. In addition to other roles and functions, managers often supervise others, but not all supervisors are managers. Supervisors contribute to meeting the mission of the organization by overseeing the daily work of front line employees.

Understanding the important concepts of **requisite managerial authority** and **power** can help us to further clarify how an occupational therapy manager is different from an organizational administrator or from an

TABLE 67.1	ADMINISTRATION, MANAGEMENT, AND SUPERVISION DEFINED
Administration	The process of guiding an organization through the authoritative control of others completed by the governing body of the organization
Management	The process of guiding a work unit by planning for future work obligations, organizing employees into functional units, directing employees in the process of completing daily work tasks, and controlling work processes and systems to assure adequate quality of work output
Supervision	The process of guiding an organization through the authoritative control of others completed by the governing body of the organization

occupational therapy supervisor. Elliot Jaques (1998) defined requisite managerial authority as "the level of control and discretion that a manager must have to be fairly held responsible for the outcomes of work groups." For example, requisite managerial authority includes the authority to hire and fire employees and to determine within reason how rewards are distributed. However, in occupational therapy, it is not uncommon for a therapist to accept a formally named position within an organization in which he or she has supervisory responsibilities but does not have requisite managerial authority. An example of such a position would be that of a *senior therapist,* an individual who might have specialized or advanced skills and who might provide clinical supervision to other therapists but who does not have the full range of managerial responsibilities.

THE FOUR TRADITIONAL MANAGERIAL FUNCTIONS

One common approach to categorizing the responsibilities of managers within an organization is to group them according to four major functions: **planning**, **organizing** (and staffing), **directing**, and **controlling**. Staffing is sometimes identified as a separate function but is often included as part of the organizing function. These functions are briefly defined and further discussed in the next sections of this chapter.

Some commonly identified functions of management are as follows:

◆ **Planning:** the process of deciding what to do by setting performance objectives and identifying the activities that need to be carried out to accomplish these objectives
◆ **Organizing and staffing:** designing workable units, determining lines of authority and communication, and developing and managing patterns of coordination
◆ **Directing:** providing guidance and leadership so that the work that is performed is congruent with goals
◆ **Controlling:** establishing performance standards, measuring, evaluating, and correcting performance

Administrators, managers, and supervisors all perform various tasks related to these four functions, but the scope of these tasks varies for the different levels of leadership. Table 67.2 provides a comparison of sample functions of administrators, managers, and supervisors organized according to the traditional four functions of management.

Planning

Planning is the process of establishing short- and long-term goals, measurable objectives, and action plans that are both congruent with the mission of the organization and consistent with the vision that current organizational leaders have established. An organization's mission is typically established by its founders and remains relatively stable. It is often expressed in the form of a mission statement that sets forth the organization's purpose, products, and services. A vision statement, by contrast, expresses an inspirational message about what a department or organization would like to become as it seeks to fulfill its mission (Hoyle, 1995).

It is common to distinguish between strategic, or long-range, planning and planning as a day-to-day management function. Strategic planning is the process of determining the long-term goals of an organization and formulating strategies to accomplish these goals (Liebler & McConnell, 2004). Goals are a reflection of the scope of the desired outcomes. Objectives are measurable steps that are taken to reach these goals. While a strategic plan may identify goals that are intended to be achieved over a three- to five-year (or longer) period of time, objectives that managers identify often are based on a one-year period that corresponds with an organization's financial cycle, or fiscal year.

Over the last several decades, strategic planning has moved in and out of favor as organizations have struggled to keep up with the frenetic pace of changes in technology, public policy, and the global economy. Operating in an environment in which change is the norm may force long-term planning, especially the related processes of mission review and visioning, to become more important (Braveman, 2006a). Because the environments in which most organizations function are constantly changing,

TABLE 67.2   COMPARISONS OF SAMPLE FUNCTIONS OF ADMINISTRATORS, MANAGERS, AND SUPERVISORS

Management Function	Organizational Administration	Occupational Therapy Managers	Occupational Therapy Supervisors
Planning	◆ Establishment of organizational mission and vision ◆ Creation of an organizational culture ◆ Strategic planning ◆ Financial forecasting ◆ Establishing organization policies and procedures	◆ Interpreting the organizational mission and vision for the staff ◆ Aligning the departmental mission and vision with the organizational mission and vision ◆ Establishing departmental objectives ◆ Creating and implementing the departmental budget ◆ Establishing departmental policies and procedures	◆ Integration of the mission and vision of the organization and department in the daily work of the department and staff ◆ Oversight of work tasks related to achievement of departmental objectives ◆ Ensuring that work is completed effectively and efficiently
Organizing and staffing	◆ Oversight of the organizational chart and determination of primary organizational structure ◆ Establishing systems for staff functions such as human resources and marketing*	◆ Recruiting, hiring, orienting, and training staff ◆ Appraising performance, determining rewards, and overseeing disciplinary actions	◆ Providing management with feedback related to the appropriateness of staffing levels ◆ Provide daily supervision, coaching, and feedback to line staff
Directing	◆ Development of parameters for staff training, education, and development ◆ Mentoring and coaching middle managers	◆ Mentoring and coaching supervisors ◆ Implementing staff training, education, and development programs	
Controlling	◆ Establishing systems to measure organizational performance and achievement of key organizational goals ◆ Setting expectations for performance for management	◆ Oversight and implementation of departmental continuous quality improvement and quality control systems ◆ Establishing performance expectations and measures for department functions and outputs	◆ Ensuring compliance with policies and procedures ◆ Measuring and recording quality indicators ◆ Alerting management to systems problems

*Staff functions relate to the overall maintenance and management of an organization (e.g., human resources, housekeeping, or marketing). Line functions relate to carrying out the primary work of the organization (e.g., occupational therapy, physical therapy, or social work in medically oriented organizations).

managers can spend a great deal of their time planning for change, employing change management strategies, and helping others to adjust to new conditions.

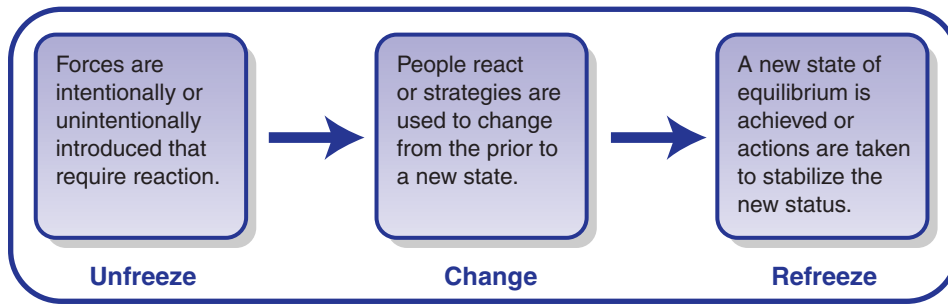
The scholarship on change management has focused on four principal aspects: (1) theoretical models and frameworks that reveal and guide organization members' and researchers' thinking about organization change, (2) approaches and tools for creating and managing change, (3) factors that are important to successful change management, and (4) outcomes and consequences of the process of change management (Branch, 2002). It is strongly recommended that new managers become familiar with theories of change and strategies for promoting successful change. For example, Kurt Lewin proposed a prominent and relatively simple approach to understanding change that includes three stages (Figure 67.1) (Lewin, 1997). These three stages are (1) unfreezing or recognizing the need to change, (2) changing, and (3) refreezing


FIGURE 67.1 Lewin's three-stage model of change

or standardizing new procedures or ways of behaving. Managers can apply this theory by identifying different strategies to use with employees during each of the three stages to facilitate the change process.

In addition to establishing goals and objectives, planning includes determining the needs for the human resources, materials, supplies, facilities, and equipment required to meet goals and objectives. Both the financial planning that is involved in developing and managing a department budget and the writing of policies and procedures that guide the use of materials, supplies, facilities, and equipment and that guide staff in daily activities are also commonly considered components of planning. Another example of planning in which an occupational therapy manager might become involved is facilities planning. Planning new therapeutic spaces can be extraordinarily complex and should not be undertaken without consultation with others who have previously been through the process and should definitely not be attempted without a qualified construction team that is experienced in the design of clinical or therapeutic spaces.

Organizing and Staffing

Ideally, administrators and managers determine the structure of an organization and its departments. The structure of an organization or a department can vary in complexity. Many organizations that have existed for some time have undergone numerous restructurings that were intended to improve efficiency and effectiveness and, often, to reduce costs. These restructurings might have been planned and executed in a logical manner, or they might have happened without an overall plan as the organization grew, added new services, or had to respond to environmental influences. An organizational chart helps to facilitate understanding of an organization's structure. Liebler, Levine & Rothman (1992) described an organizational chart as a management tool that visually depicts the following aspects of an organization:

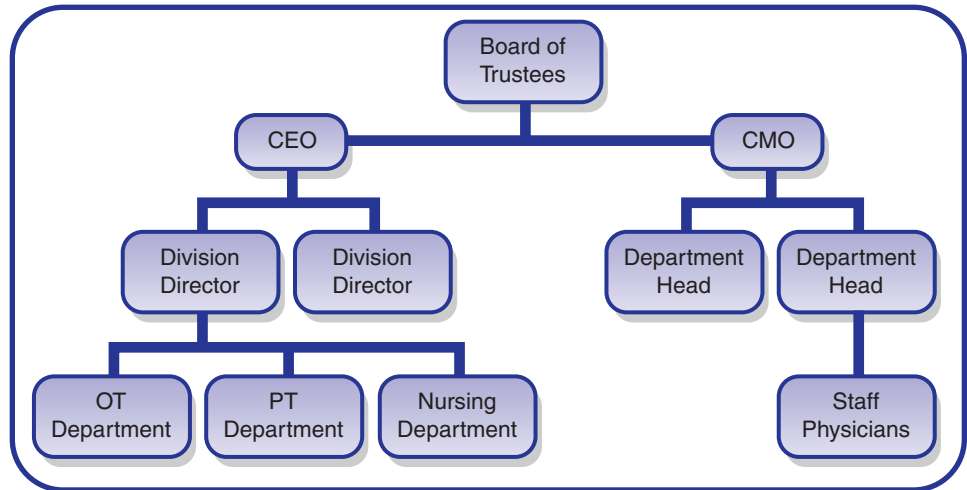
◆ Major functions, usually by department
◆ Relationships of functions or departments
◆ Channels of supervision
◆ Lines of authority and of communication
◆ Positions by job title within departments or units

When one examines an organizational chart, one must keep in mind that it is a static picture of the organization or department. It might not reflect recent changes, vacancies, or informal relationships, since written charts typically indicate only formal lines of command. The organizational chart of many large organizations support the notion that systems are often quite organic in how they grow and are restructured over time.

Although few large organizations fit the perfect theoretical profile of any formal organizational form or structure, there are a few basic structures commonly found in health care and service organizations and systems that are useful for a new manager or practitioner to understand. These structures include the dual-pyramid form of organizing: product line or service line organizations, and hybrid or matrix organizations.

The term *dual-pyramid* has been used to describe the common structure found in many medical model settings, such as acute and general hospitals. The pyramid structure is also commonly found in community-based organizations, although the second pyramid representing medical staff might be absent in these cases. A pyramid is typically used to represent an organization of personnel with upper management at the top and line staff at the bottom (Figure 67.2).

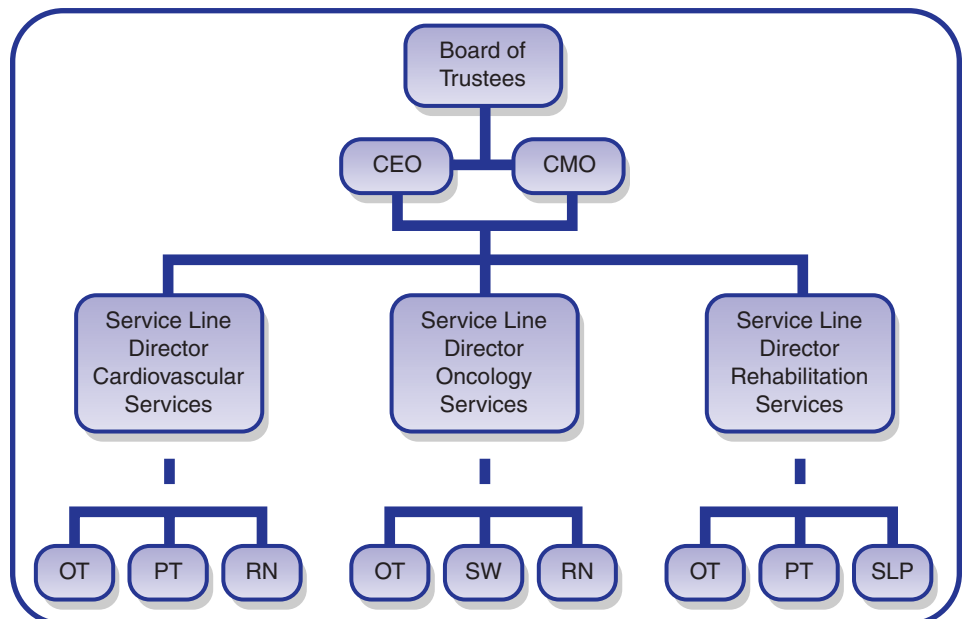
In the dual-pyramid form of organizing, the traditional relationship between medical staff and administration results in the structure shown in Figure 67.2, in which two supervisory pyramids are arranged side by side. One pyramid represents the structure of the professional staff that is organized in departments, including administration (with the chief executive officer at the top of the pyramid); allied health professionals such as occupational therapy, physical therapy and social work; and all support services such as engineering, housekeeping, and human resource personnel. A second pyramid mimics that structure but represents the organization of the medical staff with the chief medical officer at the top of the pyramid, department heads as middle management, and staff physicians as line employees (Braveman, 2006a). Although the medical staff, professional staff, and support staff all ultimately report to a board of trustees or board of directors, there are two distinct chains of command that result in the authority and accountability systems being separated on the basis of function within the organization.

FIGURE 67.2 A sample dual-pyramid form of organizing. Source: Reprinted with permission from Braveman (2005). *Leading and managing occupational therapy services: An evidence-based approach.* Philadelphia: F. A. Davis.


A second common form of organizational structure is the *product line,* or *service line,* structure. In a product line structure, personnel are organized according to the service or product that they provide rather than according to the specific function that they complete or their departments based on education or training. A board of directors maintains ultimate authority, and the chief executive officer and chief medical officer often still maintain parallel but distinct responsibilities and authority. An example of the organizational chart for a product line form is provided in Figure 67.3.

Additional ways of structuring organizations may combine elements of the two structures described above; however, the dual-pyramid and product line structures are the most common.

Each of the methods of organization has advantages and disadvantages, and understanding how structure influences the function of an organization can help one to capitalize on the system's benefits and compensate for its limitations. For example, health care organizations that have a dual-pyramid structure rely on departments structured by discipline or professional education and training to provide for strong supervision of staff and their clinical performance. Thus, communication within a professional discipline is facilitated, and the daily work of a unit may be completed more efficiently. Because a department manager or supervisor representing each discipline has direct access to staff and to the data related to routine processes and interventions, continuous quality improvement and outcome measurement of using these data are

FIGURE 67.3 A sample product line management form of organizing. Source: Reprinted with permission from Braveman (2005). *Leading and managing occupational therapy services: An evidence-based approach.* Philadelphia: F. A. Davis.


also easier to measure in a dual-pyramid organization. Nonetheless, in this form of organizing, communication across disciplines might be more complicated, which can pose potential hazards for developing and managing new programs. Problem solving and process improvement in existing programming can be cumbersome when staff members feel that it is necessary to communicate up through the chains of command. The advantages and disadvantages of the dual-pyramid and the product line forms of organizing are summarized in Table 67.3.

Once decisions have been made about how an organization or a department is to be structured, administrators and managers ideally work together to develop plans for staffing and human resources management. Functions related to staffing, such as advertising or the development of policies and procedures related to employment, may be performed by a human resources department. Occupational therapy managers are frequently involved in a num-ber of other staffing-related activities. A sample list of these activities is as follows:

◆ Human resources planning: collaborating with administrators and supervisors at all levels of the organization to forecast the short- and long-term personnel needs of the organization, based on the organizational mission, leadership vision, and strategic plans
◆ Recruitment: seeking out and attracting adequate numbers of qualified personnel to meet ongoing organizational needs, including contingencies, such as resignations and leaves of absence
◆ Hiring: selecting the appropriate personnel for vacant positions and associated activities, such as benefits counseling, background, and reference checks
◆ Orientation: introducing the new employee to organizational policies, procedures, values, personnel, and environments

TABLE 67.3   ADVANTAGES AND DISADVANTAGES OF COMMON FORMS OF ORGANIZING

	Dual Pyramid	**Product Line**
Communication	◆ Communication within a discipline is facilitated.	◆ Communication between disciplines becomes harder.
Planning	◆ Planning for activities such as professional development and clinical supervision is facilitated, but program planning becomes harder.	◆ Program planning and planning for interdisciplinary activities such as program evaluation is facilitated, but planning functions within disciplines becomes harder.
Budgeting	◆ Tracking and planning for finances related to single discipline costs are facilitated, but tracking and planning for interdisciplinary activities (e.g., cost per unit of care) are harder.	◆ Tracking and planning for finances related to programmatic costs are facilitated, (e.g., cost per unit of care) but tracking and planning for discipline-specific activities are harder.
Staffing	◆ Some needs such as providing coverage for leaves or vacancies may be easier, but the need to communicate with other managers increases. Recruitment activities are facilitated.	◆ Staffing activities influenced by other disciplines such as scheduling programmatic elements may be facilitated, but coverage for leaves or vacancies becomes more difficult. Recruitment of staff may be more difficult, or you might need to rely upon managers from other disciplines for assistance.
CQI, program evaluation, and outcomes	◆ Improving discipline-specific processes is easier, as is measuring single-discipline outcomes and indicators of program evaluation, but interdisciplinary programs require extra effort.	◆ Improving interdisciplinary or program processes is easier, as is measuring program outcomes and indicators of program evaluation, but discipline-specific elements require extra effort.
Professional development	◆ Development of discipline-specific skills related to assessment and intervention may be facilitated by the ease of access to disciplinary specialists.	◆ Development of interdisciplinary skills related to the needs of a population or program development or implementation may be facilitated.

Source: Reprinted with permission from Braveman, B. (2006). *Leading and managing occupational therapy services: An evidence-based approach.* Philadelphia: F. A. Davis

◆ Training and development: meeting the short- and long-term educational and professional development needs of employees at all levels of the organization

◆ Separation: terminating the employment of personnel due to resignation or inadequate job performance or that which may come about as the result of a decrease in organizational resources

Directing

Directing is the management function that involves giving guidance and leadership to subordinates so that the work that is performed is goal-oriented and contributes to meeting organizational or departmental requirements. More specifically, a director could assign and manage the workload, develop and implement policies and procedures to guide others in uniform completion of their work, provide mentoring and coaching for improved future performance, and appraise performance by providing feedback to employees about current performance.

Managing the workload is a complicated process that involves projecting the amount of work to be done, determining which resources are necessary to complete the work, and managing these resources to make certain that the appropriate person with the right skills and right equipment and space is available when needed. The workload is typically projected on a yearly basis as part of planning a departmental budget, but it may also be done on a week-to-week, day-to-day, or even hourly basis.

Writing policies and procedures to guide staff in both their daily tasks and their use of materials, supplies, facilities and equipment is a specific aspect of directing that is typically the responsibility of a department manager. Policies are statements of values that are congruent with the mission and that justify the boundaries that govern the services provided. They set parameters for making decisions about day-to-day operations. Procedures outline the specific tasks that should be completed or that provide specific direction about how a policy should be implemented. A manager should not only be able to cite a policy or procedure, but also be able to give the underlying logic for the policy's existence.

Most organizations follow a prescribed standard format that guides managers in deciding what to include in a department's Policy and Procedure Manual. If a policy and procedures format is not provided, the organization may purchase existing customizable resources on the Internet. The basic components of a policy and procedure protocol are presented in Box 67.1.

Managers also serve as mentors, coaches, and appraisers of overall work performance; and resources to develop the skills and knowledge necessary for these functions should be sought out both from within the profession of occupational therapy and from outside of it. The American Occupational Therapy Association has a number of resources related to supervisory tasks specific to occupational therapy assistants or to occupational therapy aides (www.aota.org). For more generic information on models of supervision, theories of motivating others, developing effective performance appraisal systems, or providing effective mentoring or coaching; managers should look outside the occupational therapy literature. For example, associations such as the American Management Association (www.amanet.org) or the National Association for Employee Recognition (http://www.recognition.org/) provide resources about how one may become an effective supervisor.

Controlling

Controlling is a management function that relates to the processes of establishing specific work performance standards and the measurement, evaluation, and correction of performance. A key responsibility of managers is to promote the delivery of appropriate intervention through the use of quality control (QC) mechanisms and continuous quality improvement (CQI). QC and CQI are related functions, but each serves a different purpose and relies on different philosophies, strategies, tools, and techniques. The focus of QC is to intervene when the quality or quantity or work output falls below predetermined measures (indicators). The focus of CQI is to improve customer sat-

---

BOX 67.1

BASIC COMPONENTS OF A POLICY AND PROCEDURE

(This is not for an entire manual but the components of a single policy and procedure statement that is typically one document within a manual.)

◆ Policy statement(s): Brief statements of the guiding principles to be communicated

◆ Purpose statement(s): Brief statements that outline the reasons for inclusion of the policies or procedures

◆ Applicability: Lists the employee groups to which the policy and procedure applies (e.g., all occupational therapy department staff members)

◆ Procedures: Statements outlining the specific actions to be taken by the identified employee groups and criteria for determining adherence to the policy

◆ Responsibility: Identifying the individuals who are responsible for oversight of the policy and procedure (e.g., all occupational therapy team leaders)

◆ Review period: Lists the date of the last review and update of the policy and procedures (typically policies and procedures are reviewed on an annual basis)

Step 1: Plan
What process could be improved and how would that lead to increased efficiency and ability to meet customer requirements?

Step 2: Do
Carry out process improvement while collecting data

The Plan Do Check Act Cycle

Step 4: Act
Study the results and make lasting changes with decisions based on data

Step 3: Check
Measure the impact of the improved process

FIGURE 67.4 The Plan, Do, Check, Act (PDCA) Cycle

isfaction by constantly striving to meet customer expectations through enhancing critical processes. A critical process is defined as any process that is performed to produce the work of an organization. Examples of occupational therapy critical processes include responding to referrals for service, administering assessments, fabricating adaptive equipment, and making postdischarge referrals.

CQI is viewed both as a philosophy of management and as an approach to managing. A CQI approach requires that managers develop a wide range of skills related to assessing tasks and people. CQI projects may be complex and time-intensive because they rely on decision making based on data and therefore require an organized and structured approach to gathering and analyzing data. Explaining CQI in depth is beyond the scope of this chapter, but Figure 67.4 provides a brief overview of commonly identified steps to choose a critical process and implementing steps that improve its performance. The Plan, Do, Check, Act (PDCA) Cycle may be invoked under other names or acronyms, but the steps of the CQI process remain constant. The most common tools and techniques and their uses are presented in Table 67.4.

FINANCIAL MANAGEMENT

An important function of most managers is the planning and controlling of a department budget. Budgets are typically planned for a calendar year or a fiscal year (e.g., many organizations operate on a fiscal year that runs from July 1 to June 30). The process of planning and managing a budget requires that a manager have a comprehensive understanding of the goals and objectives of the larger organization so that he or she can establish priorities for funding that support this mission over time.

Occupational therapy practitioners who want to become managers or directors of an occupational therapy department or to own and operate their own businesses are encouraged to learn financial planning and manage-

ment and to become well versed in the use of information management technologies, such as spreadsheets or other financial management tools. Braveman (2006b) notes that effective financial planning and management requires a working knowledge of the following:

◆ Health care systems, including city, county, state, and national systems
◆ Payment and reimbursement structures, such as Medicare, Medicaid, Worker's Compensation, private insurance, and grants or foundation support
◆ Human resources systems and costs, including salary and benefit administration, training and educational costs and systems, and recruitment and retention structures
◆ Equipment and materials purchasing and management, including medical supplies, such as splinting or assistive and adaptive equipment, office supplies, and other supportive supplies
◆ Facilities management, maintenance and improvement protocols, including cleaning and maintenance of physical plant structures

Budgets may also include revenue and expense streams, although it is not uncommon for a community-based organization manager to have oversight of only expenses with no control over direct sources of revenue. Typically, the revenues and expenses associated with each department in an organization are given some sort of marker or code in the organization's accounting system that indicates how the subset of revenues and expenses relate to that department. These subsets of revenues and expenses are commonly referred to as *cost centers.* They may represent the budget of a single department or of several related services. Common examples of revenues and expenses are shown in Table 67.5 and are further explained in the following section.

Revenues may include third-party payments for services from private and public insurers, grants from government agencies or private foundations, or gifts from

TABLE 67.4 COMMON CQI CONCEPTS, TOOLS, AND TECHNIQUES

Core Concepts	Use/Importance/Summary
◆ The Plan, Do, Check, Act (PDCA) Cycle	◆ The overarching framework for guiding and ordering CQI activities
◆ Critical processes	◆ The important processes that are repeated again and again to complete the organization's or department's work
◆ Operational definitions	◆ A quantifiable description of what to measure and the steps to follow to measure it consistently
◆ Customers and customer requirements	◆ Identifying internal and external customers or individuals who receive the output of your work and their valid requirements
◆ Quality indicators	◆ Quantitative measures of compliance to valid customer requirements
◆ Variation	◆ The spread of process output over time. Discriminating between natural "common cause" variation that is inherent in a process and the uncommon "special cause" variation that you want to eliminate from a process or emulate if positive
STRATEGIES	
◆ Ground rules for meetings	◆ Explicit agreements about how a team will work together and behave as team members
◆ Roles for effective meetings	◆ Assigning roles such as the leader, scribe, facilitator, and timekeeper can lead to more effective meetings
◆ Consensus	◆ A method for reaching agreement whereby all members agree to fully support a decision even if it is not how they would act if they were acting alone
TOOLS	
◆ Process flow charts	◆ A visual representation of the steps in a process used to highlight redundancies, rework, or bottlenecks
◆ Control charts	◆ A chart with statistically determined upper and lower control limits used to determine whether a process has changed and to highlight variation
◆ Cause and effect diagrams	◆ A tool to assist in determining possible root causes to a problem.
◆ Proposed Options Matrix	◆ A tool for comparing possible options for action against a set of predetermined criteria.
TECHNIQUES	
◆ Data stratification	◆ Methods for categorizing collection of data; it is important to decide how to stratify data before you collect it
◆ Designing an effective data collection tool	◆ Tools to gather facts on how a process works or its effectiveness that allows for accurate collection of data in the simplest manner
◆ Balancing tasks and people	◆ Attending to both the needs of team members and the work to be completed to maintain team motivation
◆ Icebreakers	◆ Short activities to help team members learn about each other or to become more comfortable interacting with each other
◆ Brainstorming	◆ A method for creatively generating lists of possible causes of problems, solutions, or processes to improve
◆ Multivoting	◆ A decision-making method to narrow a larger number of options to a number that can be reasonably discussed individually

TABLE 67.5 EXAMPLES OF REVENUES AND EXPENSES	
Revenue	**Expenses**
Individual 15 Minutes: ADL Treatment	Variable Expense—Salary
Individual 15 Minutes: Cognitive Remediation	Variable Expense—Wages
Individual 15 Minutes: Community Reintegration	Variable Expense—Office Supplies
Individual 15 Minutes: Neuromuscular Facilitation	Variable Expense—Splinting Supplies
Group 15 Minutes: Home Management	Fixed Expense—Phone
Group 15 Minutes: Communication Skills	Fixed Expense—Rent
Group 15 Minutes: Community Reintegration	Fixed Expense—Utilities

individuals or foundations. Forecasting revenues for a department requires that the manager be able to accurately predict the volume of work that a department will deliver and how that work will happen. In some settings, almost all occupational therapy intervention is provided to consumers on a one-to-one basis, while in some settings, intervention is provided to groups. By accurately predicting the total volume of work for a year, managers are able to predict the total gross revenue by multiplying the number of work units (e.g., a 15 minute unit of therapy) by the charge for each unit of service. It is important to note that in the current managed care environment, few payers reimburse at the full rate that is billed and the net revenue, or the amount of revenue after all discounts to insurers and nonreimbursed charges are accounted for, is typically much less than gross revenue.

Expenses typically include costs associated with personnel, supplies, facilities management, and equipment. As part of the process of forecasting the expense budget, managers determine the number of full-time equivalent employees that will be required to handle the projected work volume. Setting productivity standards, or the amount of work a practitioner is expected to perform in a given period, and helping staff to meet such standards is a common challenge faced by occupational therapy managers. Personnel expenses can include both salary expenses for professional staff that are exempt from the labor laws that require an organization to pay extra for overtime effort and wages for support staff that are nonexempt. Occupational therapists are often categorized as exempt, and occupational therapy assistants and occupational therapy aides are often categorized as nonexempt.

Nonpersonnel expenses; such as supplies, equipment, food, phone, continuing education, or travel allowances must also be projected. In private businesses, expenses for utilities and rent must also be considered. These expenses are categorized as either fixed or variable expenses. Fixed expenses are costs that are not directly influenced by changes in volume, such as expenses budgeted for em-

ployee continuing education. Variable expenses are those that are directly influenced by changes in volume, for example, some types of office supplies or food used for meal preparation activities. Although there might not always be a direct correlation, over time, one will be able to estimate how an increase or decrease in volume might affect expenses.

To effectively plan and control a budget, managers must learn many useful concepts and strategies Some organizations may provide training or orientation for new managers, but most often it is assumed that a new manager understands the basic information needed to develop and oversee a budget. People who are assuming their first management position would benefit from additional education or training in financial management and from networking with experienced managers. The American Occupational Therapy Association provides electronic mailing lists and other resources for managers through its Administration and Management Special Interest Section (AMSIS). More information on AMSIS and other special interest sections (SIS's) can be found at www.aota.org.

TECHNOLOGY AND MANAGEMENT

The technological advances in medicine, information management, communication, and related areas that have occurred over the last few decades are astounding. Managers must evaluate and integrate a wide range of technology into their departments, ranging from computer software programs to clinical equipment, such as driving simulators or environmental controls. Choosing and successfully integrating a new technology requires that managers synthesize information, including costs of initial purchase, maintenance, space, and training requirements and the rate at which the specific technology is advancing so that an estimate can be made of when the current technology may become outdated.

TABLE 67.6   COMMON TYPES OF DATA, SOURCES, AND POSSIBLE USES

Type of Data	Source	Use
Demographics (age, sex, educational level, etc.)	◆ Admissions records ◆ Public data sets	◆ Program planning ◆ Program evaluation
Revenue (payer source, rates, discounts)	◆ Accounting ◆ Budget reports	◆ Budgeting ◆ Program planning
Expense (accounts payable)	◆ Financial reports ◆ Purchasing records	◆ Budgeting ◆ Program planning and evaluation
Payroll (salary, benefits, leave usage)	◆ Accounting ◆ Budget reports	◆ Staffing plans ◆ Recruitment and retention
Productivity (visits, staff activity)	◆ Automated charge systems ◆ Department billing records or productivity tracking sheets	◆ Staffing plans ◆ Performance appraisal ◆ Recruitment
Personnel (licensure, competencies, professional development, performance)	◆ Human resources ◆ Departmental personnel files ◆ Professional association data sets	◆ Accreditation visits ◆ Staffing plan development ◆ Professional development plans
Clinical (diagnosis, intervention, outcomes)	◆ Medical records ◆ Outcome databases	◆ CQI ◆ Program evaluation
Legal (contracts, leases)	◆ Legal or grants and contracts department	◆ Facility planning

One major area of technology used by managers is that employed in information management; which includes the use of computers for documentation, billing, and financial management, as well as data collection and analysis for outcomes management. Table 67.6 lists common types of data and information that must be collected and managed and their possible uses. Becoming skilled at the use of software programs to organize and analyze the large amount of data available to most managers requires extra work but is well worth the effort.

MARKETING

Occupational therapy managers are often responsible for assessing the needs of the target populations served by their department or organization; determining programmatic strategies for meeting these needs; designing, implementing, and evaluating the interventions to meet identified needs; and promoting the intervention to consumers, payers, physicians, and others. These processes, collectively, are called *marketing.* Traditionally, the following four steps are identified in the marketing process:

◆ **Organizational assessment:** examination of the factors within an organization that will influence the development and promotion of a new product or service

◆ **Environmental assessment:** examination of the data and other forms of evidence, including the needs of target populations, that will guide the development and promotion of a new product or service
◆ **Market analysis:** use of the information gained during organizational and environmental assessments to validate perceptions of the wants and needs of the target populations that will receive a new product or service
◆ **Marketing communications:** packaging and promoting a product so the target populations and other key stakeholders in the new product or service have a clear understanding of what the product or service is and how it may be accessed

In larger organizations, other professionals, such as members of a marketing department, often perform portions of the marketing process, such as collecting demographic and other data about potential consumers, or may be called on to collaborate with a manager to perform these functions. However, occupational therapy managers who are also business owners or who work in community-based, nonprofit organizations might need to learn the marketing process in greater depth. These managers benefit from establishing effective networks with other managers and becoming active in professional organizations, such as their state and national occupational therapy associations and business-oriented groups such as the local Chamber of Commerce.

WHO SHOULD BE A MANAGER?

During the 1990s, numerous professions began to address managerial competencies with increasing urgency and concern, emphasizing the need to determine the initial competence of health professionals, to assess specific job competencies as professionals are hired and begin to work, and to promote the professionals' continuing development of competence (Braveman, 2006c). The assessment of initial competency and facilitation of continuing development of staff competency is a function of the occupational therapy manager.

Before assuming a role as an occupational therapy manager, one should assess one's own level of preparedness to perform the tasks associated with the role. Although the assessment of competencies for managers has not received the same attention by certifying or regulatory bodies, such as accrediting agencies, competency development and assessment have been addressed, and some empirical investigations of managerial competencies have been conducted by a number of professions (Braveman, 2006c).

Some competencies might be considered "universal" for managers. One method of identifying managerial competence is to compare their performance against the "yardstick" of previously described traditional managerial functions (e.g., planning, organizing and staffing, directing, and controlling). As a guide for this process, each of the management functions is listed below with sample areas for assessment of competency provided for each. (See Table 67.2 for additional areas for development of competencies.)

Sample Areas for Assessment of Competency for Managers

- Planning
  - Use of goal setting
  - Financial management skills
  - Understanding the changing health care environment
  - Effectiveness in decision making
- Organizing and staffing
  - Understanding team structure and flexible work design
  - Designing and leading effective teams
  - Using cooperation techniques
  - Applying coordination techniques
- Directing
  - Interpersonal competencies
    - Communication skills
    - Communicating with the boss
    - Communicating with peers and others
    - Communicating with employees
    - Being politically astute
    - Managing conflict
    - Managing diversity
  - Role model competencies
    - Demonstrating professionalism in conduct and demeanor
    - Enhancing technical competence
- Controlling
  - Empowering employees
  - Applying continuous quality improvement efforts

Other managerial competencies will depend on the nature of the manager's job. Not all managers perform the same tasks and functions, so it is important that, before accepting a management position, one understands what will be expected of one and have done a thorough assessment of readiness by identifying strengths and areas in which help might be needed. Needing supervision or help does not necessarily mean that a new manager cannot take on his or her first managerial position. But knowing when to ask for assistance is essential if one wishes to ensure success as a manager.

COMMENTARY ON THE EVIDENCE

The State of Evidence Related to Management

The existing evidence on effective managerial strategies and practices has been produced by multiple disciplines and fields such as business, organizational development, organizational psychology, social work, and nursing. The topics that have been investigated are also diverse; examples include effective leadership strategies, performance appraisal processes, factors affecting recruitment and retention, effective recognition and reward structures, change management, and continuous quality improvement.

A variety of forms of evidence, including the results of empirical studies, program descriptions, and descriptions of managerial interventions, are published widely in a range

COMMENTARY ON THE EVIDENCE   *Continued*

of professional journals, Websites, and books. Although the body of evidence specifically related to management in health care organizations might be more limited, it is growing, and occupational therapy managers who wish to use an *evidence-based* approach to management will benefit from research and science conducted by other disciplines such as those mentioned.

For example, while evidence related to effective leadership is still evolving and much of the existing evidence is descriptive, there have been well designed empirical investigations of topics such as the direct impact of leader behavior on subordinate performance (Dvir, Eden, Avolio, & Shamir, 2002; Levy, Cober & Miller, 2002). Some of these studies have included randomized control-study designs.

While they are mostly descriptive, there is a plethora of reports on factors affecting the recruitment and retention of health professionals. Much of this evidence is found outside of the occupational therapy literature, but a few studies including occupational therapy practitioners or specifically on occupational therapy have been published. For example MacRae, van Diepen, and Patterson (2007) and Daniels, Vanliet, Skipper, Sanders, and Rhyne (2007) provide reports of factors that influenced students willingness to consider placement in rural underserved areas and the

implications this had for staffing in these areas. Mills and Millsteed (2002) investigated factors affecting the retention of occupational therapists in rural Australia. Painter, Akroyd, Elliot, and Adams (2003) examined burnout in a sample of 521 occupational therapists in comparison to other health care professions and Okerlund, Jackson, Parsons, and Comsa (1995) explored factors affecting recruitment and retention of occupational therapists in Utah.

While occupational therapy managers can certainly make valuable judgments by generalizing from evidence produced in other disciplines, the profession would benefit from research specifically related to occupational therapy. Questions for investigation might include the following:

◆ What factors affect long-term retention within the profession, and how might we reduce attrition from the discipline?
◆ How might occupational therapy managers influence the delivery of culturally relevant services?
◆ What factors influence the effectiveness of interdisciplinary teams?

As in most areas of occupational therapy practice, the profession will greatly benefit from the development of further evidence on management.

CONCLUSION

This chapter has provided an overview of the numerous tasks, functions, and responsibilities that an occupational therapy manager may perform. I hope that the reader has gained a perspective on the variety and complexities of a manager's responsibilities and a greater appreciation of the need for a beginning manager to get appropriate training and education. Managers work closely with the administrators and supervisors in large organizations, but small business owners and entrepreneurs also function independently as managers. Fortunately, many resources are available that are specific to occupational therapy managers, and more resources may be found in other fields, including business, psychology, and organizational development, that are useful guides for a manger performing his or her job.

Supervision

MARY JANE YOUNGSTROM

Learning Objectives

After reading this chapter, you will be able to:

1. Understand the roles and functions of supervision.
2. Differentiate types of supervision.
3. Describe supervisory processes and implementation.
4. Describe approaches to managing performance.
5. Apply AOTA guidelines for appropriate supervision of OT personnel.

Supervision is an integral part of occupational therapy service provision. The supervisory process is consciously used in our profession to ensure that our clients receive safe and effective occupational therapy services. Although the ability to supervise skillfully is developed throughout one's practice career, the entry-level practitioner must be knowledgeable about the supervisory process and have a beginning understanding of how to give and receive supervision in a manner that is consistent with the profession's values and expectations. This chapter will provide you with an overview of what supervision is and introduce you to basic information you will need to develop positive and effective supervisory relationships. Supervisory expectations and standards specific to the occupational therapy profession will be presented.

SUPERVISION EMBEDDED IN PRACTICE

The supervision process is an everyday feature of each practitioner's work experience. It is a process that supports effective job performance as well as personal growth. Read the case study about Marta, an occupational therapist (OT), and Kim an occupational therapy assistant (OTA), which describes their career experiences with supervision.

In the case scenario, supervision was a regular feature of Marta's and Kim's daily work experience. Supervision provided feedback, direction and support for Marta and Kim as they learned to carry out their responsibilities effectively and supported them in their personal professional development to gain additional competencies. Each practitioner had a designated formal supervisor, but both Marta and Kim received informal peer supervision from other therapists. The close-knit nature of the work group and everyone's interest in providing the best possible care allowed this type of supervision to occur naturally. Adding supervisory responsibilities to their jobs expanded both Marta's and Kim's job roles and offered opportunities for personal growth.

As the case study illustrates, practitioners are involved in giving as well as receiving supervision. Supervisory skills are an expected entry-level

Outline   *Continued*

competency for OTs who are responsible for supervising OTAs (American Occupational Therapy Association, 2004). Entry-level OTAs may be responsible for supervising OT aides and later may move into supervisory roles with other OTAs. Both OTs and OTAs should know how to effectively provide supervision and benefit from it. Before exploring how to best provide supervision, let's first look at what supervision is and how it fits into the overall management structure of a work setting.

FORMAL SUPERVISION

Definition and Focus

Dictionaries trace the roots of the term *supervise* to the Latin roots *super-,* "over," + *videre-,* "to see" (Guralnik, 1987). Supervision is a process that involves "overseeing" or "watching" the work of another. The employer gives a supervisor formal authority to watch the work of others and ensure that the work meets the organization's goals and objectives. To effectively oversee the work of others, supervisors need to be familiar with the work of the positions they supervise. If individuals who move into supervisory positions do not have advanced knowledge or experience in the job positions they supervise, they are expected to familiarize themselves with the job tasks and responsibilities. This background allows them to provide the support and direction that supervisees need to solve work problems, to learn and grow in their jobs, and to better meet the organization's objectives (Figure 68.1).

How does the supervisor fit in the management structure of an organization? Braveman offers insight into the relationship of the two by defining *supervision* as "The control and direction of the work of one or more employees in a manner that promotes improved performance and a higher quality outcome" (Braveman, 2006, p. 142). Although supervisors may participate in all functions of management (planning, organizing, directing, and controlling), the majority of the supervisor's time is

---

CASE STUDY: *Marta and Kim: Supervision Embedded in Practice*

Marta began her career as an occupational therapist in a pediatric hospital. She worked with two other OTs and was supervised by Sarah, the senior OT in the setting. Although she met regularly with Sarah, Marta also sought and received feedback and guidance from the other OT, who was particularly experienced in working with children with head injuries. Marta used input from both OTs to expand her knowledge and develop her clinical reasoning skills. Six months after taking the job, she was given the responsibility of supervising volunteers who provided service in a playtime program for hospitalized children. She was responsible for orienting and training the volunteers. Periodically, she would observe their interactions with the children and was always available for questions. During her first year of practice, Marta was regularly involved in supervising both Level I OT and OTA students. She found these experiences to be rewarding. At the end of her second year

of work, she was assigned her first Level II clinical fieldwork student, whom she supervised on a daily basis. As the department's caseload expanded, an OTA, Kim, was hired, and Marta supervised Kim as they collaboratively worked to provide OT services to referred patients. Marta oriented Kim to the hospital and the department's policies and procedures. Initially, Marta closely observed Kim's treatments and/or cotreated with her. Kim came to the hospital with three years of experience with children, but her prior work had been in a school setting, so she was not as familiar with occupational therapy interventions involving acute medical conditions. Several months after Kim joined the department, she was given the responsibility for supervising the volunteers in the playtime program. She consulted with the recreational therapist, Terry, who worked on a different unit in the hospital, about strategies for expanding the play activities and improving volunteer participation.

FIGURE 68.1   Discussing weekend coverage plans and how they will be implemented is a common supervisory task in hospital-based occupational therapy.

typically focused on the directing and controlling functions (Allen, 1998, "Management Levels"). (See Chapter 67 for a discussion of management functions.) When we consider the supervisor's placement within the management hierarchy this becomes easier to understand (see Figure 68.2). Supervisors are placed closest to the staff level of the organization and typically do not supervise

others who are in management positions. Supervisors are generally considered to be the first line of management. Although they have some management responsibilities, they are not considered to be managers.

The emphasis primarily on the directing and controlling functions of management does not diminish the importance of the supervisor's role. Formal supervisors, because of their placement within the organization, serve as a bridge between the staff and higher levels of management. In this position, the supervisor must support and interpret management decisions as well as relay staff concerns to higher management. This position can be one of the most critical in the organization (Allen, 1998, "Management Levels"). How well the supervisor can convey management concerns to staff and staff concerns to management can make or break the organization's effectiveness and ability to adapt to change.

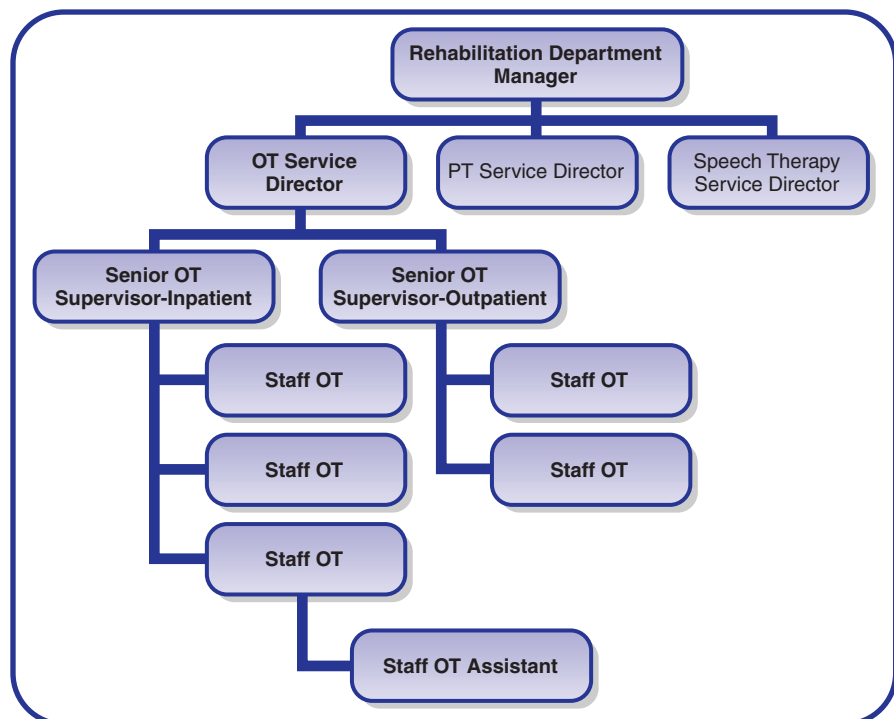
Up to this point, we have been emphasizing the supervisor's responsibility to the organization—to oversee work to ensure the organization's success. Supervision takes on an added dimension and responsibility when people who are members of a profession (e.g., occupational therapy, nursing, psychology) take on responsibilities to supervise other members of their profession in a work setting. The provision of professional supervision that is consistent with the profession's values and standards and supports the professional growth and development of the professionals who are being supervised is integrated with the supervisor's responsibility to meet the organization's needs. For example, the supervisor must not assign tasks and responsibilities that are outside of the


FIGURE 68.2   In this organization, the senior occupational therapists are supervisors, and the OT service director is a manager.

supervisee's professional scope of practice. The supervisor must be cognizant of the profession's standards and guidelines regarding frequency of supervision and requirements for training and competency. Overall, the supervisor must manage and supervise work in a manner that respects the profession's scope and that supports the supervisee's development of continuing competence.

The supervisor who is providing professional supervision must continually ask two related but different questions, which will guide the supervisor's observations, analysis, decisions, and actions:

1. Is the supervisee successfully accomplishing the work?
2. Is the supervisee demonstrating continued professional growth and development?

Supporting the supervisees' efforts to maintain and develop continuing competence does not conflict with supporting the supervisee to successfully accomplish the work. As individuals develop new skills and abilities, clients receive better care and organizations benefit from workers' improved expertise. The supervisor should be concurrently providing feedback on performance and assessing the supervisee's learning and professional development needs.

Functions of Supervision in a Professional Practice Setting

The supervisor's role in a professional practice setting encompasses three broad functions that are carried out under the broader management functions of directing and controlling. These functions are administrative, educational, and supportive functions (Kadushin, 1992). Table 68.1 lists examples of supervisory tasks for each function.

Administrative functions are directed toward managing the day-to-day work performance and process. Checking that all clients were seen and assigning clients to specific supervisees are examples of administrative tasks. Carrying out administrative functions ensures that the organization's day-to-day work is accomplished. The educational function is focused on the worker and is concerned with teaching and training, providing feedback about performance, and disciplining if necessary. Educational functions assist the supervisee to be effective in meeting job demands and also can help to promote the supervisee's own professional growth and development. The supportive function is directed toward relationships—both individual and group relationships within the workplace. This function focuses on developing harmonious relationships that will maintain a positive work environment in which people can be productive and successful.

INFORMAL SUPERVISION: PEER SUPERVISION

Supervision is typically understood as a formalized process that occurs in a work setting in which a person's work is supervised by a formally designated supervisor. In a health care professional practice environment where all staff members are committed to providing the best quality of service, informal peer supervision may also occur. Peer supervision is oversight that is provided by another professional who has no formal authority to provide supervision. The peer supervisor provides feedback and shares knowledge with the intent of influencing the peer professional's practices to improve client outcomes.

Peer supervision is a natural extension of each professional's responsibility to ensure that clients receive the highest quality of care. It may or may not be solicited by the "supervisee" practitioner. In the case study, Marta did seek input from her peers as a way of continuing to learn and grow as a professional, but not all practitioners seek input from others. When a peer therapist provides peer

---

TABLE 68.1 EXAMPLES OF SUPERVISORY TASKS WITHIN DIFFERENT SUPERVISORY FUNCTIONS

Administrative Function	Educational Function	Supportive Function
◆ Plan and assign workload ◆ Make schedules ◆ Set priorities for department's work activities ◆ Check performance against work standards ◆ Interpret policies and procedures ◆ Delegate work ◆ Provide written and verbal reports to managers	◆ Orient new staff ◆ Identify training needs ◆ Develop and provide training programs ◆ Identify and provide educational resources ◆ Assess performance and provide feedback ◆ Discipline	◆ Hold group meetings to allow for expression of concerns ◆ Meet individually with supervisee on a quarterly basis to check on progress toward work goals ◆ Provide informal and formal support for performance

supervision and feedback that is not requested, the intent is to improve client outcomes by offering information that could help other practitioners to improve their services.

In a professional and collegial work environment, peer supervision often occurs spontaneously and is seen as a benefit of working with others. Exchange and feedback among practitioners frequently occur as colleagues explore how to solve clinical problems and seek the best solutions for their clients. Such exchanges can be energizing for both parties. Engaging in peer supervision can be perceived as a method of mutual accountability and commitment to the profession's obligation to provide the best quality of services to clients

MENTORING

Being mentored by another professional is often confused with supervision. Mentorship and supervision are different types of relationships. In a mentor relationship, the mentor's primary concern is the personal and professional growth of the mentee (Robertson, 1992). The mentor does not necessarily have any formal authority to oversee the mentee's work. Although the mentor is interested in the work the mentee is doing, direct observation of work does not regularly occur as part of the mentoring function, and discussion does not focus on work performance per se. Instead, discussions between the mentor and mentee center on career options and decisions, identification of personal and professional growth needs and resources, and feedback about the mentee's behaviors and choices. The mentor supports the mentee in overall professional development and offers support, praise, and encouragement. The mentor is focused solely on the mentee's personal growth.

A mentor relationship may be sought by the mentee who is feeling the need of guidance and direction in professional growth and development. Sometimes mentor/mentee relationships occur spontaneously in a work environment or between two professionals who are attracted to each other. The mentee usually is attracted to the mentor's knowledge, skills, and accomplishments, and the mentor is attracted to the mentee's talent and potential as well as the opportunity to contribute to another professional's development. Generally, the mentor is an older and more experienced professional.

True mentoring relationships are acknowledged by both parties and require formal commitment of time and effort. Both parties discuss and agree on learning needs and goals for the relationship. A structure for the mentoring process is identified, whether it is periodic face-to-face meetings, written communication, or a combination of the two. Some work environments, recognizing the value of mentors, may formally assign a more experienced therapist who is not the employee's supervisor to function in a mentor role. The assigned mentor would provide support and guide the new employee in learning about and adjusting to new work situations (Allen, 1998, "Training"). Less structured or more informal mentoring relationships can also develop during the course of a practitioner's professional life. These relationships are less intense and usually of shorter duration.

It is easy to see how a mentee/mentor relationship might develop within a supervisory relationship. When this happens, both parties need to be clear about the different purposes and responsibilities of the two types of relationships. It is possible that what the mentor might counsel would not be what the supervisor would counsel. For example, a person who is functioning in the role of mentor might recognize that a mentee would benefit from staying in one clinical setting for several months to allow for solidification of learning. However, this same person, functioning as a supervisor, recognizes that staffing limitations require that the supervisee must be rotated to a new clinical setting each month. Holding both roles simultaneously can lead to role conflicts, highlighting the need to be very clear about the different responsibilities of each role. Table 68.2 offers a comparison of supervision, mentorship, and peer supervision.

Mentoring should not be confused with role modeling. A role model is usually watched and admired by a practitioner, but the role model does not have a reciprocating active interest in the person's development and might not even be aware that he or she is serving as a role model (Urish, 2004).

THE SUPERVISORY PROCESS

The overseeing of work is an *ongoing* process: It occurs repeatedly across time and is embedded in the everyday work experience. A supervisor, both formally and informally, observes and checks on the work of supervisees by talking to them about their work as well as observing them on a regular basis. A supervisor who observes the work of supervisees only occasionally and meets with them only annually to discuss performance during an annual performance review is not providing appropriate supervision. Supervisors should be regularly present in the workplace and have regular contact with their supervisees.

Supervision is an *orderly* process. A good supervisor establishes a process in which the supervisee understands when regular contacts and meetings will occur. The supervisor is clear about performance expectations and consistent in providing feedback. The supervisee learns to trust and value the supervisory process as a tool that promotes personal growth and success in the job.

The supervisory process, although orderly and expected, is also *dynamic*. It changes as people grow and work demands shift. Upon initial hiring, the supervisor might observe an employee daily and meet weekly. However, after several weeks, the employee might practice more independently without daily observation.

TABLE 68.2	COMPARISON OF SUPERVISION, MENTORSHIP, AND PEER SUPERVISION		
	Supervision	**Mentorship**	**Peer Supervision**
Authority	Provided by the work organization	No formal authority	No formal authority. Supported by professional responsibility
Nature of relationship and how it is established	Formal—established by the workplace	Personal, voluntary	Informal, spontaneous
Purpose	To support growth and development that will benefit the organization	To foster personal and professional growth and development that will benefit the mentee	To support growth and development that will ensure best outcomes for clients
How established	Assigned	Sought by the mentee and mutually agreed upon	Offered by a peer or may be solicited by a practitioner
Accountability for performance	Organizational	Personal	Professional
Whose needs are met—Outcomes expected	Needs of organization: Work meets organizational objectives and needs	Needs of mentee: Mentee achieves personal and professional growth	Needs of mentee and clients: Clients receive best services

Finally, the supervision is an *interactive* process. It is based on an exchange or communication between the supervisor and the supervisee. The exchange that occurs between the occupational therapy supervisor and supervisee is central to the development and maintenance of professional competence. The AOTA document "Guidelines for Supervision, Roles, and Responsibilities During the Delivery of Occupational Therapy Services" describes supervision as "a cooperative process in which two or more people participate in a joint effort to establish, maintain, and/or elevate a level of competence and performance" (2004, p. 663).

Observe, in this description, that the profession sees supervision as a two-way street. The supervisee as well as the supervisor actively participates in the process. This is in sharp contrast to the common understanding of supervision as something that is done "to" a person and that the supervisee receives or accepts. In our profession, supervision is viewed as a cooperative process in which both parties have professional responsibility. This cooperative approach to supervision stems from the profession's ethical responsibility to demonstrate concern for the safety and well-being of their clients (Principle 1: Beneficence) and to maintain high standards of competence (Principle 4: Duty) (AOTA, 2005a).

The AOTA "Guidelines for Supervision, Roles, and Responsibilities During the Delivery of Occupational Therapy Services" describes the supervisory process as having two purposes that relate to these ethical principles: (1) to ensure safe and effective delivery of occupational therapy services and (2) to foster professional competence and development (2004, p. 663). These objectives reflect the organizational duties of the supervisor as well as professional practice obligations. All OTs and OTAs have a common interest in providing the best possible care to their clients, and all practitioners are obligated to demonstrate continuing competence. The supervisory process is the tool that OTs and OTAs use to reach these goals.

DEVELOPING A SUPERVISORY RELATIONSHIP

The supervisory relationship is central to the supervisory process. An effective supervisory relationship is built on trust and integrity. To develop trust and integrity, the supervisor must be approachable and open to the supervisee's questions and concerns; the supervisee must feel that that his or her input is valued. The supervisor must be responsive and follow through with actions that indicate that the supervisee's concerns were considered; the supervisee will feel valued and confident in his or her personal abilities, and commitment to the organization will increase. The supervisor must be clear about expectations and provide regular objective feedback about performance; the supervisee will understand what is expected and feel more comfortable in the job. The supervisor must be consistent in the application of rewards and punishments and not play

favorites; the supervisee will develop a level of trust in how he or she will be treated. When communications and actions are clear, consistent, and fair, an environment of trust develops and anxiety about performance decreases. When the supervisor is approachable and responsive, the supervisory relationship can thrive. Box 68.1 provides some additional examples of supervisory behaviors that build trust and integrity.

Both supervisee and supervisor bring their own values, beliefs, and attitudes about supervision to the relationship. Each brings past experiences with other supervisors and authority figures, which may have been positive or negative. It is the supervisor's responsibility to set the tone for the relationship in a job setting and to take actions that will support an ongoing positive relationship. The following four steps will help to ensure that a positive supervisory relationship is initiated and developed:

1. **Learn about the supervisee.** Remember that you are responsible for guiding the learning of this new employee. To do this effectively, you need to understand what your new supervisee knows and how he or she learns best. You will be particularly interested in how his or her knowledge and skills match with those that are needed for this job. Interviewing the new employee about past experiences and asking for his or her current strengths and learning needs send the message that you are interested in building on what the person knows and you value the person's experiences. You might wish to develop a skills checklist that the employee can fill out to supplement the interview process. Although the supervisor never stops learning about the supervisee's abilities, gathering this information formally during orientation to use as you begin to design training and learning experiences is very helpful. Understanding not only *what* the supervisee

knows but also *how* he or she learns is also important. Does the supervisee learn best by reading, demonstration, or both? Does the supervisee prefer to work more independently with periodic review or would he or she like daily contact with you? What kind of feedback would the supervisee like, and how frequently would he or she like to receive it? Identifying the employee's learning styles and preferences can facilitate the learning process on the new job and avoid wasted time and effort for both parties.

2. **Be clear about job expectations.** During the initial orientation and training, the supervisor needs to clearly outline the performance expectations for the job. The job requirements and expectations should have been broadly discussed during the job interview and hiring process. Now is a good time to revisit this discussion and provide more specifics. Reviewing the job description is an objective method for beginning this discussion. Although job descriptions delineate major functions and lines of authority, they often do not specify in detail the quality and quantity of performance that are expected. Expectations about productivity and quality of work should be made clear to the employee. Be honest and open about consequences for various behaviors—rewards as well as punishments. In addition, organizational cultural expectations such as attitudes and behaviors employees are expected to exhibit in interdisciplinary, peer, and client/family interactions should be addressed. These expectations are often not included in a job description but are central to acceptable performance. Discuss your expectations regarding the supervisee's responsibility to learn and grow. Remember that one of your responsibilities as a professional supervising other members of your profession is to facilitate the supervisee's professional growth and competence. Share your commitment to this goal, and enlist the supervisee's commitment to it. Find out what the supervisee's personal professional goals and objectives are.

3. **Develop and implement a supervisory plan.** Our profession views the supervisory process as a collaborative one. Early in your new supervisee's employment, discuss how you view the supervisory process, and work with the employee to develop a supervisory plan that will work for both of you. Discuss topics such as frequency of supervisory contact (e.g., daily, three times per week, weekly), types of contact (e.g., informal, spontaneous, formal scheduled meeting), methods of contact (e.g., face to face, e-mail, phone, written), and preferred supervisory methods (e.g., observation, cotreatment, dialogue, documentation review). Discuss the obligations of the supervisee as well as the supervisor in supervision; for example, explain that you expect the supervisee to initiate contact with you if more frequent feedback or supervision is needed and to share his or her concerns and ideas with you openly.

BOX 68.1

KEY POSITIVE SUPERVISORY BEHAVIORS

- Praises others
- Accepts criticism and suggestion without judging
- Tells the truth
- Is supportive of supervisee—goes to bat for supervisees
- Gives credit for accomplishments
- Abides by the same rules as expects others to abide by
- Gives clear and frequent feedback
- Is dependable
- Is loyal to organization—makes decisions that are in best interest of organization
- Is respectful of differences

4. **Document supervision that is provided.** Document when you meet with your supervisee and what was discussed. A supervisory log or folder is a helpful tool that allows you to keep a record of incidents, observations, and meetings. If used routinely, the log allows you to track performance and see how it has changed. The log record provides concrete examples that can be used in your feedback and also in regular performance review meetings. Regulatory laws in some states require that supervisory logs be kept to document the supervisory process that occurs between an occupational therapist and an occupational therapy assistant to maintain current licensure.

PERFORMANCE EVALUATION: A SUPERVISORY RESPONSIBILITY

All supervisory actions are directed toward managing the supervisee's work performance. The purpose of performance management is to encourage the supervisee to meet or exceed the established job performance standards and behave safely and appropriately at work (Newstrom and Bittel, 2002, p. 335). Supervisors use a variety of methods in managing performance (e.g., incentives, job structure), but providing ongoing evaluation of performance by providing both formal and informal feedback is a central supervisory responsibility and skill.

Providing Feedback

Effective feedback is the supervisor's primary tool in influencing the employee's job performance. Employees need to know when they are meeting job performance standards and when they are not. When positive supervisory relationships have been established, feedback occurs naturally and informally throughout the work week. The supervisor comments on what he or she observes and uses the feedback to point out when performance needs to be changed as well as to verify and praise effective performance. Effective feedback needs to be descriptive rather than evaluative

> **Evaluative:** Your initial interview was poorly done.
> **Descriptive:** Your initial interview used more "closed" yes/no answer questions than open-ended questions, limiting the amount of information you were able to gather.

Effective feedback also needs to be specific rather than general.

> **General:** Your productivity performance is below our standard.
> **Specific:** We expect our therapists to see nine clients each day, and you are seeing only six.

Providing feedback that is descriptive and specific will help you to focus on the effectiveness of the supervisee's work

---

BOX 68.2

GUIDELINES FOR GIVING FEEDBACK

- ◆ Provide timely feedback—give feedback as close to when the behavior was observed as is possible.
- ◆ Provide balanced feedback—point out what is working as well as what needs to be changed.
- ◆ Provide feedback on behaviors that can be changed.
- ◆ Use "I" statements.
- ◆ Avoid the use of generalizations such as "always," "never," and "all."
- ◆ Ask the supervisee if he or she understood what you said; ask the supervisee to restate it in his or her own words.
- ◆ Ask for feedback about your feedback—how did you do?

---

behaviors and not on his or her personal characteristics or personality. This distinction is critical to the supervisee's being able to "hear" and respond to the feedback. Other suggestions for giving feedback are listed in Box 68.2.

Remember that the purpose of supervision is to support effective work performance. When supervisors evaluate employees, they are evaluating what employees do—how they behave, how they act, how effectively they are accomplishing the work. The focus of feedback in supervision—both informal and formal—is on the task, not the person. The purpose is to relay information about performance to the performer so that actions can be taken to maintain or improve performance.

Performance Evaluation and Appraisal

Newstrom and Bittel (2002, p. 293) point out four basic reasons for appraising an employee's performance:

1. To encourage good behavior or to correct and discourage below-standard performance
2. To satisfy employee's curiosity for how they are doing
3. To provide an opportunity for coaching to develop employee skills
4. To provide a firm foundation for later judgments that concern an employee's career such as promotions, pay raises, and transfers.

A supervisor should be regularly evaluating the supervisee's performance and providing feedback. However, at least once or twice a year, the supervisor should meet with the employer and provide a formal and systematic evaluation of how the person is performing, using a structured performance appraisal format. Most organizations have formal performance appraisal systems and appraisal forms.

Appraisal methods and formats may vary and could include written narratives, behaviorally anchored rating scales, management by objectives, or 360-degree feedback (Allen, 1998; Newstrom & Bittel, 2002). In a formal performance appraisal, the employee's performance is compared to established standards.

As a supervisor, you might be asked to develop job standards for occupational therapy personnel. Professional and workplace resources that can help you to identify standards include the profession's Standards of Practice (AOTA, 2005b), the "Guidelines for Supervision, Roles, and Responsibilities During the Delivery of OT Services" (AOTA, 2004), and worksite job descriptions. Standards will vary by workplace, but all standards should include *what* performance or behaviors are expected, *how* performance will be *measured,* and *when* performance is to occur. An example of a standard that includes all of these criteria is "Evaluations are completed and distributed within 24 hours of initial contact with the client."

In preparing a formal performance appraisal, the supervisor needs to complete three steps:

1. **Gather information about the employee's performance.** Review your supervisory logs, noting key incidents which you recorded. Record additional information that might have been overlooked. Review other employee records, such as attendance, training and educational records, competency check off completions. Review the previous year's performance appraisal. Talk to other members of the team both within and outside of your department to understand how the employee's performance is viewed by others. Ask the employee to perform a self-appraisal of his or her work, identifying accomplishments, strengths, and weaknesses. You can ask the employee to give this to you before the performance appraisal or have the employee bring it to the performance appraisal meeting.
2. **Compare current performance to standards.** Note areas of strength and areas in which improvement may be needed.
3. **Reflect on and synthesize information.** Consider the needs of the department as well as the professional growth needs of the supervisee. Provide feedback about the effectiveness, efficiency, and safety of performance. Note how the employee has contributed to the department's achievements. Document your comments, including both positive feedback and constructive criticism. Be careful to avoid allowing an employee's positive or negative qualities in one area to influence your assessment in other areas. Be watchful of being overly lenient or strict. Be objective and balanced, and focus feedback on task performance. Numerous websites offer information on how to perform effective performance evaluations and can alert you to additional factors to be aware of.

When the performance appraisal is completed, it is time to meet with the employee. The purpose of this meeting is to provide an opportunity for the supervisor and supervisee to discuss the employee's job performance and to collaborate on ways to improve it. Unfortunately, performance appraisal meetings are often viewed as anxiety-provoking events that focus on what the employee has done wrong. The common emphasis on the supervisor's rating of the employee tends to detract from a collaborative educational process during which supervisee and supervisor share perspectives and work together to identify barriers to improved performance. The supervisor can use several approaches to correct this problem:

1. **Demystify the process.** Make sure the employee is familiar with the evaluation process ahead of time. If a standard form is used, make sure the employee has seen it and understands any terminology or rating scales that are used. Make sure the employee is aware of the job expectations and standards. Involvement of staff members in establishing performance standards promotes adherence to and acceptance of standards. Involve the employee in the appraisal process by using a self-assessment.
2. **Plan ahead.** Notify the employee ahead of time as to when the meeting will be and allow the employee time to prepare.
3. **Establish a comfortable climate for the exchange.** Meet in private. Avoid interruptions. Allow adequate time for discussion. Put the employee at ease in the beginning, and explain that you view this time as an opportunity for mutual sharing on how to improve job performance for the benefit of the employee and the organization.

During the performance appraisal interview, be prepared to collaborate with the employee and exchange ideas. Share accomplishments, and review what has not been accomplished. If performance ratings are provided, be sure to provide reasons for your ratings that are based on actual job performance. If the employee is surprised by any of your ratings or comments, you probably have not provided enough regular feedback during the year. Take note, and work to correct that. The appraisal interview offers another opportunity to realign expectations about job performance and to target goals for the future.

Handling Work Performance Problems

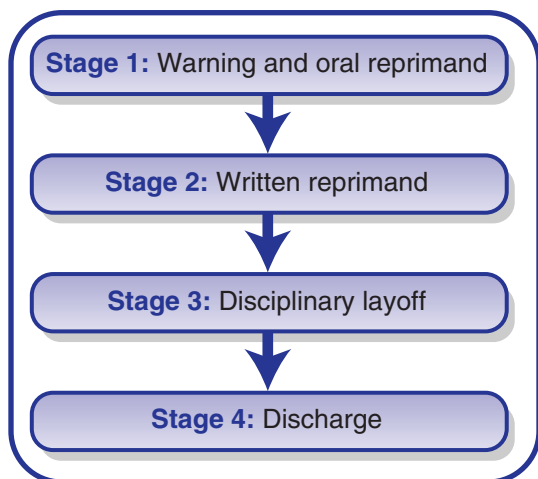
Although there are numerous types of performance problems in professional practice settings, the most common ones are behavior or conduct problems in which a rule is broken, performance that falls below the standard expected, and interpersonal issues that interfere with department morale and effectiveness. Each type of problem is handled differently, but in all situations, the actions that

are taken are directed toward helping the employee to improve performance and meet job expectations.

Behavior or Conduct Problems

Behavior or conduct problems are handled by disciplining. Behavior or conduct problems may include absenteeism, chronic late arrival, intoxication, insubordination, negligence in following procedures, and falsification of records. These are all serious infractions and should not be allowed to persist. Although individual facilities may adopt their own specific procedures for disciplining a variety of infractions, disciplining is generally handled in a progressive manner. In a progressive discipline approach, the employee is counseled repeatedly if performance does not improve, and the penalties for noncompliance with the rules become increasingly harsh (see Fig. 68.3).

In the first stage of progressive disciplining, the performance problem is discussed with the employee, clear expectations for acceptable performance are outlined, and consequences of not improving are described. In the second stage, the process is repeated, and this time, a written record of the exchange is documented. The employee signs it, and it is placed in his or her personnel file. If the behavior persists, in the third stage, the employee is laid off for a period of time and is told that when he or she returns to work, the behavior must be corrected or the employee will be discharged. The last stage occurs if the employee returns to work and another infraction occurs, at which time the employee is discharged.

A useful analogy for administering any discipline is the "red-hot stove" rule. The analogy likens the process of administering discipline to that of touching a red-hot stove and points out the four essential characteristics of a good disciplinary policy and practice. Discipline should be administered in the following manner:


- **With advance warning.** When you see a red-hot stove, you know that if you touch it, you will be burned. An employee should know what will happen if he or she breaks a rule or policy.
- **Immediately.** When you touch a red-hot stove, you will be burned right away. Administration of discipline should be done as soon after the occurrence of the behavior as possible.
- **Impartially.** No matter who touches a red-hot stove, the person will be burned. Supervisors should not play favorites in administering discipline. Everyone should receive the same penalty for the same infraction.
- **Consistently.** Every time you touch a red-hot stove, you get burned. Discipline should be administered the same way with each occurrence.

Performance Problems

Problems of substandard performance are more common in professional practice. When dealing with these types of problems, the supervisor needs to adopt an approach of collaborating with the supervisee and enlisting his or her help in resolving the problem. Typical steps in dealing with this type of problem after the performance problem is identified include the following:

1. Meet with supervisee and point out the performance problem. Review the standard, and describe the expected performance.
2. Collaborate with the supervisee to determine reasons for the problem. Work together to develop an action plan to improve performance.
3. Monitor performance.
4. Repeat the process if needed.
5. Inform employee of consequences if the standard is achieved and if the standard is not achieved.

Interpersonal Work Issues

Interpersonal work issues vary in scope and complexity and are common in all work groups. In a professional practice environment in which teamwork is central to the department's effectiveness and to the achievement of positive client outcomes, problems between workers should not be ignored. Interpersonal issues can arise between practitioners in the OT department or between team members from different disciplines. These types of work problems often stem from miscommunication and/or differences in communication styles or personalities. Lack of clarity about job roles or about expectations can also lead to interpersonal problems.

Just because two people are different or disagree does not mean that they cannot work effectively together. The supervisor's role in resolving these types of performance issues should focus not on personalities, individuals, or differences, but on the job tasks and mutual goals that need to be accomplished. The first approach to take when

FIGURE 68.3 Using a standard sequence for dealing with performance problems is required in many formal organizations and is considered good practice in most settings.

an employee complains to you about another employee is to listen carefully and encourage the person with the complaint to talk directly to the other individual. You should help the person to clarify his or her concerns and frame them in terms of how the other person's actions are affecting the person's ability to get his or her own job done. This approach often works and begins the process of opening communication.

When this approach does not work, you might need to take further action by talking to each of the parties involved. You might want to do this individually at first and then together, or you might want to approach the problem by talking to the parties at the same time. In either case, you will want to interview both to understand all of the facts and frame the issues or problems in terms of specific behavior and job performance expectations that are being affected. As the supervisor, you also must be clear about your expectations for job performance actions and attitudes and remind both of them about the department's expectations. During this discussion, each party should become more aware of his or her own behaviors as well as the behaviors of the other and how the interaction of their choices is affecting their work. Your goal in this exchange is for both parties to work out a solution that does not compromise the work of either and allows the work of the department to continue more effectively.

SUPERVISION OF OCCUPATIONAL THERAPY PERSONNEL

The profession believes that effective supervision of OT personnel is necessary to ensure safe and effective delivery of services. As was mentioned at the beginning of the chapter, supervision is embedded within the OT process. However, OT practitioners work in a broad range of work environments (medical, educational, and community-based settings). To guide practitioners in developing effective supervisory practices in these different situations, the profession has adopted supervisory guidelines that can be applied in all settings. These guidelines describe how the profession views the supervisory process, who needs to be supervised, the methods and frequency of supervision, and supervisory responsibilities of different occupational therapy personnel.

Occupational Therapists

The American Occupational Therapy Association (AOTA) describes occupational therapists as "autonomous practitioners who are able to deliver services independently" (AOTA, 2004, p. 663). Entry-level OTs are qualified to practice without supervision. The therapist's preparation to deliver services independently is based on education and training, which includes a minimum of six months of supervised fieldwork experience and successful completion of the initial certification exam. Entry-level OTs are trained as generalists and are qualified to enter general practice settings as autonomous therapists. Although entry-level therapists do not require supervision, in the past, close supervision by an intermediate or advanced level OT was recommended (AOTA, 1999). As the profession moved to entry-level master's degree preparation, thinking shifted, and responsibility is now placed on every therapist, at all levels of experience, to assess his or her personal need for supervision and seek it if needed. The current guidelines state that "Occupational therapists are encouraged to seek supervision and mentoring to develop best practice approaches and to promote professional growth" (AOTA, 2004, p. 663). This statement underscores each therapist's professional responsibility to maintain the competencies that are needed to provide safe and effective services. The therapist who enters a work setting that does not provide professional supervision should carefully compare his or her current competencies with the demands of the work setting. When this comparison reveals that current knowledge and skills may need further support or development, the therapist should seek supervision or mentoring to ensure competent practice and professional growth. Although this is not required, many entry-level therapists seek first-time jobs in which supervision will be available. These positions allow them more time to solidify clinical skills and develop confidence. Therapists beyond entry level should continue to assess their need for professional supervision if it is not provided in their work setting. Career changes, such as switching practice settings (from school to nursing home) or types of clients treated (children with autism to adults with spinal cord injuries), may challenge the therapist's current competency and alert the therapist to the need to seek supervision or mentoring (Youngstrom, 1998).

In many occupational therapy practice settings, there may be no formal supervision by another OT. This is particularly common in public school settings. In situations such as these, OTs often seek informal peer supervision from OTs in similar settings. They ask for feedback from each other and share case information, often problem solving together to plan effective interventions. This is a positive and proactive approach that helps to ensure effective professional practice and personal competence.

Occupational Therapy Assistants

Occupational therapy assistants who deliver occupational therapy services must be supervised by an occupational therapist (AOTA, 2004, 2005b). Occupational therapy assistants are trained and educated in basic occupational therapy approaches and techniques, and their role is one of assisting the occupational therapist with the delivery of services. The OT is responsible for all aspects of service delivery and works in partnership and collaboration with the OTA to provide appropriate services to clients. Entry-level OTs are expected to be able to supervise OTAs and to be

knowledgeable about the collaborative supervisory relationship that the profession values (Accreditation Council for Occupational Therapy Education, 1999a). Entry-level OTAs are expected to be knowledgeable of the supervisory partnership and to seek supervision appropriately. OTAs, by virtue of their training and education, are often well qualified to take on related work roles (e.g., assistive technologists, activity program directors). When they do take jobs in these related work positions, they are not providing occupational therapy services and consequently do not need to be supervised by an occupational therapist.

Fieldwork Students

Level II fieldwork students at the therapist and assistant level both must be supervised by occupational therapy practitioners. OT students must be supervised by an OT who has at least one year of experience after being initially certified by the National Board for Certification of Occupational Therapy (ACOTE, 1999a). Occupational therapy assistant students may be supervised by either an OT or an OTA, who also must have at least one year of experience after initial certification. (ACOTE, 1999b). If an OTA is providing the Level II supervision for the OT assistant student, it is understood that the supervising assistant is supervised by an OT. According to ACOTE, personnel who are qualified to supervise Level I OT or OTA students include OTs and OTAs as well as individuals from other disciplines such as psychology, social work, and teaching (ACOTE, 1999a, 1999b).

Other Personnel

Other types of personnel who may assist with the provision of OT services or the management of services delivery, such as office personnel, OT aides, or volunteers, may be supervised by either OTs or OTAs. Table 68.3 provides an overview of whom various personnel may supervise.

TYPES OF SUPERVISION: OVERSEEING VARIOUS ASPECTS OF WORK

Work is a complex activity. The responsibility for supervising various aspects of work is sometimes assigned to different people. It is not uncommon for an occupational therapy practitioner to receive supervision from more than one person for different aspects of their work performance. Discussion of three distinct aspects of work performance and the type of supervision used to oversee that performance will help you to see how supervision in some settings may require a multifaceted approach.

Administrative Supervision

Administrative supervision is focused on monitoring performance and making sure that the supervisee's work performance and professional development meet the objectives and standards of the employing organization. Administrative supervisors focus on the administrative aspects of job performance, such as attendance, schedules, benefit usage, and checking for appropriate completion of assigned job tasks. This type of supervision correlates closely with the administrative function of supervision discussed above.

Administrative supervision can be provided by an OT or an OTA to other OTs and OTAs or to members of other disciplines. Likewise, members of other disciplines can administratively supervise OTs and OTAs. This type of supervision commonly occurs in public school settings, in which school principals or special education administrators are the designated supervisors for occupational therapists. As the occupational therapist's supervisor, the principal or special education administrator would be supervising the administrative aspects of the occupational therapist's work.

Clinical or Professional Practice Supervision

Supervision that is aimed at providing support, training, and evaluation of a supervisee's professional performance and development is called **professional practice supervision** or **clinical supervision**. The term *clinical supervision* was the most commonly used term in the past to describe this type of supervision. However, as more OTs and OTAs have moved into work settings outside the clinical medical model (e.g., school settings), the term *clinical supervision* seems less appropriate than the broader term *professional practice supervision.* In professional practice supervision, the supervisor's responsibilities extend beyond the purely administrative aspects of job performance and are additionally aimed at assisting and supporting the supervisee's development of professional discipline specific-skills, such as interviewing skills, appropriate use of selected therapeutic techniques, and clinical reasoning.

Professional practice supervision can appropriately be provided only by a member of the supervisee's discipline. Consequently, it would not be appropriate for a physical therapist to provide professional practice supervision or clinical supervision to an occupational therapist. Likewise, an occupational therapist cannot be expected to provide professional practice or clinical supervision for a physical therapist. Professional practice supervision is the type of supervision that is provided by fieldwork educators during OT and OTA Level II fieldwork experiences. (Fieldwork educators also provide administrative supervision to students.) An OT may provide professional practice supervision to other OTs and OTAs, and an OTA may provide professional practice supervision to other OTAs. This type of supervision correlates closely with the educational and supportive supervisory functions.

Functional Supervision

A third type of supervision that is seen in some occupational therapy practice environments is **functional super-**

TABLE 68.3   PATTERNS OF SUPERVISION: WHO CAN SUPERVISE WHOM?

| | | | | OT Fieldwork Student | | OTA Fieldwork Student | | |
| | | | | Personnel to Supervise | | | | |
Type of Supervisor	OTA	OT Aide	Volunteer	Level I	Level II	Level I	Level II	OT
Entry-level OT	X	X	X	X		X		
OT with more than 1 year of experience	X	X	X	X	X	X	X	X
Entry-level OTA		X	X					
OTA with more than 1 year of experience	X	X	X	X		X	X	

vision (AOTA, 1993, p. 1088). In this type of supervision, a specific aspect of work or a "function" of clinical practice is delegated to a specified individual to provide training and oversight in that aspect of work. The supervisor who is providing only functional supervision generally has advanced knowledge, skill, and competence in the area being supervised. For example, an OT supervisor of a new employee might request that another OT who is experienced in wheelchair assessment and positioning provide functional supervision to the new employee in this area. When providing functional supervision, the supervisor is not responsible for the entire supervisory process but supervises the person in relation to his or her developing specific skills or competency and the performance in only in a selected aspect of work or job function.

METHODS OF SUPERVISION

A professional practice supervisor needs to consider what supervisory methods will be most effective in developing and monitoring performance. Supervisees have different learning styles. Worksites have varying caseload demands, administrative requirements for supervision, and time available to provide supervision. Supervisory methods need to be selected to meet the supervisee's needs and the demands of the worksite.

The supervisor is responsible for initially orienting and training the supervisee and then supporting the supervisee's professional growth and development. Careful thought should be given to the type of teaching methods that will be most effective in learning new information and developing work skills. Should information be presented verbally? In writing? Via video? How interactive should the learning be? Should the learner simply observe without demonstrating his or her own skills? Should questions

be encouraged? It is a good idea to vary methods and to select the ones that mesh with the learner's skill and comfort level. Involve the supervisee in the process by asking what learning approaches he or she prefers. Box 68.3 lists examples of various learning methods.

To monitor and evaluate performance, the supervisor can utilize direct and indirect approaches.

BOX 68.3 | **EXAMPLES OF LEARNING METHODS**

- Provide written protocols or instructions.
- Have the learner report back on what he or she learned from reading.
- Provide articles or books to read or use as reference.
- Demonstrate and have the learner return the demonstration.
- Provide a verbal explanation or lecture that covers the content.
- Provide videotapes with questions about content to answer at end.
- Have the learner participate in small group discussion to problem-solve clinical situations.
- Discuss cases or problems presented, either one on one or in small groups.
- Role-play situations.
- Provide repeated practice opportunities to apply new knowledge and skills.
- Observe others carrying out tasks; ask for the learner to describe what he or she observed.
- Model desired performance and behaviors.

Direct Supervision

In direct methods of supervision, the supervisor is present when the employee is performing the job and actually observes performance. When we think of supervision methods, this approach is generally the first one that comes to mind. Direct observation gives firsthand information to the supervisor, but this approach is time consuming, and it is not always practical to use as the only method of supervision.

Indirect Supervision

Indirect methods allow the supervisor to ascertain how the job was performed by gathering this information after performance occurs. Indirect methods include communicating with the supervisee (via phone, e-mail, or written correspondence) after performance, looking at written records (attendance records, documentation), or receiving reports from others (clients, parents, other staff or team members) about the supervisee's performance. Listening to what others say provides information about the employee's performance and provides feedback about how others perceive the performance. Supervising performance in a clinical setting by reading the supervisee's documentation is a frequently used indirect method in occupational therapy practice. Reading documentation tells the supervisor what happened when clients were seen and provides insight into the supervisee's clinical reasoning and documentation skills. However, using only the indirect method of supervision without also periodically observing performance would not give the supervisor a well-rounded picture of the employee's performance in areas such as interpersonal skill, technique application, adaptability in spontaneous clinical situations, and problem solving. Both indirect and direct methods need to be used to develop an accurate and complete picture of employee performance.

FREQUENCY OF SUPERVISION

One of the first decisions a supervisor must make when developing a supervision plan is to determine how frequently to have contact with the supervisee to teach, train, monitor and evaluate performance. The members of the profession have considered this question in relation to how frequency of supervision should be determined in supervising occupational therapy assistants (see AOTA, 2004, pp. 663–664). The factors that are outlined below can be considered in all supervisory situations. In determining frequency of supervisory contact, the supervisor should consider the following:

1. **His/her own supervisory skills.** Supervisors who are new and just developing their skills might require more frequent contact with the supervisee because they are less efficient in observing and analyzing performance. They might need more time to recognize possible performance issues and to provide supervisory interventions. The supervisor who has had more experience and/or who has previously supervised in a setting might be clearer about performance expectations and able to anticipate problems and provide guidance and direction sooner.

2. **The skills of the supervisee.** New employees who come to a job with background and experience in a similar job probably bring the needed skills to the new job. Generally, these employees will require less initial training and often move very quickly to a point at which they need less frequent supervision. The supervisor, however, must individually evaluate each employee because experience does not always guarantee performance. The employee's speed and style of learning will also affect the frequency of supervision needed.

3. **The nature of the work.** Work that is more varied and complex might require more frequent supervisory contact to allow the supervisor to observe performance at different times under various conditions and levels of complexity. The new occupational therapist working in a rehab hospital whose caseload consists only of stroke patients might require less frequent supervision than the new occupational therapist who is working in an acute care setting seeing clients with orthopedic, neurological and acute medical conditions.

4. **The expectations and requirements of the work setting.** In various work settings, standards and expectations may have developed, based on experience in that setting, that require certain levels of supervision. Although an experienced supervisor might think that weekly contact is sufficient, a worksite might require daily contact.

5. **The expectations and requirements of external regulatory or legislative agencies.** Federal or state laws and regulations and accrediting agencies may specify certain methods of oversight and contact that must occur between the OT and OTA.

Frequency of supervision is generally viewed as occurring on a continuum. At the high end of the continuum, the supervisor is continually in sight of the supervisee who is working. At the low end of the continuum, the supervisor contacts the supervisee only as needed. Table 68.4 provides a description of the various levels along the continuum. In the past, the profession recommended certain frequency levels of supervision for therapists and assistants who were at various experience levels. This approach has been replaced by a more flexible approach that recognizes the variety of factors that need to contribute to the supervisory frequency decision and allows for increased flexibility in dealing with the wide variety of practice setting and supervisory demands that exist within the profession.

TABLE 68.4   CONTINUUM OF SUPERVISION

Frequency of Supervision	Definition
◆ Continuous	Supervisor is in sight of the supervisee who is working (AOTA, 1999, p. 592)
◆ Close supervision	Requires daily, direct contact at the site of work (AOTA, 1999, p. 592)
◆ Routine supervision	Requires direct contact at least every 2 weeks at the site of work, with interim supervision occurring by other methods, such as telephone or written communication (AOTA, 1999, p. 592)
◆ General supervision	At least monthly direct contact, with supervision available as needed by other methods (AOTA, 1999, p. 592)
◆ Minimal supervision	Provided only as needed and may be less than monthly (AOTA, 1999, p. 592)

There are, however, two firm directives regarding need for supervision adopted by the profession:

1. Entry-level occupational therapists do not *require* supervision. They are, however, "encouraged to seek supervision and mentoring to develop best practice approaches and promote professional growth" (AOTA, 2004, p. 663).
2. Occupational therapy assistants must *always* receive some level of regular supervision from an occupational therapist when they are providing occupational therapy services.

THE OT/OTA SUPERVISORY RELATIONSHIP

The profession perceives the supervisory relationship between the OT and OTA as a partnership. Both levels of practitioners are trained and educated within the profession but at different levels. The OT is educated at the professional knowledge and skill level and receives an entry-level graduate degree. The OTA is educated at the technical level and receives an associate of arts degree. Each level of practitioner has complementary but distinct roles. The OT is responsible for overall service provision and can carry out all facets of service provision (i.e., evaluation, intervention planning, intervention implementation and review, and outcomes assessment). The OTA's primary role is in the implementation phase of service provision. OTAs may contribute to other aspects of service provision, such as evaluation and intervention planning under the supervision of the occupational therapist.

The "Guidelines to Supervision of Occupational Therapy Personnel" (AOTA, 2004) outlines the roles and responsibilities of each level of practitioner during the delivery of services. For the partnership to be successful, the OT and OTA each must have a clear understanding of each other's role and respect and value the contribution that each practitioner makes. When the OT and OTA work as a team, they are able to utilize and build on each other's skills and expand the number and kinds of services that can be provided to clients. When an OT partners with an OTA, the OT is often able to see more clients and to utilize the OTA's personal expertise in specific practice areas or techniques to improve client care.

Service Competency

The purpose of the supervisory process is to ensure that safe and effective services are delivered and that professional competence is fostered. The OT who carries the responsibility for overall service delivery must ensure that the OTA is performing effectively. To ensure that services provided by both levels of practitioners are safe and effective, the OT establishes service competency with the occupational therapy assistant.

> Service competency is the process of teaching, training, and evaluating in which the occupational therapist determines that the occupational therapy assistant performs tasks in the same way that the occupational therapist would and achieves the same outcomes. (AOTA, 1999)

When the OT and OTA initially start working together, the OT will establish service competency for overall job performance. In the early stages of the work relationship, the OT will need to determine what knowledge and skills the OTA has. The establishment of service competency is integrated into the normal supervisory process as the supervisor orients and trains the new employee and begins comparing the employee's performance to the established professional and worksite standards and expectations. The OT should identify the primary job tasks and skills that are needed for the OTA's job. These tasks will vary by site and service setting. The OT will observe and train the OTA and note whether the OTA can perform the identified skills and tasks and whether intervention outcomes are similar to those nor-

COMMENTARY ON THE EVIDENCE

Supervision in Occupational Therapy

The majority of research in supervision has been conducted by business and management researchers. Within the health care professions, nurses, social workers, and counseling psychologists have been the primary contributors to the research on clinical supervision. In occupational therapy, direct empirical evidence to support effective supervisory practice is lacking. The research that is available in occupational therapy is often related to management issues and/or is descriptive in focus. For example, occupational therapy managers, concerned with employee satisfaction and retention, have shown that factors such as feedback and recognition of accomplishments, realistic workloads, and autonomy and opportunities for professional growth and skill development all influence job satisfaction (Barnes, 1998; Smith, 2000). Although these studies did not directly look at supervision, the factors that were identified are all factors that a supervisor can affect, so effective supervision should attend to these factors.

Two recent studies have provided some insight into current supervisory practices. Johnson, Koenig, Piersol, Santalucia, and Wachter-Schutz (2006) reported that more fieldwork educators who supervise Level I fieldwork students are not occupational therapists than in the past. In April 2006, the National Board for Certification in Occupational Therapy reported the results of a 2005 online survey of certification OT and OTA exam candidates that included data on who the practitioner's primary supervisor was and the number of hours of direct supervision received per week (Bent & Conway, 2006). Thirty-eight percent of OTs and 23% of OTAs were supervised by members of other disciplines. Thirty-one percent of OTs and 18% of OTA received zero hours of direct supervision per week. Descriptive statistics such as these prompt us to ask other questions: How does being supervised by someone who is not an occupational therapist affect practitioners' professional growth and commitment to occupation-based practice? Does frequency of direct supervision affect the quality of services delivered and the rate of professional growth?

Both descriptive and empirical studies of supervision in occupational therapy are needed. How do supervisory practices vary by setting? What is the most efficient and effective way to establish service competency with an OTA? What supervisory approaches are most effective in supporting professional growth and development with supervisees? These are only a few of the many questions that need to be answered to provide supervisors with the evidence they need to supervise effectively.

---

mally achieved by the occupational therapist. Examples of job tasks or skills for which service competency may be established include reading the medical record, being able to record appropriate and pertinent information, and being able to appropriately grade an activity to increase its cognitive difficulty.

The concept of service competency is based on the assumption that the supervising OT is competent in the skills for which competency is being established.

Both levels of practitioners are responsible for being aware of each other's competent behaviors and providing feedback to inform each other of possible problem areas.

It is important that the supervisor establish an acceptable standard of performance or level of agreement for skills and tasks on which service competency is being established. For example, when observing client dressing performance, the OTA will rate the client's level of independence at the same level as the OT 95% of the time.

The comparison of outcomes between practitioners is an approach that helps to ensure that services clients receive are of comparable quality. It supports the validity of delegating to the OTA and ensures consistency of services. The methods the OT can use while establishing service competency could include observation, cotreatment, return demonstration of techniques or skills, review of documentation, testing for knowledge and its application, and discussion of cases to ascertain clinical reasoning and judgment.

After initial service competency is established, the OT supervisor will need to periodically recheck service competency to ensure that it is maintained. The OT may also select new tasks and skills in which to establish service competency with the OTA. For example, the OT might decide to train the OTA in how to carry out and score a particular structured assessment tool. After service competency has been established, the OT can delegate the admin-

PRACTICE DILEMMA

CHANGING PRACTICE PATTERNS: TAYLOR SUPERVISES AN OTA

Taylor recently started a new job as an occupational therapist at a large long-term care facility in her community. She works with a team of two other occupational therapists and two OTAs. She is responsible for supervising Diane, one of the OTAs. Diane has been working at this facility for five years and considers herself very experienced in dealing with this population. When Taylor started the job, she met with Diane to discuss their supervisory relationship and to determine how they would conduct their OT/OTA partnership. Taylor spent time observing and working with Diane and found Diane to be very helpful in orienting her to the facility and familiarizing her with the patients and the typical occupational therapy interventions that were being used.

Taylor has now worked at the facility for over six months and is more familiar with the clients and their individual needs. She is interested in developing intervention plans that are more individualized and that use intervention activities that relate to each patient's own needs and personal lifestyle choices, whether they will return home or remain in the nursing home's long-term care wing. Interventions in the past have been focused primarily on self-care issues, and Taylor, while not wanting to ignore these occupations, would like to emphasize more instrumental activities of daily living

and leisure occupations in which patients will want to engage if they return home or that might allow them to increase their sense of self-efficacy and control if they remain in long-term care. She has communicated this goal to Diane, and when they develop intervention plans, individualized goals are developed in these areas. However, as she follows up with Diane and observes interventions and monitors patient progress, Taylor has noted that Diane is not choosing to address these goals and continues to use the routine types of tasks and activities that she was previously using.

Questions

1. How would you define the supervisory issues and problems in this situation?
2. As a supervisor in this scenario, what are Taylor's responsibilities?
3. As a supervisee in this scenario, what are Diane's responsibilities?
4. What do you think might be some of the reasons for Diane's behavior?
5. How would you suggest that Taylor approach Diane and address this problem?
6. What do you think might be some supervisory interventions that Taylor could take that would help to improve this situation?

---

istration of this assessment to the OTA and be assured that the results of the OTA's giving the test will be comparable to the results that would be obtained if the OT administered the test. Service competency does not mean that the OTA will perform the task in exactly the same manner as the OTA would—only that the outcomes will be similar.

Frequency and Type of OTA Supervision

The decisions about frequency of supervision for the OTA will vary with practice setting and should be decided on the basis of the five factors previously discussed: skills of the supervisor, skills of the supervisee, nature of the work, expectations and requirements of the work setting, and expectations and requirements of external regulatory or legislative agencies. The OTA's level of service competency and skill will influence the frequency of supervision needed. If service competency has already been established, the need for supervision might be less frequent.

When service competency is being established in a new area or skill, the supervisor will need to change the frequency of supervision until competency is established.

Work factors that can affect frequency of supervision needed by an OTA include increased complexity of client's needs and diagnoses, rapidity of client change, more involved or complex types of interventions, and increased number and diversity of clients in the assistant's caseload. When the client population is complex and/or rapidly changing, frequent reevaluation and adjustment in types of interventions and implementation plans are needed, which require the clinical reasoning and evaluation skills of the occupational therapist. Frequency of supervision needs should be regularly reassessed as workplace demands, client needs, and supervisee skills change.

Since the supervisory process with the OTA is collaborative and both practitioners are responsible for providing safe and effective services, the OT and OTA should discuss the decision about the frequency of supervision.

Supervision frequency and methods should be mutually decided upon.

Although frequency of supervision can vary, OTAs who are providing occupational therapy services will always need some level of regular supervision. Supervision of the OTA on an irregular, spontaneous, or as-needed basis is not appropriate. It does not demonstrate that the OT is providing the ongoing oversight required to ensure safe and effective services, nor does it validate that high-quality occupational therapy is being provided. Many external regulatory and legislative agencies now specify the frequency and type of supervisory contact that must take place between OT and OTA. The Centers for Medicare & Medicaid Services (CMS) states that the OTA providing services to Medicare patients under an OT working in a physician's office must have direct or on-site (in the building but not in the line of sight) supervision on the day of treatment (U.S. Department of Health and Human Services, CMS, 2006). In February 2006, CMS also clarified that the OT is required to write a progress report every 10 treatment days or once every 30-day interval and requires that the OT perform or actively participate in treatments at this frequency level if the treatments have been delegated to an OTA (Thomas, 2006). This requirement necessitates that the OT have regular contact with the client and with the OTA who is providing services. Many state regulatory agencies outline specific supervision requirements in their laws for OTA supervision. Texas requires a minimum of two hours of supervision per month consisting of real-time interaction between the OT and the OTA or direct observation of the OTA by the OT (Executive Council of Physical Therapy & Occupational Therapy Examiners, 2006). Pennsylvania states that the OT supervisor shall have supervisory contact with the OTA equal to at least 10% of the time that the OTA works in direct patient care. Face-to-face contact must occur on site at least once a month and must include direct observation of the OTA performing occupational therapy (Pennsylvania Code, 2006).

Effective OTA Supervisory Relationship

The OT supervisor has the obligation and responsibility to supervise the OTA, and the OTA has the obligation and responsibility to seek supervision. Each is open to the other. In writing about their own collaborative relationship, Barbara Hanft and Barbara Banks (1999) identified six qualities that support the development of collaborative supervisory relationships:

◆ *"Sensitivity,* for perceiving and responding to one another's professional and personal needs;
◆ *Dependability,* for keeping commitments and responding to unexpected situations;
◆ *Attentiveness,* for actively listening to one another;
◆ *Respectfulness,* for appreciating one another's distinct knowledge, experiences and judgment

---

> ### BOX 68.4 SUMMARY OF STEPS TO TAKE IN SUPERVISING AN OT ASSISTANT
>
> 1. Orient OTA to worksite.
> 2. Share job and professional expectations.
> 3. Identify OTA's skill level.
> 4. Identify OTA's learning needs and methods of learning—ASK!
> 5. Establish service competency.
> 6. Collaborate with OTA to establish ongoing supervisory plan:
>   a. Select methods.
>   b. Select frequency.
> 7. Document ongoing supervision.

◆ *Collaborativeness,* for working toward a common goal and representing occupational therapy services together as a unit; and
◆ *Reflection,* for an ability to use self-observation to review situations objectively from different perspectives" (p. 31).

In a collaborative relationship, both parties understand their unique roles and responsibilities and respect their differences and similarities (Sands, 1998). The process of supervising the OTA will include the OTA in the decision-making process and will be individually tailored to meet the needs of the OTA and the worksite. Box 68.4 presents a summary of the primary steps that should be taken in supervising an OTA.

SUPERVISING OCCUPATIONAL THERAPY AIDES

Occupational therapy aides are individuals with no formalized education in the provision of occupational therapy services who are hired to provide supportive services to OT practitioners. Aides are trained on the job to meet the specific needs of the individual department. Aides do not provide skilled occupational therapy services, and the types of activities they can perform with clients are clearly prescribed in the "Guidelines for Supervision, Roles, and Responsibilities During the Delivery of Occupational Therapy Services" (AOTA, 2004). Aides can perform two types of tasks within the department: They can carry out (1) non–client-related tasks such as clerical work, clinic maintenance tasks, and preparation of work areas and equipment and (2) selected client-related tasks that are routine and supervised by an OT or OTA (AOTA, 2004). For a task to be considered routine, it must meet four criteria:

ETHICAL DILEMMA

Joel Supervises an Employee with Depression

Joel is a supervising occupational therapist in a large metropolitans acute care hospital. He oversees a group of three OTs and one OTA. Recently, one of his supervisees, Naomi, met with him and told him that she has been diagnosed with clinical depression. Joel is not surprised. He had noted that Naomi's work performance had changed, and he was even beginning to become concerned about the quality of Naomi's patient care decisions and her ability to handle the normally fast-paced caseload. Naomi has asked for Joel's help and support by decreasing her caseload so that she may continue to work in an effective manner.

Questions

1. Who are the different players in this scenario to whom Joel has an obligation or duty?
2. As a supervisor, what are Joel's obligations to each player?
3. How are the different needs of the players conflicting?

---

1. The outcome anticipated for the delegated task is predictable.
2. The situation of the client and the environment is stable and will not require that judgments, interpretations, or adaptations be made by the aide.
3. The client has demonstrated some previous performance ability in executing the task.
4. The task routine and process have been clearly established. (AOTA, 2004)

These criteria are based on the understanding that aides do not have the knowledge and skill to evaluate or make changes in an intervention activity but can be helpful in providing oversight or practice of selected activities when change and judgment are not anticipated.

Before a selected task can be delegated to an aide, the OT and/or OTA must be assured that the aide can carry out the task safely and effectively. They must instruct the aide and assess his or her competency in performing the delegated task. The aide also must be aware of all precautions and signs or symptoms that a particular client might demonstrate that would indicate that the aide needs to seek assistance (AOTA, 2004). Each of these requirements is intended to ensure that the aide's interaction with the client will be safe and effective. Practitioners can appropriately use aides to oversee clients who are practicing certain skills after the process has been set up (e.g., one-handed shoe tying and exercise routines). Aides can also provide another pair of hands during physical activities when additional help is needed to engage the client in an activity as when providing assistance to transfer a patient.

Aides can be supervised by either an OT or an OTA. However, when the OTA supervises the aide, the OT maintains overall responsibility for the process because of the OT's supervision of the OTA.

Frequency of supervision will vary with tasks assigned and the aide's skill. Client-related tasks may require closer supervision because of the importance of patient safety and intervention effectiveness. The supervisory plan and process need to be documented to demonstrate accountability.

SUPERVISING NON-OT PERSONNEL

The same basic guidelines and process for effective supervision should be followed in supervising non-OT personnel. The OT who assumes a supervisory or management role may supervise personnel from other disciplines who provide direct services to clients (e.g., physical therapists, psychologists, recreational therapists) as well as personnel who provide support services for the department (e.g., secretaries, reimbursement specialists, information technology specialists). The type of supervision the OT will provide to personnel from other disciplines will be administrative. OTs cannot provide professional practice supervision or clinical supervision because OTs are not trained in the other individuals' professions. Astute supervisors will ensure that their supervisees from other disciplines seek and have access to professional practice supervision and will consult with members of the supervisee's discipline to assist them in evaluating the supervisee's professional practice performance.

CONCLUSION

Supervision is a person-oriented process—much like occupational therapy. The OT supervisor must continually balance the needs of the organization with the needs of

supervisees to provide safe and effective services to clients. Awareness of the basic functions of supervision and an understanding of the supervisory process make up the first step in preparing practitioners for the supervisory role.

PROVOCATIVE QUESTIONS

1. Is it possible to be both friend and supervisor?
2. How can you effectively supervise people who are older than you and have more experience?
3. Should an occupational therapist who works alone, without any other OTs, seek supervision from another OT? Why or why not?

Payment for Services in the United States

HELENE LOHMAN AND AMY LAMB

Learning Objectives

1. Describe the historical impact of health insurance on occupational therapy practice in the United States.
2. Explain the key types of governmental and private pay insurance, as well as other methods of payment that are accessed by patients in occupational therapy practice.
3. Describe who are the uninsured in the United States and articulate issues related to lack of insurance.
4. Discuss how occupational therapists can become advocates for third-party coverage.

S usan, an occupational therapist who is a new graduate, works at an acute care hospital outpatient clinic. During her first month on the job, she had two circumstances involving reimbursement for patients that awakened her to the realities of payment. One was the case of a patient on Medicaid whom she followed for several visits. Very few patients in the clinic were on Medicaid. Susan was surprised to learn, after seeing the patient for a few sessions, that his Medicaid benefits did not reimburse for occupational therapy services in their state. He ended up paying out of pocket for some but not all of his expenses, and the hospital wrote off most of his expenses. The other patient was covered by a health maintenance organization, which required preauthorizations for therapy treatment. Not knowing the system, Susan had failed to obtain necessary preauthorization, and the patient's therapy was denied. Susan had just assumed that her manager would educate her about the specifics of payment. Susan learned from these experiences the importance of understanding the nuances of different insurance plans and methods of payment.

INTRODUCTION: OVERVIEW OF PAYMENT

Payment issues are a major force affecting occupational therapy practice (Burke & Cassidy, 1991). When major changes occur with payment sources, practice is transformed. Federal and state legislation regulating payment strongly influences the direction of these practice shifts. For example,

Medicare, Title 18 of the Social Security Act, enabled expansion of occupational therapy practice for older adults, and subsequent amendments that changed how the law was regulated resulted in shrinking practice in some areas.

In daily practice, the knowledge practitioners have about payment is often based on the typical sources that cover their patients and clients. Some therapists who handle their own billing for services are very aware of the regulations affecting the payment that they receive. Others, like Susan, depend on their billing department or their manager to keep them abreast of payment policies and procedures. We suggest that it is important for all therapists, no matter where they work, to understand payment systems that affect practice and to be proactive by being aware of changes that may affect practice. Why? Because obtaining payment is the "bread and butter" of most practices, and therapists should be involved in obtaining optimal payment. This knowledge helps to support patients in their ability to access occupational therapy services.

This chapter provides a foundation about payment systems in the United States by first providing a brief history of insurance and then reviewing the key payment sources that occupational therapists may encounter in practices. In addition, this chapter addresses the needs and issues of the growing number of uninsured people in the United States and the effect of these numbers on heath care delivery. To fully understand payment systems, knowledge is required about the legislation that affects reimbursement and associated regulations. Public policy related to payment is discussed in this chapter, supplemented by some of the information mentioned earlier in Chapter 17. Documentation, which is directly related to receiving third-party reimbursement, is discussed in Chapter 39. Therefore, it is important to consider those additional chapters to get a thorough overall picture of payment for occupational therapy services.

HISTORY OF HEALTH INSURANCE

Health insurance was introduced in the United States in the 1700s with the federal Marine Hospital Service (McCarthy & Schafermery, 2001). This insurance was an anomaly, as most people directly paid for any health care they needed until the twentieth century, when the insurance industry grew (Patel & Rushefsky, 1995). During the twentieth century, several types of insurance were introduced, which laid the foundation for insurance in the twenty-first century. Factors such as advances in medical treatment with expensive technological interventions, Americans wanting increased value for their medical care, and expanding medical costs led to the development of the insurance industry (Shi & Singh, 2004). At the beginning of the twentieth century, the first workers compensation laws were enacted. These laws were based on concerns for the well-being of injured workers. They brought about a system that remains today of state legislation regulating the care of injured workers.

Third-Party Payment

In 1929, a model for hospital-based insurance, Blue Cross, and eventually a physician/medical services plan, Blue Shield, developed that laid the foundation for modern-day health insurance. Blue Cross/Blue Shield established a third-party payment system in which health care consumers paid a set monthly premium to receive medical services (Patel & Rushefsky, 1995). Providers were reimbursed a **fee for service** based on "reasonable and necessary" criteria with minimal restrictions on the numbers and types of interventions that consumers accessed (Sandstrom, Lohman, & Bramble, 2003). Fee-for-service type of payments occurred in **indemnity plans**, in which payments were made retrospectively to the provider.

The twentieth century also saw the growth of employer-based self-insurance plans. With self-insurance, businesses established their own internally funded plans and determined what services to include. For example, businesses could choose to include or exclude occupational therapy as a service if the insurance company from which they contracted services offered therapy in its menu of options. In 1965, federalization of health care insurance was introduced with Medicare and Medicaid. Provision of these plans paralleled the fee-for-service approach toward payment of the time. During most of the remainder of the twentieth century, health care insurance was based on a fee-for-service system with indemnity plans.

Shifting from Fee for Service to Managed Care

Legislation helped the health insurance industry to grow. Because of public policies that included tax incentives for employers and provided protection of self-insurance plans from state laws (Employment Retirement Income Security Act of 1974), the insurance industry expanded, especially in the area of self-insurance. The passage of the Health Maintenance Organization Act in 1973 laid the foundation for the development and growth of **managed care** in the insurance industry. However, it was not until the 1980s and beyond that managed care came to dominate the insurance market (Raffel & Barsukiewicz, 2002).

With the advent of managed care, a paradigm shift occurred that influenced health care payment. The insurance industry no longer focused on providing unrestricted and unlimited coverage for health care services; rather, it focused on controlling costs and coverage. An analogy of this paradigm change is like a change from having unrestricted food at a cruise ship buffet without considering the costs or amount of food being eaten (fee-for-service/indemnity plans) to knowing the food allowance

before the meal and being restricted to what you can order within that predetermined amount (managed care environment). Similarly, managed care restricted payment for health care services. One result was a movement away from retrospective payment for treatments, in which payment was made on the basis of what was billed, to prospective payments, in which the amount to be paid for services was established before the treatment. In the mid-1980s, the advent of **Diagnostic Related Groups (DRGs)** for Medicare Part A patients in acute care hospitals reflected this prospective approach and the overall paradigm shift. On the whole, these measures were intended to contain the spiraling costs that resulted from Americans using their health care insurance with no limitations and thus consuming services much like those eating at a cruise ship buffet.

CONSUMER-DRIVEN HEALTH CARE

Now we are entering the age of consumer-driven health care. Some people believe that consumer-driven health care will eventually replace managed care as demand for services and costs continue to rise, especially for businesses that provide health insurance as an employee benefit. A factor that encourages this model is a large, aging baby boomer generation with high expectations for health care services (Bachman, 2004). This economically driven approach, supported by public policy, involves lowering health care expenditures while at the same time providing consumer control over health plans. Thus, decision making about health care moves to the consumer instead of to the insurer. An example of consumer-driven health care is high-deductible health plans, which are often accompanied by a **health savings account (HAS)**. These plans are also known as **health reimbursement accounts (HRA)**. HRAs or HASs allow people to save and apply pretax dollars to health related payments. Pretax dollars can be used to pay for deductibles, coinsurance, copayments, and health insurance premiums, which are traditionally paid for with after-tax dollars. The consumer can choose areas that are not always covered by some traditional insurance, such as payment for mental health services, to be reimbursed. Currently, only a small minority of Americans are enrolled in these plans (Kaiser Family Foundation, 2006). However, consumer-driven plans could grow because of regulations from the Internal Revenue Service (IRS) that allow people to roll over unused money from year to year. Regulations also include a clause to cover expenses that are not in a plan but are identified by the IRS as "qualified medical expenses under IRC Section 213 (2)" (Bachman, 2004, p. 17). Legislation will continue to push this approach forward, and the hope is that if these plans become more common, businesses will help to educate their employees about making wise choices for health care options (Anonymous, 2005).

TYPES OF PAYMENT

This section briefly describes many different methods of payment for occupational therapy services. It helps to have an overall perspective of the current status of how Americans are insured, which is presented in Figures 69.1 and 69.2. This section includes several case studies, which illustrate payment systems.

Self-Pay

In the ideal world, all people would have access to health care at a reasonable cost. Yet the reality that exists presents a very different picture. People who do not have health care insurance get sick and need therapy services. Some who do have insurance find that their plans might not cover therapy, and most plans limit the number of visits or maximum allocable charges in a given time period. For those people, self-pay is an option, and if they recognize the benefits from therapy, they might be willing to pay the bill. For example, some people choose to self-pay for occupational therapy services beyond what is offered in the school system. Some older adults or their families self-pay for therapy services if the person who needs the service does not qualify for Medicare reimbursement. Practitioners can learn from those in other fields who provide services that are not traditionally covered by medical insurance, such as

acupuncturists or neuropaths. Many health care plans do not cover such services, but some people are willing to pay out of pocket for a perceived valuable service. Another reason for self-pay might be that a clinic does not bill insurers but requires payment up front. Thus, patients must submit their own bills to the insurer for payment.

Grants (Community Agencies)

One aspect of the American Occupational Therapy Association's Centennial Vision involves "Demonstrating and articulating our value to individuals, organizations, and communities" (AOTA, 2006, p. 3). As Case Study 69-1 illustrates, assisting communities in nontraditional settings often entails obtaining grant funding. Grant writing

is an art that involves clear documentation along with understanding the focus of the granting agency. In most cases, grant proposals must follow strict guidelines, and in all cases, they require careful documentation of the proposed program, service recipients, and expected outcomes (Braveman, 2006). Grant funding can be obtained from federal, state, or local government agencies and from private organizations. This type of "soft" payment provides funding for a prescribed time period, but when the grant is completed, practitioners need to find other sources for program support.

Costs Embedded in Larger Structures

In some instances, therapists work in settings in which the cost for their services is embedded in a larger payment structure, such as a case rate. An example of this type of coverage is by DRGs in acute care settings. With DRGs, hospitals receive from Medicare a set payment that is determined by diagnosis. All hospital services that are provided to a patient, including occupational therapy, must then be embedded in the payment structure.

Government Payment in the United States

Although we do not have universal health care in the United States, as in other major industrial countries (e.g., Canada, the United Kingdom), government funding does account for a large percentage of our health care dollar, as Figure 69.1 illustrates. The following sections outline key government programs. Note that one is a federal program (Medicare), others are federal/state programs (Medicaid, State Children's Health Insurance Program, IDEA), and one is a state program (Workers Compensation).

MEDICARE

The history of Medicare is important to consider because Medicare remains the principle financier of health care in the United States (Sandstrom et al., 2003), and changes

---

CASE STUDY: *Jeff: Paying for Services in a Homeless Shelter*

Jeff had a creative idea. He wanted to develop and administer a program to help displaced families in homeless shelters. He knew from his professional education that occupational therapy services can be provided in many nontraditional settings in the community. Jeff began a process of networking with people in his state and with professors at the local university. Through this networking, he located a state grant for which he wanted to apply to finance his idea for the program. Jeff partnered with a ther-

apist at the university, and together they wrote a proposal for a grant, which was funded for three years to develop Jeff's dream program. Jeff later reflected that he would never have been able to create this program without his university partner's mentorship. Jeff also acknowledged that it was his dream paired with his knowledge that ultimately provided access to occupational therapy for people without homes, who would not have been able to afford the services.

with the Medicare law have influenced overall health care provision and occupational therapy practice. This section includes an overview of the history of Medicare followed by a discussion of what is included in the law and how it affects current occupational therapy practice.

History

Part of the impetus for the Medicare law was to provide a solution to a growing concern about providing health care coverage for all Americans. An earlier attempt during Harry Truman's presidency to amend the Social Security act to include health insurance for all workers and their dependents as well as retired people had failed. Often with public policy, when a major bill has failed, there is an attempt to provide some type of fix to appease the American people. In this case, the fix was Medicare, as it was argued that only 15% of older adults had health insurance (Bodenheimer & Grumbach, 2005) and the older adult population had significant medical and financial needs. It was also acceptable to target older adults, because everyone inevitably would age and need health care benefits (Fein, 1986; Patel & Rushefsky, 1999). In addition, because the original Social Security law also targeted the aged, it was considered appropriate for public policy to again address the needs of that population (Fein, 1986). Another factor was that President John Kennedy was not politically strong enough to push forward a national health insurance plan, having won the election by a narrow margin (Patel & Rushefsky, 1999). One more factor that helped to push forward Medicare and other health policies was the changing composition of Congress, which had become more liberal (Lammers, 1997).

Given these factors, Medicare was passed into law during Lyndon Johnson's presidency. As with any public policy, the final bill was a compromise among different competing factions. In the U.S. system, all public policies involve compromises, which are worked out in conference committees. Thus, the final Medicare bill met the agendas of Johnson's Democratic administration by including a national health insurance for older adults funded through payroll taxes and of the Republicans by including a voluntary insurance program called Medicare Part B for physician and other services, such as occupational therapy, which was funded through general revenues (Bodenheimer & Grumbach, 1999).

Where and how many therapists practice are directly linked to the Medicare law and changes made to the law over time. Therefore, it is useful to understand an overview of key changes in the Medicare law since it was enacted in 1965. Table 69.1 highlights historical changes in the Medicare law over the years that have influenced occupational therapy practice. From the inception of Medicare in 1965 until 1983, changes in the law influenced occupational therapy practice in home health and hospice. In 1983, the introduction of a prospective payment system

(PPS) in acute care hospitals titled DRGs forever changed the landscape of Medicare reimbursement and, along with that, of occupational therapy practice. As a result of the DRGs, occupational therapists began working in larger numbers in other settings besides acute care hospitals (Swartz, 1998). DRGs resulted in shortened inpatient hospital stays and patients being discharged to other systems for additional care, such as outpatient therapy, inpatient rehabilitation units, home health care (HHC), or skilled nursing facilities (SNFs). The introduction of PPS in acute care hospitals also led to the development of new delivery systems. During the 1980s, subacute care units evolved to provide cost-efficient service to more acutely ill patients who had been discharged from hospitals with complex medical and rehabilitation needs (Griffin, 1998).

The establishment of a PPS as a cost-cutting measure spread over the next 20 years (between 1983 and 2003) into many other treatment settings covered by Medicare reimbursement. Even as early as 1984, there was discussion about launching PPS in SNFs (Scott, 1984). However, most of the system changes occurred in the late 1990s (in 1997, PPS in SNFs) or early into the next century (in 2000, HHC; in 2002, PPS in inpatient rehabilitation hospitals). In each of these settings, PPS is administered differently, but in all the systems, reimbursement for Medicare beneficiaries is allocated prospectively rather than retrospectively. Other cost-cutting measures have been introduced, such as a managed care option for Medicare beneficiaries and a cap on outpatient Part B therapy. As the large numbers of baby boomers age and qualify for Medicare coverage, one can anticipate continual cost-cutting measures. Issues of solvency are and will continue to be discussed.

How the Medicare System Works

All Medicare beneficiaries are covered under Part A, and some elect to be covered under the voluntary program of Part B. Part A covers inpatient hospitalization and critical access hospitals, SNFs, HHC, and hospice care. With Part B, the beneficiary pays a set fee per month to cover physician and outpatient services such as diagnostic tests; outpatient surgery; physical, speech, and occupational therapy; HHC; blood tests; and some preventive tests. Part B also covers some durable medical equipment. In 2006, the Medicare Prescription Drug Plans were initiated. It involves beneficiaries paying a monthly premium, a yearly deductible, and partial copayments depending on the amount that is spent out of pocket (Centers for Medicare & Medicaid Services, 2005).

As with any public policy, the original Medicare law was written very generally, with the interpretation of the law written into specific regulations, which health practitioners follow to receive payment. These regulations are governed by fiscal intermediaries located throughout the United States. Fiscal intermediaries monitor and pay

TABLE 69.1   HISTORICAL HIGHLIGHTS OF CHANGES IN THE MEDICARE LAW INFLUENCING OCCUPATIONAL THERAPY PRACTICE

Year	Amendment/Change	Impact on Occupational Therapy
July 30, 1965	Medicare or Title 18 of the Social Security Act was signed into law.	Encouraged the growth of occupational therapy practice.
1972	Medicare was extended to cover populations under age 65 with disabilities and end-stage renal disease.	Extended occupational therapy services to those who were qualified to be disabled.
1980	The Omnibus Budget Reconciliation Act included occupational therapy as a qualifying service under Part B with home health and a provision established comprehensive outpatient rehabilitation facilities to be Part B providers.	Had the potential of expanding occupational therapy services in home health as occupational therapy solely could qualify a person for skilled home health services if the person was considered to be home-bound according to the law. The second provision allowed occupational therapists to receive Part B reimbursement in freestanding rehabilitation outpatient settings, which expanded treatment coverage.
1981	The Budget Reconciliation Act eliminated occupational therapy as a qualifying service with home health.	This change required nursing, speech therapy, and physical therapy to qualify the patient for skilled care before occupational therapy. (To date, this provision remains unchanged.)
1982	In the Tax Equality and Fiscal Responsibility Act, hospice benefits were enacted on a temporary basis.	Occupational therapists began to work in hospice.
1983	Change from "reasonable cost" payment to a prospective payment system in hospitals (DRGs).	Resulted in shorter acute care hospital inpatient stays, with patients often transitioned to other settings, such as SNFs, for additional treatment. Occupational therapists began working in the systems to which patients were being discharged, such as SNFs and subacute care units.
1986	In the Consolidated Omnibus Budget Reconciliation Act of 1985, hospice benefit became permanent.	Occupational therapists work in this area.
1992	Physician services paid for on a fee schedule.	Occupational therapists also bill Medicare from the fee schedule, using Physician's Current Procedural Terminology Codes for Part B services.
1997	The Balanced Budget Act (BBA) of 1997 included a Prospective Payment System for home health beginning in 2000. The act also included a prospective payment plan for Medicare Part A in SNFs beginning in 1998. The BBA also established "caps" on Part B outpatient rehabilitation services of $1500 for occupational therapy and $1500 for speech therapy and physical therapy combined. The Balanced Budget Refinement Act called for the establishment of a PPS in inpatient rehabilitation units.	Changed the approach of practice in SNFs. Several legislative attempts were made to suspend and repeal the outpatient cap.

TABLE 69.1   HISTORICAL HIGHLIGHTS OF CHANGES IN THE MEDICARE LAW INFLUENCING OCCUPATIONAL THERAPY PRACTICE   *Continued*

Year	Amendment/Change	Impact on Occupational Therapy
1999	The $1500 cap became effective in January 1999 for non-hospital-based clinics. The Medicare, Medicaid, and SCHIP Balance Budget Refinement Act of 1999 was passed, adding a two-year moratorium on therapy caps in November 1999 (became effective in 2000). Increased payment for RUGs. Added regulations for medically complex patients.	While the caps were on moratorium, OT practice with Part B remained the same.
2002	PPS was instituted in inpatient rehabilitation hospitals. (Inpatient Facility Rehabilitation Patient Assessment Instrument, IRF-PAI)	Occupational therapists participate, completing the IRF-PAI for the patient classification payment system.
2000–2005	Several acts placed moratoriums on the therapy cap (2000, 2002). Several acts were introduced to repeal the cap (2001, 2002, 2003, and 2005). The cap became effective (September 2003). Another two-year moratorium was placed on the cap December 2003.	While the caps were on moratorium, OT practice with Part B remained the same.
2006–2007	The therapy cap for hospital-based clinics was instituted. The passage of the Deficit Reduction Act of 2006 allowed for a temporary exemption process for the therapy cap for certain conditions. Legislation continues to be introduced to repeal the therapy cap.	With the exemption, occupational therapists could apply for continued treatment for some patients.

claims and perform medical reviews, audits, and investigations. Although many regulatory changes have occurred with Medicare, such as the PPS, the same guidelines remain for determining occupational therapy coverage. Reimbursement for occupational therapy treatments requires a physician's order, and treatment must be completed by a qualified occupational therapist or occupational therapy assistant under the supervision of a qualified occupational therapist. Treatment must be of reasonable duration and amount and must be appropriate for the patient's condition. Treatment must also result in practical improvements in the patient's functional performance (Centers for Medicare & Medicaid Services, 1987).

PPS in Skilled Nursing Facilities

The introduction of PPS for Part A patients in skilled nursing facilities had a significant impact on how therapists practiced in those settings. The PPS system in SNFs involves a mandated assessment structure with periodic patient reviews. The Minimal Data Set, a patient-screening form that considers the patient's status, was instituted to determine clinical care of patients and payment. Sections of this instrument help to determine the classification categories for patients and ultimately the allocation of time that patients can be followed. Patients who qualify to receive rehabilitation are divided into five resource utilization groups (RUGs) ranging from ultra-high to low. Each group has a set amount of therapy minutes that a patient receives in a week and the disciplines (ranging from one to three) that can follow the patient. For example, a patient who qualifies to be in the "very high" RUG category is followed for 500 minutes by at least one discipline (Health Care Financing Administration, 1998).

PPS in SNFs is not without controversy. When PPS was instituted, consolidations and closures of rehabilitation companies occurred, along with losses of therapy positions, salary cuts, and, in some situations, salary changes from a set amount to hourly payments (Steib, 1999). Concerns about the quality of patient care in SNFs have been voiced in pilot studies examining the impact of the PPS (Brayford et al., 2002; Kennedy, Maddock, Sporrer, &

Green, 2002). Other expressed concerns are about treatment being less client-centered, ethics of treatment, and productivity demands, as well as less evaluation, treatment, and documentation time. In addition, some therapists reported less continuing education money, reduced fieldwork placements at their worksites, downsizing of departments, and lack of job security (Brayford et al., 2002; Kennedy et al., 2002). However, practitioners can learn and have learned to work effectively with the PPS by understanding the regulations related to practice, being very time efficient, having good communication skills with other disciplines (Brayford et al., 2002), and finding a mentor (Zellis, 2001).

PPS in Home Health Settings

Often, new changes in Medicare duplicate what has been effective with earlier initiatives. Thus, similar to the PPS system, which requires use of the Minimal Data Set in skilled nursing facilities, home health practice includes an evaluation tool for Part A patients that is called the Outcome and Assessment Information Set (OASIS). The OASIS is used to evaluate patient status and monitor outcomes for quality of patient care. Occupational therapists can consult with the nurse who completes the OASIS about the primary diagnosis for which HHC is needed and about the patient's functional status. Home health agencies are paid prospectively every 60 days an established amount based on calculations. This calculation is derived from a case mix index and a clinical model from which patients are classified into groups called Home Health Resource Groups (Johnson, 2000). Other regulations that were made prior to the PPS remain intact, such as requiring home-bound status for patients under Medicare Part A and the requirement that the other health care professions of nursing, physical therapy, or speech-language pathology must skill qualify a patient to receive the Medicare benefit before occupational therapy can be provided.

PPS in Inpatient Rehabilitation Facilities

For inpatient rehabilitation facilities, the PPS includes an evaluation tool that is called the Inpatient Rehabilitation Facility-Patient Assessment Instrument (IRF-PAI). The IRF-PAI is based on the Functional Independence Measure™. Like the requirements in skilled nursing facilities, patients are classified. However, in this system, patients are categorized in several ways: by impairment group code, by rehabilitation impairment category, by case mix group, and by the presence of comorbidities. Within this system, occupational therapy practitioners can play an important role in facilitating improved patient function from their interventions, as reflected by the scores on the IRF-PAI (Roberts, 2002).

MEDICAID

Because of an unmet societal need to help low income people, Medicaid, or Title XIX of the Social Security Act, was enacted in 1965. Medicaid insures older adults, children and parents of dependent children, pregnant women, and people with disabilities who meet the eligibility requirements. The majority of Medicaid recipients are children. Yet expenses for a small proportion of the Medicaid recipients, the older adults, account for 70% of Medicaid spending because of extensive use of acute and long-term care services (Kaiser Family Foundation, n.d.). Medicaid pays for 45% of nursing home care in the United States nationwide (Kaiser Commission on Medicaid and the Uninsured, 2007a). It is not surprising that older adults need Medicaid services, especially for nursing home care, with the average cost of nursing home care

---

CASE STUDY: *Gina: Accessing Different Payment Sources to Work in One System*

Gina's favorite population to work with was older adults. She had worked for years in skilled nursing facilities, but when assisted living facilities grew as another living alternative for older adults, Gina decided to work in an assisted living setting. She at first saw residents that qualified for therapy coverage under Medicare Part B. Gina kept current on changes in regulations about the cap on therapy charges for patients receiving Medicare Part B coverage. There were many times when the therapy cap was placed on a moratorium for therapy coverage and a point when it was enacted. When the therapy cap was enacted, Gina carefully monitored the therapy dollars that were spent so that she did not go over the established amount. In some cases, when the client's condition warranted, Gina requested an extension from Medicare for continued therapy services. Gina's work with patients was well respected at the assisted living facility. As a result, the administrator asked her to provide some consultation, which was paid for directly out of the facility budget. As Gina's practice grew, she also began following some residents who paid out of pocket for her services (private pay). So at the same assisted living facility, Gina was able to provide a variety of types of services and receive a variety of types of payments.

in the United States being $74,095 per year (MetLife Mature Market Institute, 2005).

Medicaid also provides support to 4 in 10 children who have special needs. The Early and Periodic Screening, Diagnostic, and Treatment benefit covers a large amount of services for children (Kaiser Commission on Medicaid and the Uninsured, 2007a). Without Medicaid, many more people would join the growing ranks of Americans who are uninsured (Kaiser Commission on Medicaid and the Uninsured, 2007a).

Medicaid is a program jointly financed by federal and state governments that is regulated by each state. It is considered to be a *means tested* program as people qualify if their assets and incomes levels are below standards set by the program (Shi & Singh, 2004). States can chose to expand their baseline Medicaid coverage and income eligibility requirements beyond the federal minimal requirements. Medicaid programs vary; each state provides different services and different systems for delivery. Quite often, programs are administered by using managed care (Centers for Medicare & Medicaid Services, 2006). Each state has a plan that documents how the program is administered, eligibility requirements, and required and optional health services covered. Occupational therapy is one of

the optional services; therefore, in some states, occupational therapy might not be a covered benefit. In 2004, 29 states included occupational therapy as a covered benefit, and occupational therapy was not a covered benefit in 22 states (Kaiser Family Foundation, 2004). However, states are required to reimburse occupational therapy services for children covered under the Early and Periodic Screening, Diagnostic, and Treatment benefit if ordered by a physician and deemed to be medically necessary (Mary Steiner, personal communication, June 8, 2007). It behooves occupational therapists to be aware of changes on a state level and advocate for therapy coverage in their state. Table 69.2 provides examples of required and optional Medicaid benefits.

STATE CHILDREN'S HEALTH INSURANCE PROGRAM

A more recent federal health insurance program, the State Children's Health Insurance Program (SCHIP), or Title XXI, was created in 1997 as part of the Balanced Budget Act. This program provides health insurance to children and some parents in families that are ineligible for

PRACTICE DILEMMA

ANGIE: A THERAPIST WORKING WITH A PEDIATRIC CLIENT OVER THE YEARS IN DIFFERENT SETTINGS WITH DIFFERENT PAYMENT STRUCTURES

Angie has seen Jamal, a 10-year-old child with cerebral palsy, in therapy for most of his young life. Angie has found that during the time that she had seen him, not only had her skills developed as a therapist, but she had also learned about different payment systems. Angie first saw Jamal when she was a therapist working in a neonatal intensive care unit in an inpatient acute care hospital. Jamal's hospital therapy services were reimbursed by his parent's insurance plan, a managed care organization (MCO). Angie worked with the MCO to obtain proper authorizations. Her focus for therapy with Jamal was on his medical and developmental needs. Five years later, Angie again saw Jamal, this time through the school district, where she had decided to contract part-time. There, she had to learn to change her focus from working in a traditional medical model to working in an educationally based model. Angie's treatment approach with Jamal was to help him improve his learning skills and to help him better participate in school activities. She worked with Jamal directly and consulted with his teacher on

ways to improve his writing skills and self-help skills needed to participate in the classroom and to help Jamal modify some of his behaviors that were creating problems in the classroom. Angie participated in setting goals for Jamal's Individualized Education Program (IEP). When Jamal was 7½, he fell and broke his wrist. Because Angie still provided some contractual services at the hospital, she was able to follow Jamal in outpatient therapy. Again because of the setting and the medical nature of his needs, his therapy was covered by his parent's MCO. In the hospital system, Jamal's goals were based on regaining the functional use of his upper extremity.

Questions

1. Why were the therapy goals different in the school setting than in the hospital setting?
2. What public policies regulate payment for each of the settings?
3. How could Angie learn more about the payment systems in each setting?

Medicaid and for whom health insurance is either unobtainable or cost prohibitive. Like Medicaid, SCHIP is a federal- and state-financed program in which states administer their programs (Kaiser Family Foundation, n.d.). SCHIP is quite an expansive health insurance program, covering one quarter of all children in the United States. Since its inception, SCHIP has been successful in expanding health coverage and access to care as well as in decreasing the number of uninsured children in the United States (Kaiser Commission on Medicaid and the Uninsured, 2007a).

INDIVIDUALS WITH DISABILITIES EDUCATION ACT

As of 2003, the highest percentage of occupational therapists (34.4%) were employed in school-based and early intervention practice (AOTA, 2003). In school-based practice, the Individuals with Disabilities Education Act (IDEA), a federal/state program, regulates and finances services, including occupational therapy, for children with

special needs. The specifics of school-based practice are beyond the scope of this chapter. Nevertheless, therapists working in that system will need to have a strong knowledge of the regulations related to the IDEA and the focus of occupational therapy in the school system. It is beneficial for therapists to understand how IDEA finances services for children with special needs. Because it is a federal/state program, IDEA provided some federal funding, but most of the financing for IDEA comes from taxpayers in local school districts (Baumgartner, Berry, Hojnacki, Kimball, & Leech, 2002). Thus, IDEA is really a federal, state, and school district partnership. As a result, there will be differences in services among school districts and across states. Occupational therapists' salaries, like all special education staff salaries, are figured into a special education budget. A percentage of staff salaries are paid for by state dollars, and the remainder is paid for by the school district. School districts determine whether therapists are contracted or hired as staff. Finally, states determine and regulate the payment rates for therapy and that amount can vary (Steve Milliken, personal communication, June 6, 2007).

WORKERS COMPENSATION

Workers compensation programs are state programs that pay for care of workers who have injuries or illnesses due to work-related causes. Each state has a governing body that determines the administration of the state program. Like other programs that have been discussed in this chapter (Medicaid, IDEA), workers compensation programs vary from state to state, and where they are located in the state government varies. Programs generally pay for medical services to get the person back to work, for benefits for lost wages when appropriate, and for disability. Programs may include services such as vocational rehabilitation, medical rehabilitation, job placement for someone with a permanent disability, and social services (Workers Compensation Board, n.d.). Many of these programs use a managed care approach to run their programs. How workers compensation programs are funded varies from state to state. Generally, they are financed through employer insurance, state funds, or self-insured businesses.

MANAGED CARE

Currently, managed care dominates the private health care insurance market (Dudley & Luft, 2007). Therefore, therapists in many settings will likely see patients who are covered by some type of managed care plan. There are many definitions for managed care. For example, one definition states that managed care is a "comprehensive health care which is provided to participating members of an organized health care organization through the use of a network of health care providers and facilities; it uses a delivery system that secures cost effective health care"

(Medhealthinsurance, n.d.). Another definition states that "managed care is a healthcare system in which there is administrative control over primary health care services in the medical group practice. The intention is to limit redundant facilities and services and to reduce costs" (Mosby, 2002). Thus, common to most definitions is the emphasis on controlling and reducing health care costs.

Managed care "integrates the functions of financing, insurance, delivery, and payment within one organization" (Shi & Singh, 2004, p. 326), and most managed care organizations (MCO) include primary and preventive care (Shi & Singh, 2004). **Health maintenance organizations (HMO)**, **preferred provider organizations (PPO)**, and **point of service (POS)** plans are examples of managed care options. Refer to Table 69.3 for a brief description of these services. In recent years, options such as PPO plans have proven to be the most popular because of increased consumer choice (Kaiser Family Foundation, 2006; Shi & Singh, 2004). Regardless of the type of plan, managed care includes five basic characteristics (Raffel & Barsukiewicz, 2002, p.37):

- ◆ A select panel of providers
- ◆ Comprehensive health services
- ◆ Quality tracking
- ◆ Utilization review
- ◆ Cost containment

Occupational therapy practitioners need to understand how each patient's plan works in order to receive payment. Information about a patient's plan should be obtained or provided by the patient before the initiation of treatment. Some plans require preauthorization for beginning treatment or authorization for continued treatment.

? PRACTICE DILEMMA

MARK: A THERAPIST WHO LEARNED A LESSON ABOUT THE DIFFERENCES BETWEEN STATE WORKERS COMPENSATION PROGRAMS

Mark had just moved to another state and obtained a new position as an occupational therapist in a therapy clinic that specializes in orthopedics. The first patient whom he saw, Richard, had injured his right hand in a work injury. Richard's insurance coverage was workers compensation. Mark wrongly assumed that the workers compensation program would be administered in the same way as the one he had been used to working with in another state. Therefore, Mark had not been in contact with Richard's case manager.

Two weeks into therapy, the case manager called, and Mark learned from that conversation some of the differences in the state's workers compensation plan.

Questions

1. How can Mark find out what the workers compensation program in his state covers?
2. What does workers compensation cover in your state, and how is the plan administered?

TABLE 69.3 TYPES OF MANAGED CARE		
Health Maintenance Organizations (HMOs)	**Preferred Provider Organizations (PPOs)**	**Point of Service Plans (POS)**
These are the most restrictive of the managed care plans. They are based on the concept of having a gatekeeper, usually a primary care provider, monitor and control all care and referrals. As much as possible, health care is provided by the primary care provider. Payment is based on a capitated predetermined fixed rate per patient.	With these plans, participants can select from a pool of a limited number of health care providers. If the enrolled person goes outside of the PPO for care, out-of-pocket costs are higher.	These plans are a hybrid of an HMO and a PPO plan. The enrolled person has a primary care health practitioner who acts as a gatekeeper to manage care and make referrals. The enrolled person also has the choice of using a group of providers like a PPO.

Source: Raffel and Barsukiewicz (2002); Sandstrom et al. (2003).

Occupational therapists work with case managers who monitor care, and good communication is essential for coordination of care (Sandstrom et al., 2003). Finally, managed care has not been without controversy with issues from consumers and health care providers alike. The Patient Bill of Rights, an attempt at federal legislation to regulate managed care organizations better, evolved because of controversies about managed care provision (Lohman, 2003).

THE UNINSURED

In the early 1990s, President Bill Clinton advocated for health care reform, proposing a universal health care plan. One of the president's arguments was the travesty of the 37 million Americans who had no health care insurance. The uninsured were not the poor or older Americans but rather the working poor, those employed in low-wage jobs. Health insurance in the United States was primarily employment based (Raffel & Barsukiewicz, 2002), and individuals in many jobs did not receive health insurance benefits. Downsizing and corporate layoffs also contributed to the uninsured pool (Johnson & Broder, 1997; Vigilante, D'Arcy, & Reina, 1999). In addition, many of the uninsured did not meet the qualifications for public insurance, such as Medicaid.

Today, over 15 years later, the problem has worsened. There are now more than 47 million uninsured Americans (DeNavas-Walt, Proctor, & Lee, 2006). As in the early 1990s, most individuals who do not have health care insurance are employed (or are dependents of people who are employed), but the employer does not provide health insurance and individual health insurance premiums are prohibitive for the individual. Young adults age 18 to 24 years are more likely than any other age group to be uninsured (DeNavas-Walt et al., 2006). The composite of uninsured people also includes immigrants, poor people without other public coverage, and even people with higher incomes (Herrick, 2006). Employees of small businesses also contribute to the pool of uninsured numbers, as approximately two out of five small businesses do not provide health care insurance (Kaiser, Family Foundation, 2006).

Lack of insurance coverage has many negative consequences. The uninsured are less likely to seek out health care or will postpone getting needed health care because of costs. The uninsured obtain less preventive care. In addition, their medical conditions are often diagnosed in later stages, and even after diagnosis, they receive less care and have higher rates of mortality than the insured population (Kaiser Commission on Medicaid and the Uninsured, 2003).

Uninsured people often end up obtaining health care in emergency rooms, which ultimately increases costs for the health care system and may be the inappropriate place to receive care (Herrick, 2006).

Occupational therapists have a moral responsibility to be aware of and consider ways to serve patients who do not have insurance. The profession's code of ethics encourages therapists to "Make every effort to advocate for recipients to obtain needed services through available means" (Commission on Standards and Ethics & Peloquin, 2005, p. 639). On a clinical level, charging reasonable fees for services and providing some pro bono service are ways to help uninsured clients. However, ultimately, the problem is a larger societal issue that will need to be solved with legislation. To date, the United States has been unsuccessful in designing a universal health care system, in spite of many efforts (Raffel & Barsukiewicz, 2002).

COBRA AND HIPAA

As was just discussed, one group that is at risk for being uninsured is people who have changed employment or have been laid off from their jobs. As a result of this major issue, the Consolidated Omnibus Budget Reconciliation Act of 1985 (COBRA) was passed. COBRA allows employees 18 months of continued insurance coverage after leaving a place of employment. However, COBRA is very costly, as individuals pay more than their group rate to obtain this insurance. High costs limit some people who cannot afford COBRA and may ultimately contribute to the number of uninsured Americans. As a result, only 7% of unemployed people get this insurance (Dalrymple, 2003, October 9).

Therapists should be familiar with the Health Insurance Portability and Accountability Act of 1996 (HIPAA) because of the privacy regulations. HIPAA also helps people who have preexisting conditions by preventing denials of insurance coverage with a new plan. HIPAA can provide continued insurance beyond the coverage of COBRA (Shi & Singh, 2004).

ADVOCACY FOR PAYMENT

Now let's return to the scenario about Susan that was presented at the beginning of the chapter. You will recall that Susan faced a number of challenges resulting from lack of coverage for the patients she was treating. As a result of experiencing these problems, Susan might become aware of her many chances to advocate for payment for her patients directly, as well as through efforts coordinated on the state level with her state occupational therapy association and even on a national level (Sandstrom et al., 2003). At the clinical level, Susan could communicate with a case manager of the patient's managed care organization to consider reversing the decision to deny coverage because of the mistake Susan had made when she failed to obtain preauthorization. If necessary, Susan could find out the process for appealing a denied claim and then help her patient to work within the managed care organization's system or possibly contact the state insurance board.

As this discussion illustrates, every time practitioners experience problems getting payment in their daily practice, they should critically consider how best to get reimbursed. Sometimes, effective communication with case managers or other key people in an insurance system make it possible to obtain payment (Sandstrom et al., 2003). Other times, simply following through with the processes in place, such as an appeals system, can work. Sometimes, going beyond the traditional system to get funds through charitable organizations might be an option. For example, therapists might consider contacting an association that specializes in a patient condition, such as the Multiple Sclerosis Association, or might find that a client's friends, family, or faith group may donate needed funds.

The second issue that Susan encountered, that of occupational therapy not being a required Medicaid benefit in her state, demonstrates an opportunity for advocacy through the state occupational therapy association's legislative committee. Susan could choose to become involved with the legislative committee. Members of the legislative committee could methodically work through an advocacy plan to obtain occupational therapy as a required Medicaid benefit in their state. There are many resources for support with such advocacy efforts through the Public Affairs Division of the American Occupational Therapy Association. This division includes a State Affairs Group, a Federal Affairs Group, and a Reimbursement and Regulatory Affairs Group. Depending on the need for advocacy support, an occupational therapist might access one or all of the groups (AOTA, n.d.). Finally, Susan could advocate on a federal level for legislation that affects payment for her practice. For example, she could advocate for possible changes in Medicaid reimbursement. Simple efforts, such as writing letters, can make a difference.

? PRACTICE DILEMMA

ADVOCATING FOR SERVICE PAYMENT

Local practitioners as well as state occupational therapy associations are likely to be aware of problems related to payment for occupational therapy services. Additional issues may be posted on the AOTA Website or on the Websites of other professional and consumer groups. Take some time to find out what these concerns are, and then select one to work on to change. Then, keeping in mind the information discussed in this chapter, consider the following questions:

Questions

1. What kind of reimbursement system is related to the issue, and who controls the rules for payment?
2. What efforts have occurred over the past several years to improve the payment situation?
3. What advocacy approaches are likely to be most successful in this situation?
4. What will you do?

CONCLUSION

As the case examples and practice dilemmas in this chapter have illustrated, dealing with payment issues is a regular part of therapy practice. Practitioners may work with a variety of payment systems. On the surface, knowledge about payment systems might seem overwhelming, as the financial system in the United States is very complex. Yet it is every practitioner's professional duty to learn about these systems in order to be able to provide the right intervention and to advocate for payment when needed (Commission on Standards and Ethics & Peloquin, 2005). Payment systems change, and these changes often occur because of new or amended legislation. Keeping current with legislation that affects payment for one's area of practice is essential for successful practice.

RESOURCES

The Center for Medicare & Medicaid Services:
http://www.cms.hhs.gov/

The Center for Medicare & Medicaid Services provides a plethora of information and resources on these government regulations.

Families USA:
http://www.familiesusa.org/

This organization addresses issues such as Medicaid and children's health, the uninsured, Medicare, and minority health. It is very involved in the political arena.

The Kaiser Family Foundation:
http://www.kff.org/

The Kaiser Family Foundation provides a large amount of information related to health care public policy, health insurance, and the uninsured.

Kaiser Family Foundation Educational Site:
http://www.KaiserEDU.org

This is a helpful site, especially for educators. Tutorials can be obtained from

http://www.kaiseredu.org/tutorials_index.asp

Consultation

JANIE B. SCOTT

Learning Objectives

After reading this chapter, you will be able to:

1. Define terms and concepts related to consultation.
2. Identify the focus, skills, and scope of consultation services.
3. Articulate business issues that are important to consultation.
4. Identify emerging areas for consultation opportunities.

The purpose of this chapter is to discuss the individual role of the occupational therapy **consultant**. **Consultation** is a process of establishing an agreement with an individual, family, facility, community, government, or other entity to provide a discrete service that is agreed upon by all parties. Occupational therapy practitioners provide consultation services across every area of occupational therapy practice and consider every human condition. Consultants are often sought because an organization or agency is involved in a continuous quality improvement process and has determined that external consultants are needed to help improve the range of services available to meet **clients'** needs; determine ways to increase cost effectiveness; identify the type and scope of staff training needed; and create a comprehensive plan to integrate best practices throughout the department, division, or agency (Braveman, 2006).

I interviewed occupational therapy consultants (past and present), and their experiences and perspectives are interwoven throughout the chapter. The material for this chapter was based on these personal interviews, my personal experiences, and the literature on consultation in the field. Occupational therapy students and practitioners have the opportunity to learn from the experiences of others in the classroom and in practice. To communicate some real-life issues related to the consultant in the delivery of consultation services, information from the interviews will be used to underscore the elements and importance of this practice area.

BEGINNING A CONSULTATION PRACTICE

A premise of this chapter is that consultation is an advanced level of practice. Before becoming consultants, the majority of occupational therapy practitioners have years of specialized experience. Chapter 68 described the distinctions between the practices of the occupational therapy assistant and the occupational therapist. These naturally extend into occupational therapy consultation. Before starting a consultative practice, practitioners should research key aspects and then consider their own characteristics, skills, and competencies. Additionally, practitioners should reflect on the domain of the profession as it relates to opportunities to provide

consultation. Each of these is discussed in the following subsections.

Research

The occupational therapy practitioner who is interested in consultation should research through his or her state board of occupational therapy practice to verify that the focus of the work the practitioner intends to do is within the occupational therapy scope of practice. Wood (2004) discussed the responsibility of striving for evidence-based practice that fulfills our passions while contributing to the profession and society. An occupation-based, evidence-based foundation in occupational therapy helps to preserve the essence of the professions' work in the community and elsewhere. Wood cautioned against practicing occupational therapy in a "decapitated" manner. As the profession assumes more of a consultative role in the community, we have the responsibility to be thoughtful in our practices, using the available evidence to support our work. This responsibility is also articulated in Principle 4 of the American Occupational Therapy Association's *Occupational Therapy Code of Ethics* (AOTA, 2005): "Occupational therapy personnel shall achieve and continually maintain high standards of **competence** (DUTY)." All principles articulated in the Code have specific relevance to the roles and responsibilities that the occupational therapy consultant assumes and performs.

Research must inform practice, particularly when the focus of the occupational therapy practice is consultation. The consultant has a responsibility to ensure that the translation of evidence to practice is delivered in a way that meets the recipient's needs, literacy level, and language competency (Hammon Kellegrew, 2005).

Skills and Competencies

Once an opportunity presents itself or you identify a potential opportunity, the next step is to assess your skills and competence. Many occupational therapy practitioners decide to venture into the consultation arena because they have amassed years of experience in a particular practice area and they want to expand the scope of their work. For example, Cindy Barrows had worked for many years with people who had mental illness. She stated:

> When I saw the opportunities to inform organizations about how occupational therapy can help address some of the behavioral and daily living issues clients and program staff faced, I offered to do presentations to community based programs. (C. Barrows, personal communication, August 17, 2006)

Later, Cindy developed a proposal that identified what occupational therapy could provide to the individual client in community-based mental health programs. A review of the information that Cindy provided led the agency to realize that they needed an occupational therapist to develop a transition program to help deinstitutionalize clients. An occupational therapist mentor suggested that Cindy provide consultation services in the area of functional and work behaviors for individuals with persistent mental illness. Cindy stepped forward and offered her services as a consultant to the agency.

Assessing your skills and competencies can be a challenging and important task in defining your potential scope of consultation. Not only do you have to consider what clinical and academic preparation you have that equips you to be an expert or consultant in a particular area, you also need to have demonstrated the competencies to perform the specific roles and duties required of a consultant in a particular situation. (See Chapter 25 for more information about assessing your own competence.) Competence may be demonstrated by advanced certifications, scholarly publications, and extensive experiences in specialty areas. The consultant has an ethical and legal obligation to the client as well as to the individuals who are served by or through the agency to offer the best, most informed services possible. Just because an opportunity sounds good, this does not necessarily mean that you should provide the consultation. An objective evaluation of your skills and careful matching of these skills to the consultation opportunities are important for success. Your **ethics** and integrity as a professional must be paramount.

Characteristics of Occupational Therapy Consultants

An analysis of information from consultants interviewed for this chapter, along with literature within the field (Braveman (2006), Dunn (1990), Epstein & Jaffee (2003), Loukas (2000), Merryman (2002), O'Connor (2000), Palisano (1989), and Scott (2006).), suggests certain characteristics that promote success in delivering occupational therapy consultation services. These include the following:

◆ **Expertise:** The consultant needs to have experience well beyond entry level in the area of the consultation. Consultants are experts who have the knowledge and experience to deliver their services.
◆ **Listening skills:** Consultants need to listen to clients and understand the corporate culture.
◆ **Flexibility:** Flexibility of thought is required to respond to current issues that are presented in the environment in which the consultation is occurring. That flexibility allows the consultant to customize his or her services on the basis of what the clients want to receive.
◆ **Awareness of opportunities relevant to occupational therapy:** Consultants maintain ongoing awareness of typical problems for clients, current occupational therapy practice relevant to these problem, the "market" or opportunities to provide services, and future trends that might affect clients.

Becky Austill-Clausen began her consultation and private practice with a sound background in occupational therapy in **contexts** that included home health, skilled nursing facilities, and school system practice. She emphasized that a consultant has to be willing to build trust with those who are involved in the **contract**:

> The occupational therapy practitioner must demonstrate a high level of ethical conduct, integrity, be a good listener and get people to talk about their problems and concerns. The consultant cannot be satisfied with the status quo. A successful consultant will collaborate with the client to determine the appropriate intervention for the environment, and be able to deliver the contract's outcomes in the good hands of the contract owner and walk away. (B. Austill-Clausen, personal communication, August 15, 2006)

Ethics and the Consultant

Awareness of the ethical obligations of occupational therapy practice is also an important characteristic of the consultant. There are many influences and temptations in fulfilling the role of a consultant. Every one of the seven principles articulated in AOTA's *Occupational Therapy Code of Ethics* (AOTA, 2005) has relevance to the occupational therapy practitioner who practices as a consultant. (Readers are encouraged to review the Code and familiarize themselves with its application to this specialized practice area.) There are temptations that need to be recognized and avoided, such as placing personal prosperity before the client's needs. Examples of this are the use of deceptive language and offering of services that the consultant does not have the competency to deliver and that could potentially harm the client physically, psychologically, or financially.

Truby LaGarde explains how she became a consultant:

> Initially, it didn't feel like I was starting a business. I was trying to find work for myself. As the shift from institutional care to home care occurred, I knew that I needed to learn more about consultation and private practice. AOTA was a great resource for me. I connected with a presenter that I heard at an AOTA conference (who became my mentor). Understanding, assertiveness, and experience equaled strength of commitment to sell ideas and inform Medicare surveyors about outcomes anticipated through occupational therapy interventions. The hospital wanted me to provide occupational therapy services for them; however, I felt that I would be more effective serving as an independent contractor/consultant. (T. LaGarde, personal communication, September 6, 2006)

In this situation, Truby recognized the good occupational therapy foundation that she had gained through her 12 years of experience. She used her grounding in ethics and her professional reasoning skills to decide on the focus of her consultation efforts.

DEFINING YOUR FOCUS

Personal interests and market demands often define the focus of consultation services. Part of the role of an entrepreneur is to "seize the day" and take advantage of available opportunities. For example, my academic background has been rich with diversity. When working at the state department for health and serving as a volunteer in my state association, I became more aware of unmet needs in my community. There was a demand for occupational therapy services for individuals with autism. The role of consultant began with clinical consultation in the direct service model for one client. Ultimately, that role expanded as the agency's needs became clear: adding in-service education to staff; identification of community resources and potential employers for the clients; and occupational staff recruitment, hiring assistance, and supervision.

DETERMINING THE SCOPE OF CONSULTATION TO INDIVIDUALS, ORGANIZATIONS, AND AGENCIES

Consultants need to differentiate the consultation services they will offer. Some consultation is provided to an individual, whereas other consultants may focus on a group or organization.

Individual Consultation

Individual consultation is a collaborative relationship that is established between a consultant and a client. Clients

---

CASE STUDY: *Determining Focus: Cindy and Truby*

Cindy Barrow's work as a consultant and her community involvement with mental health programs led to requests for her to consult on task forces and help the groups to address specific problems. Cindy developed program recommendations that included needs assessments for clients. She offered suggestions on how to organize households, create more effective milieus, and revise programming to more effectively address client needs.

Truby LaGarde's awareness of changes in **regulations** and market trends helped her to expand her consultation services through diversification. She provided consultation to home health agencies, agencies that were committed to improving the deinstitutionalization process, and individual clients.

may pay directly, or the service may be covered by a third party, such as insurance. For example, consultation services can be extended to older individuals and their families, focusing on the environment, fall prevention, or lifestyle redesign. In these situations, consultation reflects a stance of providing information or options, and the client takes the primary responsibility for adopting and implementing the suggestions.

In a somewhat different situation, the consultation arrangement may be initiated by an agency, which in turn connects the client and the consultant. In these circumstances, the agency may be the payer, receiving funding through a third party such as government funding. The client's competence may be one of the determining factors in whether the consultant has a direct relationship with the client or whether the agency manages the consultative relationship. This also touches on the importance of recognizing who the stakeholders are in the consultation. In some situations, the consultant can have responsibility to primary, secondary, and tertiary stakeholders and owe a different level of responsibility to each.

An example of consultative services mediated through an agency is those funded by the Individuals with Disabilities Education Improvement Act of 2004 (P.L. 108-446) [IDEA]. The occupational therapy consultant has opportunities to provide consultation services to the classroom teacher, the student, parents, and the school. IDEA gives the occupational therapy consultant an increased number of opportunities to address the broad range of educational possibilities for students, and the school or an educational agency serves as the arbiter.

Consultation to Organizations

Many occupational therapists have been successful in providing consultation to industries. O'Connor's work (O'Connor, 2000) focused on prevention of musculoskeletal disorders in the work environment. Fontana (1999) provides industrial consultation to analyze and advise about injury prevention, ergonomics, work hardening, and implementation of federal regulations (e.g., the Americans with Disabilities Act) in business and industry. And as was noted in the previous section, occupational therapists may provide consultation to school systems regarding maximizing educational options for students with special needs. Cindy Barrows, one of the consultants I interviewed, found consultation opportunities in mental health programs to develop new programs and revise existing ones (C. Barrows, personal communication, August 17, 2006). Home health agencies were initially Becky Austill-Clausen's consultation focus (B. Austill-Clausen, personal communication, August 15, 2006). She taught agencies how to utilize occupational therapy, physical therapy, and speech language pathology services; establish service delivery systems; develop referrals; and establish quality assurance programs. Eventually, her consultation included schools

and rehabilitation programs, often using a continuous quality improvement model.

THE EVOLUTION OF THE PRACTICE

A consultant's range and scope of services can stay focused over time or can expand. The growth of the practice can depend on the practitioner's interests and skills and the opportunities that exist or can be created. As in other areas of occupational therapy practice, the occupational therapy practitioner can specialize (e.g., providing consultation services to industry focusing on injury prevention) or may choose to provide a broader range of consultation services (e.g., to builders, contractors, and architects about incorporating accessibility and universal design concepts in to new construction and renovations, as well as working with local area agencies on aging to create fall prevention programs in senior centers, assisted living facilities, and individual homes).

MANAGING AND MARKETING THE BUSINESS OF CONSULTATION

Being a consultant often means being a business owner as well, although some individuals do provide consultation as a service offered by their employer. For those who are functioning as independent consultants, there are a number of business factors that must be addressed. For instance, the consultant needs to develop a system to document all project-related activities. Policies need to be established, such as routinely negotiating in advance if you are going to charge for missed appointments. Consultation plans must be developed that detail the services under contract, the timelines for the consultation, and anticipated income and expenditures. Adequate provisions for reserving finances for paying taxes will be required, as they often are unlikely to be deducted by the client. If you establish a home office, consult tax law and an accountant to determine the deductions that are allowable for equipment, transportation, supplies, utilities, furniture, rental expenses, and other items.

The Small Business Administration (SBA) is an excellent resource for small businesses and can answer many of the questions from consultants who are beginning new businesses or services. (See the On the Web section for the SBA website.) Mentors are sometimes available through the SBA; if one is not, new consultants should try to locate a local expert who is willing to provide guidance and assistance. These resources can assist you to lay a foundation within your community and think about how to develop the networks where you wish to provide consultation services. The more you are known and respected by those in the arena in which you wish to provide services, the more you will be able to create opportunities for yourself. If the target for consultation services will be individuals or businesses that currently are unfamiliar with occupational

---

CASE STUDY: *Growing a Consultation Business:*
Cindy, Truby, and Roxanne's Experiences

Cindy Barrows's consultation services grew as a result of her marketing efforts. Her service on committees increased her visibility in the community. She was asked to provide direct clinical consultation that focused on functional evaluations to determine the level of care a client would need in the community. Her services evolved to providing consultation to staff, making recommendations on how housing staff can optimize client's occupational performance. A further evolution occurred when the state department of mental health read Cindy's reports, recognized the quality of her recommendations, and wanted to access her expertise.

Truby LaGarde's consultation practice expanded from home health care to group homes for individuals with developmental disabilities. This **consultation process** included creating strategies for addressing some of the behavioral issues that the clients were exhibiting and recom-

mending the removal of environmental barriers that were hampering the clients' independence.

Roxanne Castaneda had formal training in consultation through graduate school in applied behavioral science with a major in organizational development. She took classes in process consultation, which provided her with techniques and models used for organizational consultation. As she states, "This was a nice complement to my OT degree" (R. Castaneda, personal communication, September 29, 2006). Roxanne recognized that her background in occupational therapy and her academic knowledge had prepared her to expand her scope of services from direct service to include consultation. She also gained consultation experience as a volunteer with the Maryland Occupational Therapy Association, contributing to her profession while gaining further knowledge that could be reflected on her resume and in practice.

---

therapy, the networking and marketing will need to be outside of traditional occupational therapy circles. Marketing plans can include presentations to community groups, publication of articles in community papers and newsletters, and teaching continuing education activities.

All consultation should begin with a structured, easy to follow plan. Boxes 70.1 and 70.2 provide some experts' advice on creating a focused and needs based consultation plan, including strategies for communicating with the agency and engaging them in the development of the plan to achieve greatest "buy in."

Sources for Reimbursement Basics

If the consultation is a client-focused role, the reimbursement for consultation services may be the traditional ones (e.g., Medicare, Medicaid, schools). Consultation to programs for individuals with developmental disabilities may be funded through state developmental disabilities programs. Organizations, agencies, and industry may have separate line funding for consultation services. Occupational therapy practitioners may also collaborate with agencies to write grants that would support the consultant and the scope of the work. Part of the preparation for providing consultation is doing one's homework to investigate where the funding streams are. AOTA can be a good source of reimbursement information that can help to connect the consultant to resources and links to others.

Some Important Elements
to Include in a Contract

When the consultant has an agency as a client, the consultant has to understand the priorities of the agency, the

outcomes the agency desires, the focus of the business or service delivery, and whether or not the consultant has direct access to staff and management. It is important to clarify the length of the consultation and whether ongoing communication with staff is possible or expected. In some consultation situations, the consultant is hired to develop a product and has minimal, as opposed to regular, contact with the administrator who initiates the contract. The consultant in collaboration with the client should determine the contract focus, the communication process, the need for ongoing interactions, and whether the purpose of the consultation is to assess the environment, analyze and develop recommendations independently, and submit reports to the client at the conclusion of the consultation.

For example, in a consultation that was established with the Veterans Administration to supervise and guide the competency development of a new graduate and advise about program development, it was important to understand the lines of communication and ultimate authority. Each party to the agreement needed to know how the recommendations would be considered and adopted. Some of the questions were as follows:

1. If the consultant made recommendations to the new occupational therapy graduate, would the new graduate be expected to carry out the consultant's suggestions?
2. Who should receive recommendations about (a) performance expectations, (b) standards of occupational therapy practice, (c) treatment program suggestions—the occupational therapist, the administrator or both?
3. What obligations, if any, did the occupational therapist have to adopt and implement the program development recommendations?

BOX 70.1

THE CONSULTATION PLAN: TIPS FROM THE EXPERTS

Preplanning

- Set up a time to learn about the agency or situation from a key player in the agency.
- Obtain information about the agency and its purpose, key audiences, and goals.
- Listen for problems that might be effectively addressed by an occupational therapist.
- Explore the agency's understanding of occupational therapy.
- Ask whether you can meet again and perhaps discuss ways in which you might help.
- Send a thank you note, and call for another appointment.

Preparing the Preliminary Plan

- Develop a structured plan.
- Include concrete steps or phases.
- Develop clear goals.
- Identify ways to measure goal accomplishment.

Presenting the Plan

- Set up an appointment with key players who can make decisions about the plan.

- Present and discuss the plan.
  - Provide a written summary.
  - You might need a formal oral presentation if appropriate to the setting.
- Solicit desired adjustments to the plan and be open to changing it.
- Discuss policies that might guide implementation.

Finalizing the Plan

- Background or summary of current issues
- Focus of consultation
- Process
  - Concrete phases or steps and related time frames
  - Policies related to implementation of consultation
- Expected outcomes, including how they will be measured
- Summary of fees, related costs, and payment timelines
- Send with a letter of agreement and/or contract and cover letter.

Source: Based on information from B. Austill Clausen (personal communication, August 17, 2006), C. Barrows (personal communication August 17, 2006), R. Underwood (personal communication April 12, 2007).

BOX 70.2

RECOMMENDATIONS FOR NEW CONSULTANTS

The experienced consultants have these recommendations for those who are new to consulting.

Becky Austill-Clausen: Get the Facts

Make sure that you get the services of a lawyer and an accountant, learn the tax requirements, and understand funding streams. When questions arise, go to the top of the administration or organization so that you are sure that the information you are getting is knowledge based and reliable (B. Austill-Clausen, personal communication, August 15, 2006).

Roxanne Castaneda: Spell Out Your Needs

If verbal contracts are proposed, the consultant should summarize the understanding in writing to share with all involved parties. Administrative overhead, travel expenses, and time associated with data gathering must be taken into consideration during the contract negotiation process. Access to office space and facilities "on the road" is crucial (R. Castaneda, personal communication, September 29, 2006).

Corkey Glantz and Nancy Richman: Honor Your Promises

Always carry out promises, and do not promise what you cannot deliver (Glantz & Richmond, 2003).

The consultation can be established to deliver the services face-to-face, over the telephone, by e-mail, via video conference, or by other methods. If the consultation is delivered in a team environment, all participants should be aware of the consultation and its focus and should agree to collaborate in the process.

The language in contracts varies according to the scope of the work. Some of the elements that should be included in a contract are responsibilities of the individual or agency issuing the contract; responsibilities of the consultant, typically including the duties or expectations established between the two parties; fees and payment (e.g., what the agency agrees to pay the contractor). Include the rate or fees that will be charged and reimbursed by the hour, completion of a specific project, content of invoices, and frequency of their submissions. The section on termination will specify the starting and ending date of the agreement and the opportunity to end the contract if the conditions change, if the work is unsatisfactory, or both parties agree to end the agreement prematurely. It is useful to include in the contract language on what will occur if the agency requests extension to the scope of the work or work needs to be redone because of changes in the agency ideas and a requirement that the consultant be paid for the additional work at the same rate.

Box 70.3 lists the important elements of the contract.

IMPORTANT ISSUES IN MAINTAINING RELATIONSHIPS AND BUILDING NEW ONES

The operation of a successful consultation practice depends on establishing and maintaining good relationships with individuals and organizations. Glantz and Richman (2003) suggested that from the first phone contact to the follow-up, the consultant must have an enthusiastic, energetic attitude and philosophy. Demonstrate flexibility to promote feelings of confidence in you and the consultation services that you offer. The end of the consultation period does not mean that the relationship needs to end. Stay in contact with the individual or agency, providing information about new services offered, sending greeting cards, and supplying additional information that may meet the interests of the agents.

EMERGING AND EVOLVING PRACTICE AREAS

All of the experts agreed that the consultant needs to be aware of emerging practice areas, such as the following:

◆ Driving consultation services, which are expanding. The occupational therapy practitioner will have opportunities for consultation to the individual, family, the

---

BOX 70.3 ELEMENTS OF A CONTRACT

◆ Purpose/focus of the contract
◆ Timelines
◆ Hours per week
◆ Hourly rate versus flat fee
◆ Documentation expected
◆ When you will get paid
◆ Billing procedures
◆ Type of equipment: telephone access, bring own laptop versus use the equipment available on site
◆ Environment: Will the agency designate work space for you or will you take whatever is available?
◆ Contact person for agency for contractor
◆ Restrictions, such as consultation exclusivity
◆ Confidentiality clause
◆ The agency's right to inspect the work in progress
◆ Ownership: Is this a joint effort or exclusive. If joint, do both parties own and have rights to any work that is created?
◆ Parties in the contract: Can you hire others to assist in carrying out the deliverables
◆ Qualifications: Drug testing, background checks, licensure status, liability coverage
◆ Independent contractor versus employee
◆ Cancellation notice and conditions

Source: B. Austill-Clausen (personal communication, 2006).

---

primary physician, motor vehicle administrations, medical advisory boards, and others
◆ Consultation to local area agencies on aging to coordinate CarFit and other senior driving programs in collaboration with AAA and AARP
◆ Work on behalf of local businesses to modify their places of business to provide more employment opportunities for the disabled veteran
◆ Provision of environmental evaluations on behalf of Centers for Independent Living
◆ Consultation services to toy manufacturers to advise in product design to minimize repetitive motion injuries and develop appropriate packaging identifying developmental factors and age appropriateness
◆ Consultation to preschools in designing universal design environments and activities that promote development and social opportunities for all children
◆ Caregiver organizations, assisting in analyzing needs of caregivers (e.g., stress management, fall prevention, ergonomics)

SUMMARY

Consultation is an advanced practice in the majority of circumstances. There are certain characteristics that appear to be common across individuals who are successful in their consultative roles. These include expert practice skills, knowledge of regulations governing occupational therapy practice and service payment, a strong ethical foundation, and a vision of how occupational therapy can help society. Establishing, valuing, and maintaining relationships with others is key to having the referral network that is necessary for ongoing success. Communication skills are important, and one must master the ability to communicate thoughts enthusiastically both in writing and orally. The effective consultant makes learning, knowledge acquisition, and application of that knowledge to practice a lifelong journey. Consultants must be open to possibilities, since consulting opportunities might not be labeled "occupational therapy." The innovative consultant can identify how occupational therapy can be the solution to address many organizational and business needs. At the same time, successful consultants understand the ethical and conceptual bounds of the profession.

ACKNOWLEDGMENTS

PRACTICE DILEMMA

RACHAEL AND HER CONSULTATION OPPORTUNITY

Rachael graduated with an entry-level degree in occupational therapy two years ago. Her first and only job has been as a staff occupational therapist in a community hospital's pediatric rehabilitation unit. A gerontology provider wants to establish community-based, aging services in Rachael's area and is recruiting occupational therapists who are qualified to serve as consultants to advise on the needs of the aging community, the services they will need, and design programs that will meet their needs. Rachael has always been interested in gerontology.

1. Should Rachael apply for this consultant position/opportunity? Why or why not?
2. What sections of the Occupational Therapy Code of Ethics are relevant to Rachael's dilemma?
3. Rachael might need to identify funding sources for these new programs. Where should she look for information?
4. What personal factors should Rachael evaluate before making a decision?

PROVOCATIVE QUESTIONS

1. Courtney, an occupational therapy assistant, has worked at a skilled nursing facility for the past four years. She sees opportunities in her community to support aging-in-place initiatives by becoming a home modifications consultant.

2. Craig was asked by a community developmental disability program to come and assist in a continuous quality improvement program, evaluating client programming and staff training needs and developing recommendations for improvement. Craig's seven years of experience have been in hospital-based mental health programming for adults.

XV

COMMON CONDITIONS: RELATED RESOURCES AND EVIDENCE

ALCOHOLISM

Sara N. Baker

Alcoholism, or alcohol dependence, is a chronic disease characterized by the following (National Institute on Alcohol Abuse and Alcoholism, 2001):

◆ *Craving:* the need or compulsion to drink
◆ *Loss of control:* the inability to limit the amount of alcohol consumed
◆ *Tolerance:* an increase in amount of alcohol required to achieve the same effects
◆ *Physical dependence:* the presence of withdrawal symptoms if intake ceases abruptly

Alcohol abuse is the continuation of drinking when, within a 12-month period, the person's ability to fulfill the obligations of a major life role has been impaired and/or when drinking is continued despite negative life consequences such as relationship issues, legal issues, or dangerous behaviors (National Institute on Alcohol Abuse and Alcoholism, 2001).

PREVALENCE

Approximately 21.6 million American adults met the criteria for alcoholism or alcohol abuse in 2003 (National Clearinghouse for Alcohol & Drug Information, 2005). Heavy drinking is more prevalent among people who are unemployed, male, ages 18–29 years, and of American or Alaskan native, Pacific Islander, or white racial or ethnic background (Substance Abuse and Mental Health Services Administration, 2003).

COURSE AND PROGNOSIS

Alcoholism is a chronic addictive disorder that may develop over a period of years and can begin at any age. There is no cure, and the person with alcoholism may go through alternating periods of sobriety and relapse. Most people relapse at least once during recovery (National Institute on Alcohol Abuse and Alcoholism, 2001).

Symptoms of Withdrawal

Withdrawal symptoms reflect overreactivity of the autonomic nervous system; they range in severity and may include headache, nausea, anxiety, agitation, insomnia, rapid heart rate, fever, convulsions, and visual hallucinations. Withdrawal symptoms usually begin within 6–48 hours after alcohol consumption has stopped and abate within the following 24–48 hours (Myrick & Anton, 1998).

RISKS OF ALCOHOLISM

Following are some of the risks involved in alcoholism (National Institute on Alcohol Abuse and Alcoholism, 2002):

◆ Birth defects resulting in fetal alcohol syndrome; malformations and dysplasias of the heart, bone, kidney, visual and hearing systems; CNS neurodevelopmental abnormalities; and/or cognitive deficits
◆ Impaired judgment
◆ Job loss
◆ Life stress increases risk for relapse
◆ Medication interactions

EFFECTS OF ALCOHOL ON THE BODY

Heavy use of alcohol has been shown to negatively affect a number of body structures and systems, including the following:

◆ Internal organs (especially the liver and pancreas; also associated with cancers of the mouth, stomach, breast, liver, and pancreas) (National Institute on Alcohol Abuse and Alcoholism, 2000, 2002)
◆ The immune system (National Institute on Alcohol Abuse and Alcoholism, 2000)
◆ The cardiovascular system (cardiomyopathy, hypertension, stroke) (National Institute on Alcohol Abuse and Alcoholism, 2000)
◆ The skeletal system (decreased bone mass) (National Institute on Alcohol Abuse and Alcoholism, 2000)
◆ Psychosocial functioning (depression, anxiety) (Johnson-Greene, Adams, Gilman, & Junck, 2002)
◆ Cognitive functioning (Wernicke-Korsakoff's syndrome, alcohol-related dementia) (Hazelton, Sterns, & Chisholm, 2003)

Alcoholism co-occurs with high incidence with a number of conditions, including mental illness and traumatic injury (Johnson-Greene et al., 2002).

CONCERNS OF FAMILY AND FRIENDS

Family members and friends of people with alcohol dependence have the following concerns (National Association for Children of Alcoholics, 1998):

◆ Aggression and/or violence
◆ A variety of cognitive, physical, and psychosocial difficulties that may occur in children of people with alcoholism

◆ Concern regarding genetics of disease
◆ Marital and/or relationship conflict

OT EVALUATIONS

Occupational therapists working with adult and adolescent populations should screen for alcohol disorders. There are numerous quick, self-report screens for identifying the presence of alcohol use disorders (AUDs).

Alcohol Use Disorders Identification Test (AUDIT)

The AUDIT is a 10-question, multiple-choice screening instrument for adults that identifies people who are alcohol dependent and at risk. The score determines whether brief intervention, advice, or referral is indicated (Babor, Higgins-Biddle, Saunders, & Monteiro, 2001).

If an AUD is identified, the *Canadian Occupational Performance Measure* (COPM) may assist in identifying ADLs and/or IADLs that are being affected. Occupational performance and alcohol-specific measures available include the following:

◆ Alcohol and Drug Consequences Questionnaire (ADCQ)
◆ Alcohol Dependence Scale
◆ Barth Time Construction (BTC)
◆ Beck Depression Inventory (BDI-II)
◆ Brief Situational Confidence Questionnaire (BSCQ)
◆ Clinical Institute Withdrawal Assessment for Alcohol–Revised (CIWAA-R)
◆ Coping Behaviors Inventory (CBI)
◆ Drinker Inventory of Consequences (DrInC)
◆ Drinking Expectancy Questionnaire (DEQ)
◆ Form 90
◆ Interest Checklist
◆ Inventory of Drinking Situations (IDS)
◆ Routine Task Inventory (RTI-2)
◆ Short Alcohol Dependence Data questionnaire (SADD)

The type and method of evaluation that are used in practice will be determined by a number of factors, including the client's treatment priorities, the presence of alcohol-related cognitive impairment, comorbid disorders, and time constraints.

OT INTERVENTIONS

OT interventions that focus on reducing or stopping the intake of alcohol include the following (Stoffel & Moyers, 2004):

◆ *Brief interventions:* One or multiple short sessions providing the results of the screening, education about the risks of alcohol misuse and the benefits of moderation, provision of advice and encouragement for change, goal setting, and referral to available resources.
◆ *Cognitive-behavioral therapy (CBT):* Emphasizes the development of coping behaviors and self-efficacy to change what a person thinks and does regarding alcohol use. Relapse Prevention (RP) is a specific CBT program that targets clients who have begun abstinence.
◆ *Motivational techniques:* Identify and facilitate the client's motivation to change. Specific motivational techniques include motivational interviewing, decisional balance exercises, FRAMES, and motivational enhancement therapy.
◆ *Twelve-step program facilitation:* Social and spiritual support groups that facilitate maintenance of abstinence. Occupational therapists may work with the person to incorporate these supports into a daily routine.

Occupational therapy focuses on building and refining the skills that are needed to maximize the client's occupational and role performance and reduce the risk of relapse. Some skills that may be important to address include the following:

◆ Job skills
◆ Leisure skills and planning
◆ Life management skills, such as money management and time use
◆ Self-care skills, including eating and nutrition
◆ Social skill development, including assertiveness, communication skills, and interpersonal and social responsiveness
◆ Stress management and coping skills

Skill training and practice may be done in individual settings. However, group sessions are beneficial, as they promote drug-free socialization and are cost-effective (Cecilia, Marques, Lucia, & Formigoni, 2001). Occupational therapists' role in working with people with AUDs and their families includes education, making appropriate referrals for treatment of the disorder, and facilitating the awareness and use of community resources.

OT AND THE EVIDENCE

◆ Research indicates that brief interventions that are longer than 20 minutes reduce alcohol consumption, frequency, episodes of binge drinking, and number and length of hospitalizations for at least six months after intervention for adults who are screened for hazardous alcohol use in emergency rooms, general hospitals, and outpatient clinics (Stoffel & Moyers, 2004).
◆ CBT, including RP, appears to be most effective when used in conjunction with motivational and twelve-step strategies or pharmacological treatment. It is effective in individual and group settings and may be more effective at improving psychosocial functioning than at reducing alcohol consumption (Irvin, Bowers, Dunn, & Wang, 1999; Stoffel & Moyers, 2004).

◆ Motivational strategies are effective for people with AUD but may take longer to reduce drinking amount and frequency than other approaches (Stoffel & Moyers, 2004).

◆ Twelve-step facilitation might be most effective for people who have previously relied on external supports or who are open to spirituality; however, people who attend twelve-step programs are more likely to continue to attend meetings after cessation of formal treatment (Stoffel & Moyers, 2004).

ALZHEIMER'S DISEASE

Hsin-yu Kuo

Alzheimer's disease (AD), the most common form of dementia, is a progressively degenerative disorder that occurs most frequently in the elderly population. AD not only impairs an individual's broad aspects of life, but also affects the whole family and increases social burdens. With the current trend of longer life, the rates of AD have increased. It is critical to address concerns relative to maintaining the overall quality of life of individuals with AD and their families (Dooley & Hinojosa, 2004).

INCIDENCE

AD usually occurs in individuals older than 65 years of age, although in a few cases, this disorder may develop before the age of 50 years (American Psychiatric Association, 2000) or even as early as 30 years (Small et al., 1997). The incidence rate increases from approximately 1% annually among people aged 65 to 70 years to approximately 6% to 8% for people over age 85 (Mayeus, 2003).

PREVALENCE

On average, individuals with AD usually live from 3 years to 20 years after symptom onset (Mayeus, 2003). Approximately 6% to 8% of all individuals older than 65 years old have AD, and the prevalence of AD may double every 5 years after the age of 60 (Small et al., 1997). In 2000, there were 4.5 million individuals with AD in the U.S. population. Researchers estimate that the number may increase to 13.2 million by 2050 (Hebert, Scherr, Bienias, Bennett, & Evans, 2003).

SYMPTOMS

AD is characterized by gradual onset and progressive degeneration in cognition; it is accompanied by behavioral and psychological symptoms (APA, 2000; Chen, Borson, & Scanlan, 2000; Förstl & Kurz, 1999; Hart et al., 2003).

Motor declines are also usually present in later stages (APA, 2000; Förstl & Kurz, 1999).

Although the experience of symptoms and the time when symptoms may occur can vary greatly from one individual to another (Volicer, 2001), the progression of Alzheimer's symptoms can be described in terms of three stages: early/forgetfulness, middle/confusional, and late/dementia stages (Schneck, Reisberg, & Ferris, 1982).

Early/Forgetfulness Stage

- *Cognition:* Mild impairment in memory, especially short-term memory, which is often the sign that is most apparent in the early stage; lack of concentration and ability to learn new materials; mild impairment in language, including shrinking vocabulary, decreasing word fluency, or less precise expressive language
- *Behavioral and psychological:* Personality alterations; increased depression, anxiety, or irritability
- *ADL:* No significant deterioration in ADL; still able to live independently for most of the time but might need support with a variety of organizational matters

Middle/Confusional Stage

- *Cognition:* Severe impairment in recent memory; more obvious language difficulties, such as aphasia or word-finding difficulties; apraxia, agnosia, disorientation, visuospatial dysfunction, impaired judgment, and impaired executive functioning
- *Behavioral and psychological:* Increased aimless activities (e.g., wandering); disrupted sleep; delusions, hallucinations, or aggression
- *ADL:* Require extensive assistance with daily activities, including dressing, eating, and toileting

Late/Dementia Stage

- *Cognition:* Profound disturbances in orientation and memory; more distant memories are lost; unable to recognize close family members; severe intellectual

declines; language reduced to simple phrases or even single words

◆ *Behavioral and psychological:* Apathetic and unresponsive except for facial grimacing
◆ *Motor:* Severely impaired motor function; abnormal reflexes; soon progresses to a bedridden stage, with limb rigidity and incontinence of urine and feces
◆ *ADL:* Loss of basic daily living abilities; completely dependent in all aspects of daily living

PRECAUTIONS

As the course of AD progresses, the global functions of individuals with AD decline. These individuals become increasingly unable to take care of themselves. The following principles should be noted in order to adapt to each change in the individual's behavior and functioning as well as prevent unexpected events (Reed, 2000):

1. Avoid leaving individuals with AD alone, because they can become lost easily even in familiar environments.
2. Avoid overstimulating individuals with AD; this may exacerbate their behavioral or psychological problems.
3. Avoid arguing with individuals with AD when they do not tell the truth.
4. Minimize dangers. A safe home environment enables individuals with AD to experience increased security and more mobility.

MEDICAL MANAGEMENT

There is currently no cure or prevention for AD. However, for some individuals with early- and middle-stage AD, cholinesterase inhibitors (ChEIs), the first pharmacological treatments to be approved by the U.S. Food and Drug Administration, can assist in temporarily delaying some symptoms from worsening and in maintaining a higher level of cognitive function (Standridge, 2004). The therapeutic effect of ChEIs is associated with enhanced performance of activities of daily living, reduced behavioral disturbances, stabilized cognitive impairment, decreased caregiver stress, and delay in the first dementia-related nursing home placement (Cummings et al., 2002; Standridge, 2004). Nausea, vomiting, diarrhea, dizziness, and anorexia are the most common side effects of ChEIs and occur more frequently during dose escalation than during maintenance therapy (Standridge, 2004).

OT EVALUATIONS

The fundamental evaluation method that is used in occupational therapy for AD is observation and interview. Observe clients' involvement in activities of daily living and corroborate other information obtained from interviewing

family members or caregivers (American Occupational Therapy Association, 1994). Several performance-based measures and self- or proxy-report questionnaires have been documented to assess individuals with AD as follows:

◆ Assessment of Motor and Process Skills (AMPS)
◆ Cognitive Performance Test (CPT)
◆ Daily Activities Questionnaire
◆ Disability Assessment for Dementia (DAD)
◆ Functional Performance Test (FPT)
◆ Kitchen Task Assessment (KTA)

OT INTERVENTIONS

The main purposes of OT intervention for individuals with AD are (1) to maintain functional capacity, (2) to promote participation in activities that optimize physical and mental health, and (3) to ease caregiving activities (AOTA, 1994). The OT interventions are mainly divided into two categories: the environment and the caregiver.

Environment

Environmental Modification or Adaptation

Amount of distractions, degree of safety, and level of physical and emotional comfort are crucial points that need to be incorporated into the environmental modification (Day, Carreon, & Atump, 2000). Keep environments consistent to decrease confusion, increase lighting or install ramps to promote safety, or provide a low-stimulus environment, such as painting a room in soft colors, to decrease aggression or disturbances (Dooley & Hinojosa, 2004; Gitlin & Corcoran, 1996). Putting familiar pictures or names on the door and clearly labeling physical structures with unique symbols, such as arrows for direction are also beneficial for people with AD (Nolan, Lawrence, Mathews, & Harrison, 2001).

Task Simplification

Engaging patients with dementia in familiar daily living tasks can enhance their well-being as well as lower stress on their caregivers (Hasselkus, 1998; Teri, Logdon, Uomoto, & McCurry, 1997). Task simplification is an economic way of helping people with AD to continue to engage in their ADL by diminishing the complexity of the environment and its demands on task performance. It usually involves establishing daily routines or increasing verbal, visual, or tactile cueing (Gitlin & Corcoran, 1996).

Assistive Technology and Equipment

Because users must learn how to use devices, such as medication dispensers or pill reminder boxes, to compensate for their deficits, these devices are more useful for people with mild-stage AD whose cognition and learning

abilities are mildly impaired (Förstl & Kurz, 1999). Otherwise, such devices can cause further confusion and frustration (Day et al., 2000). For caregivers, monitoring systems, door alarms, grab bars, safety locks, and tub benches may be beneficial in decreasing caregiving burden (Gitlin & Corcoran, 1996).

Caregivers

Caregiver Training or Education

Through teaching or counseling of caregivers to increase their knowledge of AD, to enable them to take advantage of environmental modifications or assistive technology, to help them to deal with specific issues, such as wandering, and to enable them to cope with the stress, occupational therapists can help caregivers to alleviate their loads and increase their self-efficacy (Corcoran & Gitlin, 2001; Dooley & Hinojosa, 2004; Toth-Cohen, 2000).

Provision of Resources and Referrals

Occupational therapists have a primary role to provide information on community resources and encourage caregivers to use these resources. Resources may include respite care, in-home support services, or support groups so that the caregiver can take a break from the 24-hour-per-day care requirements (Schultz-Krohn, Foti, & Glogoski, 2001).

OT AND THE EVIDENCE

OT interventions can result in fewer declines in daily living skills and enhance the quality of life of people with AD as well as increasing caregivers' self-efficacy and decreasing their feelings of being burdened (Dooley & Hinojosa, 2004; Corcoran & Gitlin, 2001).

CAREGIVER CONCERNS

When considering the burdens of AD on society, except for financial costs, we cannot understate the emotional toll of AD on caregivers. The emotional stress on patients and their caregivers is profound and a significant source of caregiver morbidity (Small et al., 1997). Caregivers of individuals with AD may develop psychological morbidity, such as depression or anxiety (Nobili et al., 2004). Behavioral disturbances of individuals with AD seems to cause more caregiver distress than psychological symptoms do, aggression, irritability and sleep disturbance being the least well tolerated (Chen et al., 2000; Hart et al., 2003). Low income, longer hours spent caregiving, and poor functional independence of caregivers as well as younger age, lower level of education, and higher independence of individuals with AD could be predictors of

caregiver depression (Covinsky et al., 2003). Unless the quality of life of both patients and their caregivers is included, any economic assessment is likely to underestimate the true cost of AD to society (Russell, Gold, Siegel, Daniels, & Weinstein, 1996).

AMYOTROPHIC LATERAL SCLEROSIS

Rachel Fleming, Kate-Lyn Stone, and Meredith Grimell

Amyotrophic lateral sclerosis (ALS), also referred to as Lou Gehrig's disease, is a rare, progressive, degenerative disease that affects the motor neurons in the corticospinal pathways, the motor nuclei of the brain stem, and the anterior horn cells of the spinal cord. ALS, like Parkinson's disease and multiple sclerosis, is a motor neuron disease. Decreased function of the nerve cells in the brain, brain stem, and spinal cord caused by ALS results in weakening of the muscles, which eventually leads to paralysis but does not affect personality or cognition. No known cure for ALS exists.

INCIDENCE AND PREVALENCE

- In the United States, 20,000 people currently have ALS, and 5,000 additional people are diagnosed with ALS each year.
- Individuals of all races are affected by ALS.
- The age of onset is typically between 40 and 60 years.
- More men are affected than women.
- 90–95% of all cases are of no known cause.
- 5–10% of all cases are of genetic origin.

TYPICAL COURSE

The onset of the disease varies from one individual to another. Some people experience a weakness in the arms with difficulty lifting or doing fine motor tasks or in the legs with difficulty walking or in the muscles that control speech and swallowing. Some experience generalized muscle fatigue. If the weakening begins in the hand, it will progress through the affected limb before becoming more generalized. Problems with speech or swallowing occur when motor neurons die in the brain stem. The disease progresses and eventually affects the person's ability to walk and continue performing ADL. The disease affects only the motor pathways; therefore, eye movement, bowel and bladder functions, cognition, personality, and skin sensation remain intact. Respiratory weakness ultimately is affected as the muscles deteriorate, and death usually follows unless the individual is put on a ventilator.

POTENTIAL SYMPTOMS

- Damage to lower motor neurons (in the spinal cord) leading to flaccid paralysis, decreased muscle tone, and decreased reflexes
- Damage to upper motor neurons (in the brain) and to the corticospinal tract leading to spasticity and hyper-reflexia (exaggerated reflexes)
- Muscle weakness
- Muscle atrophy (distal to proximal)—a symptom that is unique to ALS
- Fatigue
- Stumbling and falling due to lower extremity weakness
- Fasciculation (muscle twitching)
- Decreased ability to regulate body temperature
- Loss of emotional control/depression
- Dysphagia (difficulty swallowing)
- Dysarthria (difficulty speaking) due to impaired cranial nerves controlling speech
- Impaired respiration due to muscle weakness
- Sialorrhea (excess drooling)
- Night cramps
- Weight loss
- Loss of endurance
- Loss of dexterity

MEDICAL MANAGEMENT

No specific assessment is used to diagnose ALS. Magnetic resonance imaging (MRI), electromyography, blood tests, and/or nerve conduction velocity are done to eliminate other diseases as possibilities. Currently, no known cure or treatment to reverse ALS exists. In 1995, the Food and Drug Administration approved Rilozule, the first drug to result in prolonging survival by several months. The drug is believed to work by decreasing damage due to the release of glutamate. The drug may extend the length of time before a person needs ventilation support.

Respiratory therapists, speech pathologists, physical therapists, occupational therapists, psychologists, and social workers typically work together to sustain the client's quality of life and to support the family. Compensatory

strategies using adaptive equipment and energy conservation are common foci of treatment for an individual with ALS.

PROGNOSIS

- Most people with ALS die secondary to respiratory failure
- People who go on a ventilator generally live longer than people who do not
- 90% of people with ALS live 3–5 years after the onset of the disease
- 10% of people with ALS survive for 10 or more years after the onset

PRECAUTIONS

- Pneumonia and pulmonary emboli
- Ventilators: intermittent positive pressure ventilation (IPPV) or bilevel positive airway pressure (BiPap)
- Inability to cough to clear normal amount of mucus from airway
- Pressure sores due to decreased mobility
- Swallowing problems could lead to choking
- Posture and balance could lead to falls
- Emotional lability (outbursts of laughing or crying)
- Difficulty maintaining weight
- Shoulder subluxation
- Joint contractures

OCCUPATIONAL THERAPY EVALUATIONS

Comprehensive Evaluations

- ALS Functional Rating Scale

IADL/Leisure Evaluations

- Activity Card Sort

Upper Extremity Function Evaluation

- Purdue Pegboard
- Manual muscle testing
- Range-of-motion testing

Balance Evaluations

- Berg Balance Scale

Quality of Life/Life Satisfaction Evaluations

- COPM (Canadian Occupational Therapy Performance Measure)

OCCUPATIONAL THERAPY INTERVENTIONS

- Energy conservation: choosing which activities are most important to the client
- Compensatory strategies, such as using gravity-eliminating devices
- Use of adaptive equipment (e.g., raised toilet seat, built-up handles)
- Prevent deconditioning of remaining muscles
- Continue meaningful life roles and occupations to provide a sense of accomplishment
- Therapeutic exercise to preserve strength
- PROM (passive range of motion) and/or AROM (active range of motion) to prevent contractures at joints
- Thermoplastic resting splints for wrists and hands to assist in maintaining muscle length
- Shoulder supports to prevent subluxation
- Augmentative communication
- Postural support
- Home modifications

OT AND THE EVIDENCE

When a person is facing a life-threatening illness, the use of occupation is more powerful than ever. Occupation during this phase of life can carry many meanings. Being engaged in occupation can help to remediate physical function, challenge the mind, provide meaning in the person's new stage of life, and offer a sense of well-being to a person with ALS. Learning new skills and being challenged can be very rewarding for someone with a terminal illness, even though the person might be constrained by the illness.

Bremer, Simone, Walsh, Simmons, and Felgoise (2007) suggest that maintaining an individual's quality of life as ALS progresses should also be focused on as an important part of occupational therapy intervention. They found that two major contributing factors to good quality of life were the individual's perception of his or her health and the person's religiosity. Bello-Haas et al. (2007) examined another aspect of quality of life in their study concerning the efficacy of resistance exercise in individuals with ALS. They found that resistance exercise contributed to better function as measured by the ALS Functional Rating Scale as well as improved overall quality of life.

CAREGIVER CONCERNS

People who develop ALS experience a sudden change in life roles that can be overwhelming. Because of the rapid progression of ALS, it can be difficult for caregivers to adapt to a loved one's inability to continue life roles. Discontinuation

of work after the diagnosis of ALS is common and can lead to financial strain. The sudden decrease in ADL/IADL capabilities can be difficult for the family. Caring for a family member with ALS can be physically and psychologically demanding and draining. It is important to address the issue of coping not only with the client but also with the family members. Because so much is unknown about ALS, caregivers often have many unanswered questions. Caregiver support groups can be beneficial in providing the family with necessary support and information.

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Ling-Yi Lin

Attention deficit/hyperactivity disorder (ADHD) is the most common childhood behavioral disorder and is probably two or three times more frequent in boys than in girls (National Institute of Mental Health, 1999). It is characterized by a persistent and frequent pattern of developmentally inappropriate inattention and impulsivity, with or without hyperactivity (American Psychiatric Association, 2000). Individuals with ADHD have impaired functioning in multiple environments, including home and school, and in relationships with peers. Some children with ADHD have sensory-processing difficulties or delayed motor skills related to performing tasks and activities.

PREVALENCE

- The prevalence of ADHD has been variously estimated as ranging from 3% to 7% in school-age children (APA, 2000).
- Up to two-thirds of children with ADHD continue to experience significant symptoms in adolescence and adulthood (Barkley, 1998).

CAUSE AND ETIOLOGY

- The cause and etiology of ADHD are not completely understood (Resnick, 2000).
- ADHD is a complex disorder that is undoubtedly the result of multiple interacting genes (NIMH, 1999).
- Other causal factors are low birth weight, prenatal maternal smoking, and additional prenatal problems (NIMH, 1999).

TYPICAL COURSE AND SYMPTOMS

ADHD symptoms arise in early childhood unless they are associated with some type of brain injury later in life. Some symptoms persist into adulthood and can pose lifelong challenges (APA, 2000). The symptom-related criteria for the three primary subtypes, adapted from *DSM-IV,* are as follows (APA, 2000):

1. *ADHD predominantly inattentive type (ADHD-I):* Individual who daydreams or seems to be in another world, is easily distracted by what is happening around him or her, and has difficulty organizing work.
2. *ADHD predominantly hyperactive-impulsive type (ADHD-HI)*: Individual who acts quickly without thinking first and has difficulty remaining seated; walks, runs, or climbs around when others are seated; and talks excessively when others are talking.
3. *ADHD combined type (ADHD-C):* Individual meets both sets of inattention and hyperactive/impulsive criteria.

PRECAUTIONS

- ADHD often co-occurs with other disorders, including learning disabilities and behavioral disorders, such as oppositional defiant disorder and conduct disorder (Pliszka, Carlson, & Swanson, 1999).
- More likely to smoke, drink alcohol, and take drugs as teenagers and a higher risk of substance abuse in adults with ADHD (Resnick, 2000).
- Higher rates of various accidental injuries (Pliszka et al., 1999).
- Ritalin may have negative side effects relating to appetite, sleep, and growth (Wender, 2000).

INTERVENTION

Medication Therapy

- Stimulants, including methylphenidate, amphetamine, and pemoline, are the most widely researched and most commonly prescribed treatments for individuals with ADHD (Wender, 2000).

◆ Research has demonstrated that methylphenidate treatment in individuals with ADHD causes successive improvements in behaviors and cognitive tasks (Wender, 2000).

Multimodal Treatment Study of ADHD

◆ The comprehensive multimodal approach to treating children with ADHD requires medical, educational, behavioral, and psychological interventions and consists of parent and child education about diagnosis and treatment, specific behavior management techniques, stimulant medication, appropriate school programming, and supports (MTA Cooperative Group, 1999a, 1999b).

◆ An MTA study conducted by the National Institute of Mental Health and cosponsored by the U.S. Department of Education is a 14-month randomized clinical ADHD trial. The multitreatment approaches and combinations of interventions that were researched include medication management, behavioral treatment, combined medication management and behavioral therapy, and community care. The results indicated that a combination of medication and psychotherapy is particularly effective (MTA Cooperative Group, 1999a, 1999b).

Educational Management

◆ Other interventions for children or adolescents with ADHD include tutoring and special education.

◆ The direction of educational management of ADHD aims to maximize attention and concentration, counter impulsive behavior, improve self-esteem and socialization, assist in overcoming learning difficulties, and promote consistency of management between home and school (Pliszka et al., 1999; Rief, 2003).

OT EVALUATIONS

Social Skills, Home Life Routine, and Participation in Household Tasks in Family

◆ Children's Assessment of Participation and Enjoyment (CAPE) and Preference for Activities of Children (PAC)
◆ Child Routines Inventory (CRI)
◆ Home Situations Questionnaire (HSQ)
◆ Perceived Efficacy and Goal Setting System (PEGS)
◆ Social Skills Rating System (SSRS)

Academic Functioning

◆ Academic Performance Rating Scale
◆ School Function Assessment (SFA)
◆ School Situations Questionnaire (SSQ)

Marital Relationship and Family Functioning

◆ Dyadic Adjustment Scale (DAS)
◆ Locke-Wallac.nce Inventory (PAI)

Behavior

◆ Behavior Assessment System for Children
◆ Child Behavior Checklist
◆ Adolescent Behavior Checklist
◆ ADHD Behavior Checklist for Adults

Self-Perception

◆ Piers-Harris Children's Self Concept Scale

Sensory and Sensory Motor Processing

◆ Sensory Integration and Praxis Tests (SIPT)
◆ Sensory Profile

Visual Motor Integration

◆ Beery-Buktenica Developmental Test of Visual-Motor Integration
◆ Test of Visual-Perceptual Skills–Revised

OT INTERVENTIONS

Behavior Modification

◆ Behavior modification includes strategies such as rewarding positive behavior changes and communicating clear expectations of children and adolescents with ADHD (DuPaul & Eckert, 1997).

◆ Parents and teachers then use the behavioral skills in their daily interactions with their children with ADHD, resulting in improvement in the children's functioning (Abramowitz & O'Leary, 1991; DuPaul & Eckert, 1997).

◆ Behavior modification has proven effective in children and adolescents with ADHD for improving both social and academic behaviors (MTA Cooperative Group, 1999a, 1999b; Pelham, Wheeler, & Chronis, 1998).

Cognitive Strategy Training

◆ Cognitive strategy training is one of the cognitive approaches that is a top-down or occupation-based approach (McCormick, Miller, & Pressley, 1989).

◆ Cognitive strategy training consists of five problem-solving steps: task analysis, anticipation of the difficulties, exploration and selection of task-specific strategies,

application of a strategy to the task, and evaluation of its effectiveness (McCormick et al., 1989).

◆ Cognitive strategy training teaches the child to identify, develop, and use cognitive strategies to perform daily occupations effectively (McCormick et al., 1989).

◆ Research has demonstrated that children with ADHD who were receiving cognitive strategy training (training in strategies to control impulsive behavior) and were on medication decreased their impulsivity, as reflected by performance on the delay task, which improved significantly (Brown, Wynne, & Medenis, 1985; Hall & Kataria, 1992).

Cognitive-Behavioral Therapy

◆ Cognitive-behavioral therapy (CBT) integrates the cognitive strategy training with the behavioral modification techniques. It is an action-oriented form of psychosocial therapy that assumes that maladaptive or faulty thinking patterns cause maladaptive behavior and negative emotions (Enright, 1997).

◆ Instructional strategies that are used in this kind of therapy include modeling, role-playing, and self-instruction. CBT attempts to increase self-control and problem-solving abilities by helping children with ADHD (Enright, 1997).

◆ CBT is effective in managing behavior problems in children with ADHD and can assist adults with ADHD in problem solving (Abikoff, 1987; Fehlings, Roberts, Humphries, & Dawe, 1991).

Sensory Integration

◆ Children with ADHD may have sensory modulation challenges. Sensory modulation difficulties are often the basis for interventions for children with ADHD, especially in addressing attention within the classroom (Mangeot et al., 2001).

◆ Occupational therapy for children with sensory integration dysfunction enhances their ability to process lower-level sensory information related to alertness, body movement and position, and touch. Intervention may help children pay more attention to the higher-level senses of hearing and vision (Mangeot et al., 2001).

◆ The effectiveness of the sensory integration approach has demonstrated that it can help children with ADHD to use self-regulation strategies (sensory-based activities or sensory diet) and increase their school performance such as in seated behaviors, ability to listen and attend, finishing classwork, and improvements in regulation of aggressive behavior (Arnold, Clark, Sachs, Jakim, & Smithies, 1985; Field, Quintino, Hernandez-Reif, & Koslovsky, 1998; Schilling, Washington, Billingsley, & Deitz, 2003; VandenBerg, 2001; Werry, Scaletti, & Mills, 1990).

Social Skills Training

◆ Occupational therapy practitioners working with older children, adolescents, or adults with mental health problems often use social skills groups to promote coping effectiveness and occupational performance (Case-Smith, 2001; Eklund, 1999).

◆ Current intervention approaches may also involve education and counseling (individual, couples, and family), consultation with professionals in schools and community programs, peer support and activity groups, and development of supportive social networks (Case-Smith, 2001).

◆ Social skills training can help children or adults with ADHD to learn new behaviors, problem-solving strategies, and methods of dealing with their interpersonal relationships, such as using appropriate communication skills (Ansthel & Remer, 2003; Colton & Sheridan, 1998; Frankel, Myatt, Cantwell, & Feinberg, 1997).

OT AND THE EVIDENCE

Children with ADHD may benefit from occupational therapy with a sensory integrative approach to enhance sensory processing and promote adaptive responses to environmental demands (Arnold et al., 1985; Field et al., 1998; Schilling et al., 2003; VandenBerg, 2001; Werry et al., 1990).

CAREGIVER CONCERNS

◆ Caregivers will need to provide the necessary structure and manage the environmental factors to help their children be successful, anticipating potential problems and planning accordingly (e.g., safety issues) (Rief, 2003).

◆ As with all children, the best way to manage the difficulties of those with ADHD is through watching for positive behaviors and recognizing children when they are doing well (Rief, 2003).

◆ Many adults with ADHD and parents of children with ADHD find it useful to join a local or national support group. Members of support groups share frustrations and successes, referrals to qualified specialists, and information about successful techniques (Rief, 2003).

RESOURCES

Associations

◆ Attention Deficit Disorder Association
P.O. Box 543
Pottstown, PA 19464
Telephone: 484-945-2101

Website: www.add.org
ADDA provides information, resources, and networking opportunities to help adults with ADHD lead better lives.

BIPOLAR DISORDER

Alyssa Wells Arnold and Kate-Lyn Stone

Bipolar disorder, also known as manic-depressive illness, is a brain disorder that causes unusual shifts in a person's mood, energy, and ability to function. Bipolar disorder causes dramatic "mood" swings, or episodes of mania, hypomania, and major depression, with periods of normal mood in between. In other words, a person who has bipolar disorder may experience a mood that alternates between the "poles" of mania "highs" and depression "lows" (National Institute of Mental Health, 1999). The diagnosis of bipolar disorder is distinguished by the presence of a major depressive episode (American Psychiatric Association, 2000). Depending on the dominant mood, bipolar disorder is usually classified as either bipolar I or bipolar II (Cara, 2005).

- ◆ *Bipolar I:* Symptoms of major depression, coupled with the occurrence of full-blown mania or mixed symptoms
- ◆ *Bipolar II:* Symptoms of major depression, coupled with the reoccurrence of depressive episodes with hypomania, which is a persistent state of inflated or irritable mood that presents like symptoms of mania but are much milder (APA, 2000)

PREVALENCE

The prevalence of bipolar disorder has been estimated to affect about two million adult Americans, or about 1% of the adult population (NIMH, 1999). An equal number of men and women develop this illness: however, men tend to begin with manic episodes, and women tend to begin with depressive episodes (APA, 2000).

TYPICAL COURSE AND SIGNS AND SYMPTOMS

Bipolar symptoms usually arise in late adolescence, although they can begin in early childhood and can even initiate later in life. Episodes of mania and depression typ-

ically recur across the life course. The diagnosis of bipolar disorder is made on the basis of symptoms, course of illness, and, when available, family history (NIMH, 1999). The most prevalent symptom-related criteria for mania and depression are adapted from the DSM-IV.

Mania

- Increased physical and mental activity and energy
- Exaggerated optimism and self-confidence
- Decreased need for sleep without experiencing fatigue
- Grandiose delusions
- Impulsiveness and poor judgment
- Delusions and hallucinations in severe cases

Depression

- Prolonged sadness and persistent lethargy
- Significant changes in appetite and sleep patterns, irritability
- Feelings of guilt and worthlessness
- Inability to concentrate
- Inability to take pleasure in former interests and social withdrawal

CAUSE AND ETIOLOGY

Research suggests that bipolar disorder is linked to genetics and is most likely caused by a single gene (NIMH, 1999). Research also suggests that other factors such as biochemical, neuroendocrine, socioenvironmental, and psychosocial in combination play an active role in possible causes of bipolar disorder (Cara, 2005).

AFFILIATED PROBLEMS

Alcohol and drug abuse are very common among individuals with bipolar disorder and should be considered in the treatment plan (Strakowski & DelBello, 2000). Anxiety disorders, including posttraumatic stress disorder and obsessive-compulsive disorder, also commonly co-occur with bipolar disorder (Mueser et al., 1998).

INTERVENTIONS

Medications

Antidepressants, mood stabilizers, and antipsychotic medications such as lithium, Depakote, Risperdal, and Seroquel are the most widely researched and most commonly prescribed treatments for individuals with bipolar disorder (NIMH, 1999). Lithium is the most common mood-stabilizing medication and is often very effective in preventing the reoccurrence of both manic and depressive episodes (NIMH, 1999).

Psychoeducation

Teaching individuals with bipolar, along with their families, about the illness and its treatment includes the recognition of signs and symptoms of relapse in order to initiate early intervention (NIMH, 1999).

Electroconvulsive Therapy

If the combination of treatments proves to be ineffective, electroconvulsive therapy (ECT) is another alternative. ECT has been found to be highly effective in treatment for severe depressive, manic, and mixed episodes (NIMH, 1999).

OT EVALUATIONS

Basic and Instrumental Activity of Daily Living Skills

- Kohlman Evaluation of Living Skills (KELS)
- Milwaukee Evaluation of Daily Living Skills (MEDLS)

Self-Perception

- The Canadian Occupational Performance Measure (COPM)
- The Occupational Questionnaire (OQ)
- The Role Checklist

OT INTERVENTIONS

Cognitive Therapy

Cognitive therapy (CT) is a technique that is used in combination with occupational therapy in order to replace negative thoughts with more realistic appraisals to reduce

the impact of distorted thinking styles. This technique allows occupational therapists the opportunity to examine the meaning associated with functional activities (Giles, 2003). A recent study indicates that the combination of medication and CT has long-term positive effects with individuals who are experiencing bipolar disorder when compared to medications alone (Hensley, Nadiga, & Uhlenhuth, 2004).

Interpersonal and Social Rhythm Therapy

Interpersonal and social rhythm therapy (IPSRT) is based on the idea that disruptions in daily routines and problems in interpersonal relationships can cause reoccurrence of the manic and depressive episodes that characterize bipolar disorder. During treatment, occupational therapy practitioners help clients to understand how changes in daily routines, the quality of their relationships, and their social roles can affect their mood. Practitioners teach clients to identify triggers of mania and depression and then teach them how to better manage stressful situations and better maintain positive relationships (Frank, Swartz, & Kupfer, 2000). This intervention stresses the importance of maintaining a regular schedule of daily activities and stability in personal relationships. A recent study suggests that disruptions in an individual's medical treatment plan or routine can contribute to relapse and a worse outcome (Frank et al., 1999). Regular routines and sleep schedules can help to protect against manic and depressive episodes (NIMH, 1999)

OCCUPATIONAL THERAPY AND THE EVIDENCE

There is strong support throughout the literature for cognitive behavioral and psychosocial approaches in treating individuals with bipolar disorder. Ball, Mitchell, and Corry (2006) found cognitive behavioral therapy (CBT) to be a valuable tool for increasing behavioral self-control and increasing the amount of time between episodes in individuals with bipolar disorder. CBT used in combination with mood stabilizers (versus medication alone) has also been reported to contribute to fewer bipolar episodes, fewer hospital admissions for bipolar episodes, higher social functioning, less variability in manic symptoms, and better coping with manic symptoms (Lam et al., 2003). On the basis of the study using cognitive therapy (CT) (Hensley et al., 2004) and the study on interpersonal and social rhythm therapy (Frank et al., 1999), individuals with bipolar disorder may also benefit from occupational therapy with a cognitive behavioral approach in order to integrate the concepts of CT and IPSRT to enhance the individual's ability to self-regulate and promote improved performance patterns in the areas of habits, routines, and roles, which will improve overall participation in activities of daily living.

Psychosocial approaches used in group settings have had a positive impact on mood stabilization and preventing relapse, as well as enabling individuals to go beyond their symptoms and achieve life goals. Group psychoeducation, in addition to pharmacotherapy, improves perceived quality of life, especially concerning physical functioning, in individuals with bipolar disorder (De Andres et al., 2006; Huxley, Parikh, & Baldessarini, 2000; Michalak, Yathman, Wan, & Lam, 2005).

CAREGIVER CONCERNS

Caregivers must understand the signs and symptoms of bipolar disorder, the course of the disease, the importance of a medication schedule and good sleep hygiene, and that suicide is always a possible threat.

Books

◆ Jamison, K. R. (1995). *An unquiet mind: A memoir of moods and madness.* New York: Vintage Books.
  The psychology memoir, *An Unquiet Mind,* looks into manic depressive disorder from the perspectives of both the client living with the illness and the provider who is trying to heal the client. The author recounts her own experience living with this disorder; talking about the costs of the illness and even what she found to be the benefits.

◆ Grant, R., & Ferber, E. (1999). *Why am I up, why am I down?: Understanding bipolar disorder.* New York: Dell. This informative book discusses several aspects of bipolar disorder, including: who is at risk, what causes bipolar disorder, the symptoms of both the manic and depressive phases, how to get help, the latest facts on the disorder, as well as other topics that can help lead to successful management of bipolar disorder.

◆ Miklowitz, D. J. (2002). *The bipolar disorder survival guide: What you and your family need to know.* New York: Dell.

In this book, Miklowitz covers the origins, symptoms, and treatments for bipolar disorder. It is intended for patients and has a strong emphasis on current medications used to treat bipolar disorder.

◆ Fast, J. A., & Preston, J. D. (2004). *Loving someone with bipolar disorder.* Oakland, CA: New Harbinger Publishers.

This unique book, written by someone who has bipolar disorder, provides a guide on living with someone who has the illness. It provides advice on how couples can work together as a treatment team dealing with how to live with the illness while also maintaining a loving and joyful relationship.

CANCER

Kate-Lyn Stone

DIAGNOSIS

Cancer is characterized by the unrestrained growth and spread of abnormal cells, which develop because of damaged DNA. These cells spread throughout the body via the blood and lymph systems (National Cancer Institute, 2007). Cancer can result in death if the spread of these cells remains uncontrolled. Cancer is the second leading cause of death in the United States. Any individual of any race or gender can be diagnosed with cancer at any age; however, the rate at which cancer occurs varies from group to group. The sooner the cancer is detected and diagnosed, the better the outcome (American Cancer Society, 2007b).

INCIDENCE AND PREVALENCE

◆ Cancer is the second leading cause of death (after heart disease) in the United States (American Cancer Society, 2007a).

◆ Cancer is responsible for one of every four deaths in the United States (American Cancer Society, 2007a).

◆ Over one million people are diagnosed with cancer each year (American Cancer Society, 2007a).

◆ About 10.5 million Americans were living with a history of cancer in January 2007 (American Cancer Society, 2007a).

◆ Age is the leading risk factor for developing cancer; 56.5% of all cancers are diagnosed in individuals 65 years of age and older (Centers for Disease Control and Prevention, 2007).

◆ Breast cancer is the most common type of cancer diagnosed in women; prostate cancer is the most common type of cancer in men (American Cancer Society, 2007a).

THE CAUSE AND ETIOLOGY

Cancer can be caused by both external and internal factors. Examples of external factors include smoking cigarettes, radiation, and chemicals. Internal factors can include hormones, immune conditions, and inherited cell mutations. These factors can act alone or in combination with one another to lead to cancer (American Cancer Society, 2007b).

Risk factors for cancer can be divided into two groups: modifiable (things that are changeable) and nonmodifiable (things that cannot be altered). Major modifiable risk factors include tobacco use, unhealthy eating habits, infectious agents (such as the hepatitis B virus), ultraviolet radiation, and physical inactivity. Other modifiable risk factors can include alcohol use, occupational exposures, socioeconomic status, obesity, food contaminants, and environmental radiation. Nonmodifiable risk factors are ageing, ethnicity, race, heredity, and gender (Mackay, Jemal, Lee, & Parkin, 2006).

TYPES

There are over 100 different types of cancer that can be broken down into five main categories (National Cancer Institute, 2007):

1. *Carcinoma:* cancer in skin or tissue over internal organs
2. *Sarcoma:* cancer in bone, fat, muscle, cartilage, or blood vessels
3. *Leukemia:* cancer that begins in tissue that creates blood (e.g., bone marrow)
4. *Lymphoma and myeloma:* cancer of the immune system
5. *Central nervous system cancers:* cancers in the brain or spinal cord

An individual's prognosis, or likelihood of survival, depends on the type and stage of cancer. Precancerous abnormal cells are generally associated with the best prognosis, followed by localized cancer, then regional cancer.

Metastatic cancer is associated with the worst prognosis for survival (Mackay et al., 2006).

TYPICAL COURSE AND SYMPTOMS

All cancers, no matter what type, begin in the cells of the body. When the DNA of the cells becomes damaged, mutations are produced that affect the normal development of the cell. Because of these mutations, the cells do not die when they are supposed to and can eventually contribute to the growth of a tumor. If the tumor is malignant (cancerous), it can spread to other parts of the body (American Cancer Society, 2007b).

A symptom is an indication of a disease or condition that is noticed by the individual who experiences it but is not noticeable to other people. A sign is an indication of a disease or a condition that is observed by a health care provider. General signs and symptoms of cancer include the following:

◆ Unexplained weight loss, usually of 10 pounds or more
◆ Fever
◆ Fatigue
◆ Pain
◆ Skin changes, such as darkening, yellowing, reddening, itching, or excessive hair growth

There are, of course, specific signs and symptoms for each type of cancer. To find more information on symptoms for a specific type of cancer, the reader is referred to the American Cancer Society's Website at www.cancer.org.

SEQUENCE OF CARE

Once an individual has been diagnosed with cancer, the sooner a course of treatment is decided on, the better the outcome in most cases. The sequence of care for the treatment of cancer depends on the type of cancer, the stage of the cancer (how widespread it is in the body), and other factors for each individual, such as overall health and lifestyle. There are four major types of treatment: surgery, radiation, chemotherapy, and biologic therapies. In addition to these four, there are also hormone therapies and complementary and alternative therapies. Surgery and radiation are generally used to treat localized cancers. Chemotherapy, which involves using powerful medications, is used to treat cancer that has spread to other parts of the body. Biologic therapies, also known as immunotherapy, biotherapy, or biological response modifier therapy, use the immune system to fight cancer (American Cancer Society, 2007b).

Throughout treatment for cancer, an individual may receive services from physicians, pharmacists, counselors, physical therapists, occupational therapists, nurses, respiratory therapists, massage therapists, case managers, surgeons, and social workers. The spectrum of health care providers who are seen will depend on the type and stage of cancer.

OT ROLE

Thanks to improving and advancing technology, more and more people are surviving cancer. Because of this, the role of occupational therapists in treating cancer has also grown. Occupational therapists can work as part of a specialized team in a cancer center, in the community, and in palliative care (Crompton, 2004). In general, the goal of the occupational therapist is to improve the client's quality of life. This can be done in several ways beyond the basic self-care that is typically thought of as occupational therapy. Occupational therapists can also help the client by educating the client and his or her family, finding resources, strengthening weaknesses secondary to tumors, dealing with cognitive changes due to chemotherapy treatment, and improving endurance. Occupational therapists can also help clients with lifestyle management, fatigue management, medication management, and symptom management (Crompton, 2004).

Dr. Mack Ivy explains that "as an occupational therapist, I'm not in charge of curing cancer" (Strzelecki, 2006). What Ivy says here is important for occupational therapists to realize and remember: we cannot cure cancer, but we have the ability to improve the quality of life of individuals who are living with cancer. That can be a very powerful tool, as Ivy goes on to explain: "occupational therapy is so powerful and important because we are a discipline that addresses sensorimotor skills and cognitive and psychosocial aspects. We look at the environment and we also try to find out functional goals, as well as coping and leisure activities" (Strzelecki, 2006).

OT EVALUATIONS

Basic and Instrumental Activity of Daily Living Skills

- Kohlman Evaluation of Living Skills (KELS)
- Assessment of Motor and Process Skills (AMPS)
- Functional Independence Measure (FIM)
- Klein-Bell Activities of Daily Living Scale (Klein-Bell)
- Satisfaction With Performance Scaled Questionnaire (SPSQ)

Psychosocial Skills

- The Assessment of Occupational Functioning (AOF)
- Beck Depression Inventory (BDI)
- The Occupational Performance History Interview II (OPHI II)
- Ways of Coping Checklist (WCC)

Self-Perception

- The Canadian Occupational Performance Measure (COPM)

- The Role Checklist
- Worker Role Inventory

Other Assessments

- Manual muscle testing
- Range-of-motion testing
- Pain scales
- Home assessment

OT INTERVENTIONS

- ADL
- Energy conservation techniques
- Strengthening exercises
- Pain management
- Assistive technology
- Adaptation of the environment
- Adaptive equipment
- Patient and family education
- Home planning
- Self-management education
- Caregiver adjustment

OT AND THE EVIDENCE

Several studies discuss the benefits of psychosocial interventions for improving quality of life in individuals with cancer (Barsevick, Sweeney, Haney, & Chung, 2002; Uitterhoeve et al., 2004). More specifically, Osborn, Demoncada, and Feuerstein (2006) found cognitive behavioral therapy (CBT) to be an effective intervention for treating depression, anxiety, and quality of life in individuals with cancer. They found CBT to have short-term effects on depression and anxiety, thus reducing emotional distress, as well as short- and long-term effects on quality of life. They also found that CBT was more effective when used individually rather than in groups. Another psychosocial intervention approach that has been found to be effective in improving overall quality of life is social cognitive theory (SCT). Graves (2003) found that using SCT-based interventions improved overall quality of life in adults with cancer.

CARDIAC CONDITIONS

Kate-Lyn Stone

DIAGNOSIS

The term *cardiac condition* is an umbrella term for several more specific heart diseases and conditions. Coronary heart disease is the most common cardiac

condition in the United States (Centers for Disease Control and Prevention, 2007). The following text provides general information about cardiac conditions. For more specific information on three individual heart conditions, please refer to the resource sheets for con-

genital heart disease, congestive heart failure, and myocardial infarction.

INCIDENCE AND PREVALENCE

◆ Heart disease is the leading cause of death in the United States (Medline Plus, 2007a).
◆ Approximately 700,000 people in the United States die of heart disease each year, which is about 29% of all U.S. deaths each year (Centers for Disease Control and Prevention, 2007).

ETIOLOGY

There are several risk factors, which include conditions and lifestyle factors that can increase an individual's chances for developing a cardiac condition. The conditions include high levels of low-density lipoprotein (LDL) cholesterol, high blood pressure, and diabetes mellitus. Behavioral factors that contribute to the development of cardiac conditions include smoking and other tobacco use, poor diet, physical inactivity, being overweight or obese, and excessive alcohol use. One last factor that can increase an individual's chances of having a cardiac condition is heredity, since heart disease can run in a family (Centers for Disease Control and Prevention, 2007).

TYPES

As was previously noted, the term *cardiac condition* is a broad term that covers several more specific heart conditions. The following list provides more specific terminology for other heart diseases and conditions (Centers for Disease Control and Prevention, 2007):

◆ Acute coronary syndrome
◆ Arrhythmias
◆ Cardiomyopathy
◆ Congenital heart disease
◆ Coronary heart disease
◆ Heart attack (myocardial infarction)
◆ Heart failure
◆ Peripheral arterial disease
◆ Rheumatic heart disease

For more information on these conditions and others, the reader is referred to the Websites for the American Heart Association and the Centers for Disease Control and Prevention.

TYPICAL COURSE AND SYMPTOMS

The typical course, signs, and symptoms will vary for each condition and disease.

MEDICAL INTERVENTION

Cardiac conditions generally go unnoticed and undiagnosed until a person has chest pain, a heart attack, or a stroke. If these telltale signs do not lead to a medical emergency and the physician suspects a cardiac disease, the physician will use a variety of tests to narrow it down to a specific diagnosis. Tests that may be used include electrocardiogram, echocardiogram, stress test, catheterization, and carotid artery scan. Once a diagnosis has been determined, the individual might need to make serious lifestyle changes, take medication, undergo surgery, or a combination of the three (Dowshen, 2007).

Cardiac surgery has been made possible by two major advances in medical technology. First, the heart-lung machine takes over the work of the heart and lungs while surgery is performed, allowing blood and oxygen to be pumped throughout the body. Second, body-cooling techniques allow the heart to be stopped for longer periods of time without doing damage to the heart. If temperatures in the body are cooler, the heart requires less oxygen (Texas Heart Institute, 2007).

There are several different types of cardiac surgery. Cardiac surgery can be used to insert devices into the heart chamber, repair or replace valves, bypass or widen blocked arteries, repair aneurysms, replace weak cardiac muscles with stronger ones taken from the abdomen or back, or transplant a heart from a donor (Medline Plus, 2007b). The following are possible types of cardiac surgery that can be performed, depending on the condition that is present:

◆ *Coronary artery bypass:* Coronary artery bypass grafting, also known as coronary artery bypass graft surgery, coronary bypass, or bypass surgery, is the most common cardiac surgery. This surgery involves taking a vein or artery from another part of the body and replacing a section of a diseased coronary artery. This allows more blood to flow easily to the heart (Texas Heart Institute, 2007).
◆ *Valve repair or replacement:* In valve repair, a damaged valve is fixed so that it will work properly. In valve replacement, a damaged valve is replaced by a biological valve taken from an animal or human or by a mechanical valve made of plastic, carbon, or metal (Texas Heart Institute, 2007).
◆ *Arrhythmia surgery:* Arrhythmia surgery includes Maze surgery. Maze surgery is used to treat the most common type of arrhythmia, called atrial fibrillation. In Maze surgery, surgeons create a new "maze" of electrical pathways to allow electrical impulses to get through the heart easily (Texas Heart Institute, 2007).
◆ *Aneurysm repair:* Aneurysm repair involves using a graft, or a patch, to replace a weakened section of a blood vessel or the heart (Texas Heart Institute, 2007).

◆ *Transmyocardial laser revascularization:* Transmyocardial laser revascularization uses lasers to make channels in the heart muscle to allow blood to flow directly into the heart chamber (Texas Heart Institute, 2007).

◆ *Carotid endarterectomy:* Carotid endarterectomy involves inserting a tube above and below a blockage in the neck to reroute blood flow and then removing the fatty plaque that is causing the blockage. Carotid endarterectomy is the most common surgery to treat carotid artery disease (Texas Heart Institute, 2007).

◆ *Heart transplantation:* Heart transplantation is generally the last option after medicines, mechanical devices, and other therapies have failed (Texas Heart Institute, 2007).

Patients with a cardiac condition generally participate in cardiac rehabilitation after receiving their medical treatment. These rehabilitation programs usually support an individual through education and counseling services centered on increasing physical fitness, promoting health and well-being, and decreasing the risk of future cardiac conditions (American Heart Association, 2007). The physical fitness portion of the rehabilitation will be created on the basis of the type of cardiac condition that the client has and the treatment that the client has received.

PREVENTION

An individual can help to prevent the development of heart disease by following some simple guidelines (Medline Plus, 2007a):

◆ Maintain a good blood pressure.
◆ Lower cholesterol.
◆ Exercise on a regular basis.
◆ Do not smoke.
◆ Maintain a healthy weight.

OT ROLE

An occupational therapist will often be a member of the cardiac rehabilitation multidisciplinary team treating clients who have cardiac conditions. Occupational therapists help clients with motor and sensory skills following surgery or other medical intervention. Occupational therapists also help clients learn to break activities down into smaller parts to help in the conservation of energy (Heart and Stroke Foundation, 2006). Occupational therapists work with clients to prevent further cardiac conditions from developing by promoting healthy lifestyle routines and habits.

OT EVALUATIONS

Basic and Instrumental Activity of Daily Living Skills

◆ Kohlman Evaluation of Living Skills (KELS)
◆ Assessment of Motor and Process Skills (AMPS)
◆ Functional Independence Measure (FIM)
◆ Klein-Bell Activities of Daily Living Scale (Klein-Bell)

OT INTERVENTIONS

◆ ADL
◆ Energy conservation techniques
◆ Strengthening exercises
◆ Pain management
◆ Stress management
◆ Assistive technology
◆ Adapt environment
◆ Adaptive equipment
◆ Patient and family education
◆ Home planning
◆ Self-management education

OT AND THE EVIDENCE

Cardiac rehabilitation programs conduct most of the research on interventions for cardiac conditions. Following extensive training, an occupational therapist can often be a member of the multidisciplinary team working in cardiac rehabilitation. Cardiac rehabilitation has been proven

to be effective in patients of all ages. Macchi and colleagues (2007) looked at cardiac rehabilitation for individuals aged 75 and older who had undergone some kind of cardiac surgery. The researchers found positive outcomes for these individuals. Kardis, Sherman, and Barnett (2007) found similar positive improvements across all age groups in their study regarding age and quality of life after cardiac rehabilitation. They do, however, suggest that there be a greater focus on emotional support for the younger individuals participating in cardiac rehabilitation. Other studies look at the efficacy of home-based versus center-based rehabilitation. One study suggests that for low-risk clients, home-based rehabilitation is no less effective than center-based cardiac rehabilitation, on the basis of measures concerning capacity for exercise, systolic blood pressure, and total cholesterol (Jolly, Taylor, Lip & Stevens, 2006). Dalal and colleagues (2007) found results similar to those of Jolly and colleagues (2006), in that there were no significant differences between patients who received cardiac rehabilitation in the hospital versus those who received the rehabilitation at home. Dalal and colleagues (2007) used the measures of depression, anxiety, and total cholesterol levels to compare the two groups and found no statistically significant differences between the results.

CEREBRAL PALSY

Stacey Halpern

Cerebral palsy (CP) is a term that is used to describe motor disorders that are characterized by impaired voluntary movement resulting from either prenatal developmental abnormalities or perinatal or postnatal central nervous system damage occurring before age 5 years (Merck, 1999). Common difficulties associated with CP include cognitive delays, speech difficulty, seizure disorders, feeding problems, impaired vision and hearing, abnormal sensation and perception, difficulty with bowel control, breathing problems due to poor posture, and skin conditions as a result of pressure sores (United Cerebral Palsy Association, 2001a).

CLASSIFICATION OF CEREBRAL PALSY

- *Spastic:* Results in hypertonicity ranging from mild to severe and is the most common type
- *Athetoid:* Characterized by slow, writhing, involuntary movements or abrupt, jerky movements
- *Ataxic:* Characterized by weakness, incoordination, and intentional tremor
- *Mixed:* Commonly combines spasticity and athetosis (Merck, 1999)

INCIDENCE

Approximately 8,000 infants are diagnosed with CP each year (United Cerebral Palsy Association, 2001a).

PREVALENCE

Approximately 764,000 children and adults in the United States demonstrate signs of CP (United Cerebral Palsy Association, 2001a).

COURSE AND SYMPTOMS

There are currently no interventions that can repair the damage to the areas of the brain that control muscle coordination and movement (M. Goldstein, 2004). However, medical and therapeutic interventions help to reduce the symptoms associated with CP and/or improve functional abilities in people with cerebral palsy.

Although CP is not a progressive disorder, motor abilities may decrease as the person grows and the resistance of gravity increasingly takes effect. Secondary conditions that are seen in adults with CP include pain, musculoskele-tal deformities, overuse syndromes, fractures, and fatigue. People with CP typically live well into adulthood (Zaffuto-Sforza, 2005).

PRECAUTIONS

- Seizure disorders
- Difficulty swallowing
- Impaired vision/hearing
- Abnormal sensation/perception (United Cerebral Palsy Association, 2001a)

ALTERNATIVE TREATMENT APPROACHES

Medical Interventions

- Antispasticity medications are used to decrease nerve cell sensitivity. These medications can be given orally or through implanted pumps.
- Botulinum toxin injections can relax muscles for a period of four to six months.
- Selective dorsal rhizotomy surgery involves cutting sensory nerve fibers posterior to the spinal cord as a method for reducing muscle tone.

Complementary Alternative Medicines

These are treatment approaches that have not been accepted by mainstream practice:

- Hyperbaric oxygen therapy is believed to stimulate brain tissue by adding oxygen in increased amounts and under greater atmospheric pressure. This intervention has not been shown to produce benefits and is controversial (Hardy et al., 2002).
- Conductive education is an educational method that promotes independent functioning through practice, repetition, and verbal self-guidance. This approach has been shown to produce gains, but current research has not shown it to be better than conventional methods (Liberty, 2004; Rosenbaum, 2003).
- The Adeli suit was designed in Poland and is based on the suits from the Soviet space program. It allows for controlled exercise against resistance to strengthen muscles and increase proprioception. Research regarding this intervention is limited (Rosenbaum, 2003).
- Therapeutic electrical stimulation is believed to benefit people with CP by stimulating the increase of active movement. This approach has not been shown in re-

search to produce significant benefits (Dali et al., 2002; Sommerfelt, Markestad, Berg, & Saetesdal, 2001).

OT EVALUATIONS

The basis of occupational therapy assessment for clients with CP is to determine the client's ability to participate in society. Evaluation of the need for assistive technology is important for clients across the life course, as needs can change with age.

Pediatric Evaluations

Pediatric evaluations may include the following:

ADL

- Pediatric Evaluation of Disability Inventory
- WeeFIM

School-Specific

- School Function Assessment
- School Setting Interview

Functional Mobility

- Gross Motor Classification System

Play/Leisure

- Knox Preschool Play Scale
- Transdisciplinary Play-Based Assessment
- Play History

Adolescent/Adult Evaluations

Adolescent and adult evaluations may include the following:

General Occupational Performance

- Canadian Occupational Performance Measure
- Occupational Performance History Interview
- Occupational Circumstances Assessment Interview and Rating Scale

ADL

- Functional Independence Measure

Work

- The Work Environment Impact Scale

Leisure

- Adolescent Role Assessment
- Leisure Assessment Inventory

Additional client factors that may be assessed include cognition, tone, spasticity, sensation, fatigue, and ROM (Andren, & Grimby, 2004; Campbell, 1996; MOHO Clearinghouse, 2005).

OT INTERVENTIONS

When working with people who have CP, occupational therapy practitioners focus on adapting tasks and the environment to help enhance participation and quality of life. Occupational therapy practitioners may play a key role in helping people with CP to choose and access assistive devices and supports that will promote function. Practitioners can play an important role throughout the life course depending on the individual's needs and may be a part of early intervention, school, and rehabilitation services (D. N. Goldstein, Cohn, & Coster, 2004; Ketelaar, Vermeer, Hart, van Petegem-van Beek, & Helders, 2001; Zaffuto-Sforza, 2005).

Interventions may include the following:

- Client and caregiver education on range of motion to prevent contractures (United Cerebral Palsy Association, 2001c)
- Fabrication of orthotics or splints to align bones and maintain range of motion (M. Goldstein, 2004; United Cerebral Palsy Association, 2001b)
- Neurodevelopmental treatment (NDT), which has been associated with increased function in mobility and self-care for children with CP in small studies (Knox & Evans, 2002) but NDT has not been found to be any more effective than other approaches (Butler & Darrah, 2001)
- Constraint-induced therapy, which has been linked to gains in quality of movement and amount of use of the effected arm for young children with hemiparesis associated with CP (DeLuca, Echols, Ramey, & Taub, 2003; Taub, Ramey, DeLuca, & Echols, 2004)

OT AND THE EVIDENCE

Studies addressing the therapeutic approaches that are used by occupational therapists and other rehabilitation professionals have found that the motivation of the client, the degree of impairment, the therapist-client interaction, the intensity and duration of treatment, and the environment where therapy takes place can have more of an effect on the success of treatment than the particular intervention approach itself (M. Goldstein, 2004).

Additionally, interventions that target only physical capabilities, such as NDT, have been shown to provide only limited carryover (Law et al., 1998).

Therefore, it is most appropriate to utilize a family-centered, functional approach that promotes functional

performance, identifies and changes the primary constraints of the task, and encourages practice to improve performance in all areas of occupation (Law et al., 1998).

CAREGIVER CONCERNS

- ◆ Most people with CP will need at least some type of assistance from a caregiver throughout the life course.
- ◆ It is important for caregivers to allow their loved ones to maintain as much independence as possible.
- ◆ As parents age, they might become physically unable to care for their adult children and will need to find alternatives, such as group home placement.
- ◆ It is important to make sure caregivers take care of themselves and seek assistance from others when needed. (United Cerebral Palsy Association, 2001c; Zaffuto-Sforza, 2005)

CEREBROVASCULAR ACCIDENT

Kristin Knesek

A cerebrovascular accident (CVA), also known as a *stroke,* is caused by a disruption of the blood supply to the brain, which results in anoxia and brain tissue death (World Health Organization, 2005). A CVA is characterized by a sudden or gradual onset of neurological deficits. The location of the lesion, extent of the injury, and mechanism by which the vascular injury occurred each play a role in the typical course and prognosis for recovery. Some individuals may experience small *lacunar* strokes from which they recover fully, while others may experience complete strokes from which the symptoms never fully subside. *Ischemic strokes,* which account for approximately 88% of strokes, are caused by vessel blockage secondary to arteriosclerotic or hypertensive stenosis (American Stroke Association, 2005a). *Hemorrhagic strokes,* in which recovery is often less promising, result from rupture in an arteriosclerotic blood vessel (ASA, 2005a).

INCIDENCE AND PREVALENCE

- Stroke killed an estimated 163,538 people in 2001 (the nation's third leading cause of death).
- Each year, about 700,000 people experience a new or recurrent stroke. About 500,000 are first attacks, and 200,000 are recurrent attacks.
- About 4.8 million stroke survivors live in the United States today. (ASA, 2005a)

TYPICAL COURSE

Although recovery has traditionally been thought to peak within the first three months after stroke, with slower recovery for up to one year, new evidence indicates that recovery of function is possible for many years (Liepert, Bauder, Miltner, Taub, & Weiller, 2000; Taub & Unswatte, 1998). The course of recovery is unpredictable; some individuals regain full function, and others regain very little.

POTENTIAL SYMPTOMS

- Hemiplegia/paresis: decreased function on one side of the body
- Aphasia: problems with communication
- Apraxia: motor planning problems
- Dysarthria: neuromotor speech output problems
- Visual-perceptual deficits (e.g., homonymous hemianopsia)
- Somatosensory deficits: sensory problems

- Cognitive deficits (e.g., decreased insight, safety awareness, and/or judgment)
- Psychosocial deficits (e.g., depression, decreased motivation, decreased social participation, and/or isolation)
- Incontinence: inability to control excretory functions

GENERAL SAFETY PRECAUTIONS

- *Medical status/stability:* This should be assessed daily when the individual is in the acute stage of recovery (i.e., the therapist should be familiar with symptoms of progressing/recurring stroke).
- *Cardiac/respiratory precautions:* Watch for blood pressure changes, dizziness, breathing difficulties, chest pain, excessive fatigue, and/or altered heart rate or rhythm.
- *Fall prevention:* Provide appropriate supervision and assistance during all transfers and functional mobility.
- *Shoulder subluxation/pain:* To avoid shoulder injury, never pull or lift an individual's affected upper extremity.
- *Skin integrity:* This could become an issue because of decreased sensation, visual deficits, and/or neglect; therefore, it should be monitored frequently.
- *Swallowing status:* Determine swallowing ability and use safe swallow techniques as needed. Refer to a speech-language pathologist as needed.
- *Poor safety awareness/impulsive behavior:* Provide appropriate level of supervision.
- *Muscle stiffness:* Range of motion should be performed on the affected upper extremity to prevent muscle stiffness and/or contractures.
- *General safety concerns:* Educate the individual, the family, and other health care providers regarding all precautions in order to maximize safety at all times.

MEDICAL MANAGEMENT

Medical management for stroke is as follows (Express Scripts, 2005).

Acute Treatment

1. *Thrombolytic agents ("clot busters"):* These dissolve the clot that is blocking the flow of blood through the vessel. Thrombolytics are considered a first line of treatment.
2. *Anticoagulants:* These prevent the formation of the hematoma (blood clot) or inhibit its growth. Anticoagulants are considered a second line of treatment.
3. *Antiplatelet treatments:* These work by preventing platelets in the blood from sticking together and form-

ing a clot. Antiplatelets are considered a second line of treatment and are also used to decrease the risk of a second stroke.

New drug therapies for the prevention of stroke aim to improve or reverse the effects of an acute stroke. These drugs include prostacyclin and calcium channel–blocking agents. Use of a combination of aspirin and calcium channel blockers has been used very early after ischemic stroke (during hospitalization) with encouraging initial results.

SURGERY

Carotid endarectomy is a surgical procedure that is used to treat and prevent acute ischemic stroke. This is an effective treatment for protecting against a first stroke in individuals with severe stenosis of the major blood vessels in the brain. For individuals who have intact awareness and have persistently progressing ischemic strokes, this procedure may also be utilized (Express Scripts, 2005).

Surgical treatment for hemorrhagic stroke involves removing the hematoma from the area. Individuals who remain conscious and have a small hematoma (less than 20 cc or less than 3 cm in diameter) often improve without surgery. In contrast, individuals who are in a coma secondary to a large hematoma (greater than 80 cc or 6 cm in diameter) often do poorly regardless of treatment. Individuals who have moderate to large hematomas and remain conscious are the most likely candidates for surgery (Express Scripts, 2005).

OCCUPATIONAL THERAPY EVALUATIONS

Comprehensive Evaluations

- American Heart Association Stroke Outcome Classification (AHA.SOC)
- Functional Independence Measure (FIM)
- National Institutes of Health Stroke Score (NIHSS)

ADL Evaluations

- Assessment of Motor and Process Skills (AMPS)
- Barthel Index (BI)

IADL/Leisure Evaluations

- Activity Card Sort (ACS)
- Frenchay Activities Index

Upper Extremity Function Evaluations

◆ Fugl-Meyer Upper Extremity Motor Performance Test
◆ The Functional Test for the Hemiplegic/Paretic Upper Extremity
◆ The Modified Ashworth Scale (spasticity)

Range of motion (via goniometry), strength (via manual muscle testing, dynamometer, and/or pinch meter), and edema (via volumeter) may be measured as needed.

Balance Evaluations

◆ Berg Balance Scale (fall predictor)
◆ Postural Assessment Scale for Stroke Patients (PASS)
◆ The Motor Assessment Scale

Cognition and/or Perception Evaluations

◆ Behavioral Inattention Test (BIT)
◆ Lowenstein Occupational Therapy Cognitive Assessment (LOTCA)

Quality of Life/Life Satisfaction Evaluations

◆ Canadian Occupational Therapy Performance Measure (COPM)
◆ Short-Form 36 Health Survey (SF-36)
◆ Stroke Impact Scale (SIS)
◆ Stroke-Specific Quality of Life Scale (SS-QOL)

OCCUPATIONAL THERAPY INTERVENTIONS

General

◆ ADL/IADL retraining
◆ Training in the use of adaptive equipment
◆ Environmental adaptation

Upper Extremity Function

◆ Constraint-induced therapy
◆ Modified constraint-induced therapy
◆ Mental imagery
◆ Robot-assisted rehabilitation
◆ Sensory stimulation
◆ Task-specific training utilizing shaping techniques
◆ Use of compensatory strategies
◆ Use of meaningful, purposeful, client-chosen occupations as therapeutic change agents
◆ Virtual reality

Cognitive/Perceptual Rehabilitation

◆ Cognitive retraining
◆ Use of compensatory strategies (e.g., verbal cueing, use of anchoring techniques for neglect)

Endurance, Balance, Functional Mobility

◆ Therapeutic exercise
◆ Use of compensatory strategies

OCCUPATIONAL THERAPY AND THE EVIDENCE

Occupational therapy effectively improves performance of ADLs/IADLs and role participation for individuals who have experienced stroke. Goal-specific teaching and practice of meaningful, client-chosen activities in a familiar context along with provision of necessary adaptations and training in the use of these adaptations has proved to be effective for improving occupational performance after stroke (Trombly & Ma, 2002). Treatments that occupational therapists use to remediate impairments are generally beneficial, especially those that involve activity and/or occupation to bring about change (Ma & Trombly, 2002).

CAREGIVER CONCERNS

According to Visser-Meily, van Heugten, Post, Schepers, and Lindeman (2005), caregiver burden is quite common after stroke, and high levels of burden are often related to deterioration of the caregiver's own health status, social life, and well-being. Jonsson, Lindgren, Hallstrom, Norrving, and Lindgren (2005) concluded from low emotional-mental scores on the SF-36 that informal caregivers are often under considerable strain. Furthermore, caregiver depression can worsen the depression of an individual who has had a stroke and may predict poor response to rehabilitation (Visser-Meily et al., 2005). Isolation from people other than the ones they are caring for is also a major concern for caregivers (ASA, 2005b). It is imperative that caregivers be educated about taking care of themselves, including their physical, emotional, mental, spiritual, interpersonal, and financial health (ASA, 2005b).

The following recommendations for informal caregivers have been adapted from the American Stroke Association (2005b):

◆ *Set goals and limits:* Think realistically about what you can and cannot do.
◆ *Be organized:* Have a "job description" in which you define what you and the one you are caring for need (i.e. assistance with housekeeping, shopping).

◆ *Recognize your own limits:* Realize when you need a break and take time for yourself.
◆ *Involve others:* Involve other family members and friends in the caregiving experience.

As occupational therapists, we can utilize these recommendations to educate and assist caregivers with regard to their role in caring for the individual who has had a stroke.

First-Person Accounts

◆ Klein, B. S. (1998). *Slow dance: A story of stroke, love, and disability.* Berkeley, CA: Rage Mill Press.
In her mid-forties, Bonnie Klein, a brilliant filmmaker, experienced a catastrophic stroke that changed her life. She provides a moving account of her struggle first to survive, then to "reinvent" rehabilitation, and finally to accept the challenge of living with a disability. This is also a remarkable love story.
◆ Mayer, T. K. (2000). *Teaching me to run.* Boston: Prince Gallison Press.
This is an inspirational story of one middle-aged woman's struggle back from the debilitating effects of stroke. The author battles to relearn not only to walk, but also to run, against all odds.
◆ McCrum, R. (1998). *My year off, recovering life after a stroke.* New York: Avon Books.
Robert McCrum had a right CVA in 1995 at the age of 42. He presents an account of the physical and psychological effects of stroke, including impaired speech, impaired left arm and leg function, and the inability to engage in a valued life role: work.
◆ Simon, S. (2002). *A stroke of genius: Messages of hope and healing from a thriving stroke survivor.* Delray Beach, FL: The Cedars Group.

This book was written by a man who had a cerebral hemorrhage at the age of fifty-six. He explains the causes of the two major types of stroke and reveals information about other medical issues involved with stroke. Simon gives advice to his audience, including medical doctors and therapists, on how to deal with the various physical and psychosocial implications of stroke.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Kim Bennet, Kate-Lyn Stone, and Meredith Grinnell

Chronic obstructive pulmonary disease (COPD) is characterized by an obstruction to airflow that interferes with normal breathing. COPD is a permanent and progressive condition that includes both chronic bronchitis and emphysema. Chronic bronchitis is a longstanding inflammation of the mucous membranes of the bronchial airways. Chronic bronchitis is characterized by an increase of mucus secretion and a chronic productive cough for at least three months in two consecutive years for which other causes (e.g., infection, cancer, chronic heart failure) have been ruled out. Emphysema is defined by an abnormal permanent enlargement of the airspaces in the lungs, with the progressive and irreversible destruction of the alveolar walls. These changes result in loss of lung elasticity, which impairs gas exchange (oxygen, carbon dioxide) (American Lung Association, 2007).

ETIOLOGY

There are several causative factors related to COPD, of which smoking is considered to be the most significant. Other risk factors include prolonged inhalation of lung irritants such as pollution, dusts, or chemicals; passive exposure to cigarette smoking; and genetics (alpha 1 antitrypsin deficiency) (Daniel & Strickland, 1992).

INCIDENCE AND PREVALENCE

- COPD is the fourth leading cause of death in the United States for all ages and both genders.
- Approximately 16 million people in the United States have some form of COPD.
- COPD is responsible for over 13.4 million office visits per year and is the third most frequent justification for home care services.
- People with COPD commonly become symptomatic during the middle adulthood. The incidence of COPD increases with age (American Lung Association, 2007).

TYPICAL COURSE AND SYMPTOMS

COPD develops slowly and progresses in the following four stages:

- People who are at risk of COPD. At this stage, individuals have normal lung function but suffer chronic cough and sputum production.
- Mild COPD. At this stage, there is mild airflow limitation, but patients might be unaware that their lung function is abnormal.
- Moderate COPD. By this stage, the airflow limitation is causing symptoms such as shortness of breath on exertion. Patients usually seek medical attention at this stage.
- Severe COPD. By this stage, airflow limitation is severe, symptoms are severe, and exacerbations may be life threatening (National Heart Lung and Blood Institute, 2007).

TYPICAL INTERVENTIONS AND EXPECTED OUTCOMES

Management of COPD requires a long-term therapeutic approach. Treatment focuses on symptom management through education about the disease and actively engaging the patients with COPD in care management. Pulmonary rehabilitation programs are designed to address the aspects of COPD management as follows.

Education About COPD

Patients are educated in preventive care (e.g., minimizing potential irritants in the home and work environment) and optimization of medications (e.g., purpose of medication, dosage, side effects, and schedule of administration).

Smoking Cessation

Patients are encouraged to discontinue smoking because stopping smoking is the single most effective step in

slowing the progression of COPD. Benefits to smoking cessation include reduction in the number of respiratory infections, improvement in the function of the mucociliary clearance of the lungs, decreased cough and dyspnea, increased appetite, and decreased sputum production. Smoking cessation programs are helpful in assisting and supporting lifestyle change.

Medication

Medications may include a broad-spectrum of antibiotics to avoid an exacerbation, flu vaccinations, and bronchodilators. Corticosteroids may be considered to control severe acute episodes of bronchospasm.

Nutrition

Patients with COPD who experience dyspnea may also experience difficulty eating, resulting in weight loss and nutritional deficits. These two factors tend to decrease respiratory muscle strength; therefore, patients need to be instructed on the benefits of eating high-fat, low-carbohydrate food in small, frequent meals.

Exercise

Exercise is an important component in pulmonary rehabilitation. Exercise reduces cardiovascular disease risks, improves musculoskeletal functioning, and may help to prevent bone loss in older patients.

Oxygen Supplementation

Oxygen therapy decreases morbidity and mortality for patients with COPD, especially when used more than 18 hours per day. Oxygen supplementation is typically used to enable daily activities and exercising.

Breathing Retraining

The goals of breathing retraining include decreasing the work of breathing, improving oxygenation, increasing the efficiency of breathing patterns, and promoting the client's control of breathing. Diaphragmatic and pursed-lip breathing are two types of breathing techniques that are used. Diaphragmatic breathing improves the efficiency of breathing and the patient's awareness of breathing patterns. Pursed-lip breathing allows patients to slow their breathing, increases the expiration pressure, improves the oxygenation, and reduces respiratory rate.

Chest Physiotherapy

Chest physiotherapy includes chest percussion, postural drainage, and vibration and rib shaking. These techniques are used to aid patients in clearing pulmonary secretions.

Pulmonary Hygiene

Pulmonary hygiene includes hydration, deep breathing exercises, and coughing techniques (Weilitz, 2000).

PROGNOSIS

COPD is a chronic disorder that cannot be totally reversed or corrected. The prognosis is dependent on the patient's present clinical status, recent functional history, and response to current functional activity. At any level of lung impairment, prognosis improves when the patient stops smoking. The best indicator of prognosis is the forced expiratory volume (FEV) or the volume of air that is forcefully expelled in 1 second. A patient with an FEV1 greater than 1.5 L has a very good prognosis, expected survival rate being 10 to 20 years. A patient with an FEV1 of 1.0–1.25 L is considered to experience moderate lung impairments with predicted survival for 6–10 years. Patients with an FEV1 less than 0.75 L are considered to have severe lung impairments and have a mortality rate of 2 to 6 years. (Daniel & Strickland, 1992).

PRECAUTIONS

1. Patients should avoid exposures to cigarette smoke, fumes, dust, odors from solvents, powders or spray aerosols, and other respiratory irritants.
2. Interventions should be stopped if the patient becomes nauseous, dizzy, or fatigued; has shortness of breath; or has chest pains.
3. If oxygen is to be administered, the patient should be informed and aware of appropriate safeguards.
4. Be aware of cyanosis and refer to the physician immediately. (Daniel & Strickland, 1992)

OT EVALUATIONS AND INTERVENTIONS AND SEQUENCE OF CARE

Occupational therapists are responsible for providing appropriate services for the patient with COPD; assisting the patient with COPD in achieving the maximal functional level of independence; educating the patient and family regarding ongoing treatment and ensuring consistent home management of the patient on discharge; and assisting the patient and the family in adjusting to disability and life changes. The following are occupational performance areas and components that are assessed. All areas are assessed in relation to functional performance. Various performance areas and skills are identified to create realistic client-centered treatment goals (Paul & Orchanian, 2003).

Assessment of Performance Areas

◆ Activities of daily living: basic ADL and IADL skills
◆ Work and productive activities: home management, care for others, and vocational activities
◆ Play or leisure performance (Huntley, 2002; Paul & Orchanian, 2003)

Assessment of Performance Components

◆ *Neuromusculoskeletal:* range of motion, muscle tone, strength, endurance, postural alignment
◆ *Psychosocial skills:* psychological, social, and self-management (Paul & Orchanian, 2003)

Standardized Assessment Tools

◆ Borg Scale of Perceived Exertion
◆ Klein-Bell Activities of Daily Living Scale
◆ Kohlman Evaluation of Daily Living Scale
◆ Assessment of Motor Process Skills (AMPS)
◆ Functional Independence Measure (FIM)
◆ Tinetti Test of Balance and Gait
◆ Berg Balance Test
◆ Self-Assessment of Leisure Interests
◆ Interest Checklist
◆ Self-Esteem Scale
◆ Tennessee Self-Concept Scale–Revised (TSCS) (Paul & Orchanian, 2003)

Other Tests

◆ Chronic Obstructive Pulmonary Disease Evaluation Form and Procedures
◆ Range-of-motion testing(AROM/PROM)
◆ Manual muscle testing
◆ Home Assessment and Recommendations Evaluation Form (Paul & Orchanian, 2003)

OT INTERVENTIONS

◆ Maintain or improve upper extremity strength, ROM, and tolerance
◆ Maximize or improve the patient's independence in ADLs
◆ Assist the patient and family with psychological adjustment to disease
◆ Ensure safety and accessibility in home
◆ Increase the patient's and family or caregiver's knowledge of rehabilitation process for patient with COPD
◆ Increase the patient's endurance to sustain daily activities and exercise
◆ Explore avocational interests and assess adaptations needed to allow the patient to engage in them
◆ Assist the patient in learning appropriate relaxation techniques to decrease tension, stress, and fear

◆ Increase the patient's ability to cope with cognitive deficits
◆ Increase the patient's independence and accessibility within the community
◆ Increase the patient's independence in driving and driving safety (Daniel & Strickland, 1992; Huntley, 2002)

OT AND THE EVIDENCE

Lorenzi and colleagues (2004) evaluated the effectiveness of OT as an adjunctive measure to comprehensive pulmonary rehabilitation for disabled hospitalized COPD patients. Results showed that OT for basic domestic activities during comprehensive pulmonary rehabilitation specifically improved the outcome of patients with severe COPD.

Guided imagery has been found to be an effective intervention for developing more effective breathing patterns in individuals with COPD. Louie (2004) found that these relaxation sessions, which connect the mind, body, and spirit, lead to raised oxygen saturation in the blood. Another intervention to promote the management of acute exacerbations of COPD is the development and implementation of an action plan. Action plans incorporate guidelines for independently initiating strategies if there is a change in the state of an individual's COPD that could lead to an exacerbation (Turnock, Walters, Walters, & Wood-Baker, 2007). These plans are useful to increase an individual's sense of self-efficacy in managing his or her disease.

Community-based settings offering groups for individuals with COPD have also been evaluated and found to have positive psychosocial outcomes. Woo and colleagues (2006) found that people were empowered and enthusiastic about the social support they received from the group setting. Group activities include education about COPD, breathing exercises, use of medication, nutrition, relaxation strategies, and strengthening and aerobic exercises.

CAREGIVER CONCERNS

As COPD progresses and the patient's activity becomes more restricted, many patients become more dependent on family members and develop a sense of isolation, loss of control, and depression. It is important for the health care professional to give caregivers the tools to recognize these feelings and encourage the patient to talk about them; professional support from psychiatrists or psychologists may be helpful. Gentle encouragement to exercise regularly and recognition that activities must be carefully planned in advance will help to ensure a better quality of life.

First-Person Accounts

Carter, R., Nicotra, B., & Tucker, J.-V. (1999). *Courage and information for life with chronic obstructive pulmonary disease.* Peabody, MA: New Technology Publishing.

Jo-Von Tucker has taken an active role to prevent COPD from controlling her life. She passes along valuable tips, information, and details of daily living to give hope and support to those who suffer from COPD. Jo-Von Tucker combines the experience and insights as a patient with expertise of medical and rehabilitation professionals (the two other authors). The purpose of this easy-to-understand book is to help people with COPD actively manage their own health care.

Vogel, L. G. (2004). *Huffin' n' puffin': Living with COPD.* West Conshohocken, PA: Infinity Publishing.

Written by a COPD patient, this book provides realistic information about living with COPD. Using stories and poetry in a lighthearted manner, the author explains what COPD is; explores diagnosis, treatment, medications, doctors and caregivers; and describes living and coping with the disease on a daily basis. Including a glossary and COPD resource guide, the book is essential reading for every COPD patient and family member.

CONGENITAL HEART DISEASE

Kate-Lyn Stone

DIAGNOSIS

The term *congenital heart disease,* also known as congenital heart defects, cyanotic heart disease, heart defects, or congenital cardiovascular malformation, implies that there is a defect in the heart that has been present since birth (National Heart Lung and Blood Institute, 2007). This is the most common type of birth defect (Medline Plus, 2007). The normal flow of blood through the heart is altered because of congenital heart defects (National Heart Lung and Blood Institute, 2007).

INCIDENCE AND PREVALENCE

- Approximately 8 of every 1,000 newborn babies have a congenital heart defect (Baffa, 2007).
- In the United States, more than 35,000 children are born each year with a congenital heart defect (National Heart Lung and Blood Institute, 2007).

ETIOLOGY

The cause of most congenital heart defects is unknown. It is known that these defects develop because of abnormal development in the heart of the fetus early in the pregnancy (Baffa, 2007). It is thought that heredity might play a role in some congenital heart defects; for example, a parent with a heart defect might be more likely than another parent to have a child with a heart defect at birth (National Heart Lung and Blood Institute, 2007).

TYPES

Congenital heart defects can vary from simple ones, such as a hole in an interior wall of the heart, to complex ones, which are generally a combination of simple defects (National Heart Lung and Blood Institute, 2007). There are several different names for congenital heart defects, including the following (Baffa, 2007):

- Aortic stenosis
- Atrial septal defect
- Atrioventricular canal defect
- Coarctation of the aorta
- Hypoplastic left heart syndrome
- Patent ductus arteriosus
- Pulmonary atresia
- Pulmonary stenosis
- Tetralogy of Fallot
- Total anomalous pulmonary venous connection
- Transposition of the great arteries
- Tricuspid atresia
- Truncus arteriosus
- Ventricular septal defect

For more information about these types of heart defects, the reader is referred to the Nemours Foundation Website: http://kidshealth.org/parent/medical/heart/congenital_heart_defects.html.

SIGNS AND SYMPTOMS

Telltale signs of congenital heart disease include cyanosis (a bluish color) to the skin around the mouth, on the lips, or on the tongue; increased breathing rate; heart murmur; inability to gain weight; sweating; and weak strength of pulse. Symptoms include poor appetite and difficulty breathing (Baffa, 2007).

SEQUENCE OF CARE

If it is suspected that a child has a congenital heart defect, the primary care physician will probably refer the child to a pediatric cardiologist. The cardiologist will complete a full physical examination and order a chest X-ray to look at the heart and lungs. An electrocardiogram will also be done to look at electrical signals from the heart. Cardiac catheterization, using colored dyes, allows a better look at the heart's inner structures. The catheter can also measure pressures and oxygen levels within the heart (Baffa, 2007). Once a child has been diagnosed as having a congenital heart defect, the surgeon may repair the defect with either surgery or perform another surgical procedure using a catheter. In the more severe and complex cases, a heart transplant might be the best option for the child (National Heart Lung and Blood Institute, 2007).

IMPLICATIONS FOR OT

See the resource sheet on cardiac conditions.

CONGESTIVE HEART FAILURE

Kate-Lyn Stone

DIAGNOSIS

The term *congestive heart failure,* or simply *heart failure,* is the name for the condition in which any of the four chambers of the heart—the atria, the upper chambers, the ventricles, or the lower chambers—loses its ability to keep up with the amount of blood that is flowing through the heart (American Heart Association, 2007). Heart failure is a chronic disease with no cure.

INCIDENCE AND PREVALENCE

- Approximately 5 million people are living with heart failure in the United States (American Heart Association, 2007).
- 550,000 new cases of heart failure are diagnosed in the United States each year (American Heart Association, 2007).

ETIOLOGY

Everybody's heart loses some ability to pump blood as the person ages. Heart failure occurs because of the added stress of other health conditions in addition to aging. These conditions include: coronary artery disease, past heart attacks, high blood pressure, abnormal heart valves, heart muscle disease, heart defects from birth, severe lung damage, diabetes, severe anemia, overactive thyroid, and abnormal heart rhythm (American Heart Association, 2007).

TYPES

Left-Sided Heart Failure (Left Ventricular Heart Failure)

Left-sided heart failure involves the left ventricle of the heart. Systolic failure occurs when the left ventricle loses its ability to contract normally, which means that the heart cannot pump enough blood into circulation. Diastolic failure occurs when the left ventricle cannot relax normally, which means that the heart does not adequately fill with blood between each pump. In either case, the heart's ability to circulate blood properly decreases, and fluid builds up throughout the body. This explains the term *congestive heart failure* (American Heart Association, 2007).

Right-Sided Heart Failure (Right Ventricular Heart Failure)

Right-sided heart failure usually occurs secondary to left ventricular heart failure. When the left ventricle is not working properly, blood backs up to the lungs, essentially damaging the heart's right side in the process (American Heart Association, 2007).

TYPICAL COURSE AND SYMPTOMS

Heart failure can affect the right side, the left side, or both sides of the heart; however, it generally begins in the left side. This condition generally occurs little by little over time. To compensate for the loss of ability, the heart first tries to enlarge, develop more mass, and pump faster. These are temporary changes that the body makes to address heart failure that mask the condition but do not cure it. This helps to explain why some people are not diagnosed with heart failure until several years after it first develops. Eventually, the heart can no longer mask the problem, and the symptoms of heart failure begin to emerge (American Heart Association, 2007).

Symptoms of heart failure include the following (American Heart Association, 2007):

- Shortness of breath or breathlessness
- Pain in the abdomen
- Difficulty sleeping
- Loss of appetite
- Increased fatigue

Signs of heart failure include the following (American Heart Association, 2007):

- Sudden weight gain
- Increased swelling in the lower extremities
- Swelling in the abdomen
- Frequent cough

MEDICAL INTERVENTIONS AND TREATMENTS

Medications

The following are medications that are commonly used to treat heart failure (American Heart Association, 2007):

- *ACE inhibitors (angiotensin-converting-enzyme inhibitors):* Considered the primary drug used to treat heart failure. ACE inhibitors act as vasodilators (expand blood vessels) and have been proven to slow the progression

of heart failure. They lower the levels of angiotensin in the body, which is a substance that can lead to an increase in blood pressure.

◆ *Diuretics (water pills):* Cause the body to eliminate more fluid than usual. Diuretics help the heart to work less by decreasing the amount of fluid the heart has to pump throughout the body.

◆ *Vasodilators:* Expand the blood vessels, which allows blood to flow more easily through them, thus decreasing the amount of work the heart has to do.

◆ *Digitalis preparations (also known as digoxin):* Increases the heart's contractions as well as slowing some irregular heartbeats.

◆ *Beta blockers:* Decrease the heart's inclination to beat faster.

◆ *Blood thinners:* Thin the blood, which allows the blood to flow more easily through the vessels.

◆ *Angiotensin II receptor blockers:* Completely block effect of angiotensin on the heart and blood vessels.

◆ *Calcium channel blockers:* Used to treat high blood pressure by decreasing calcium's role in the contraction of the muscles of the heart. The muscles relax, thus allowing the heart to work less.

◆ *Potassium:* Helps to control the rhythm of the heart.

Valve Replacement Surgery

In valve replacement surgery, the inefficient valve is removed and replaced with a mechanical valve made from metal, plastic, or human or animal tissue or a valve taken from a donor.

Angioplasty

Angioplasty is used to open blocked blood vessels.

Coronary Artery Bypass

Coronary artery bypass is used to reroute the blood supply around a section of artery that is blocked.

Defibrillator Implantation

A defibrillator provides pacing to the heart when an abnormal rhythm is detected.

Heart Transplant

A transplant involves removing the damaged heart and replacing it with a heart from a donor.

Left Ventricular Assist Device

The left ventricular assist device is a mechanical pump that helps to maintain the pumping of the heart.

DEPRESSION

Laurie Dossett and Kate-Lyn Stone

Depression is a serious mental illness. It is a disorder that affects one's thoughts, moods, feelings, behavior, and physical health. There are two main types of depression: major depression (interferes with daily occupations) and dysthymia (less severe with chronic symptoms that do not disable but can lead to major depression) (National Institute of Mental Health, 2000).

INCIDENCE AND PREVALENCE

Depressive disorders affect approximately 9.5% of adult Americans, or about 19 million people in a given year (NIMH, 2005). Depression often begins between the ages of 15 and 30 but can occur at any age, including childhood.

Women are two times as likely as men to experience depression. Depression (not including bipolar disorder) is the leading cause of disability among men and women of all ages in the United States and worldwide, according to the World Health Organization (2001).

DIAGNOSIS

At least five of the following symptoms must be present for a diagnosis of depression (American Psychiatric Association, 2000):

◆ Depressed mood, nearly every day during most of the day

- Marked diminished interest or pleasure in almost all activities
- Significant weight loss (when not dieting), weight gain, or a change in appetite
- Insomnia or hypersomnia (excess sleep)
- Feelings of worthlessness or inappropriate guilt
- Impaired psychomotor agitation or psychomotor retardation
- Fatigue or loss of energy
- Feelings of inability to concentrate or indecisiveness
- Recurrent thoughts of death, recurrent suicidal ideation

These symptoms must be present during the same two-week period and must represent a change from a previous level of functioning (American Psychiatric Association, 2000, p. 356).

The diagnostic criteria for a single episode or recurrent major depression differ from the above symptoms, and a complete description of these criteria is beyond the scope of this document.

ETIOLOGY

There is no single cause of depression. Stressful life events can trigger depression, or depression can occur spontaneously with no identifiable cause. Depression can be familial, suggesting that there may be a genetic component (NIMH, 2000). Biological factors and changes in body chemistry can also be causes of depression (American Psychological Association, 2005).

AFFILIATED PROBLEMS

Depression often co-occurs with other serious illnesses, such as heart disease, stroke, diabetes, cancer, and Parkinson's disease. Depression can and should be treated when it co-occurs with other illnesses, as untreated depression can delay recovery from these other illnesses or worsen them (Agency for Healthcare Research and Quality, 2000; NIMH, 2000).

PRECAUTIONS

Individuals with severe depression are at risk for harming themselves and possibly for suicidal ideation. The primary risk factor for suicide in both the general population and the clinical population is a mood disorder such as depression (often with comorbid substance abuse) (AHRQ, 2004). Heavy drinking and other forms of substance abuse increase one's risk of a mood disorder such as depression (Ramsey, Engler, & Stein, 2005).

TREATMENT

In a time of crisis, if a person has thoughts of harming himself or herself or of committing suicide, a hospital emergency room may be able to provide temporary help (NIMH, 2000). The person with depression can then be referred to other services for long-term care, such as family doctors; mental health specialists such as psychiatrists, psychologists, social workers, or mental health counselor; community mental health centers; hospital psychiatry departments and outpatient clinics; or private clinics and facilities (NIMH, 2000).

Psychotherapy

- Talk therapies help clients to gain insight into and resolve their problems through verbal exchange with the therapist.
- Behavioral therapists help clients learn how to obtain more satisfaction and rewards through their own actions and how to unlearn the behavioral patterns that contribute to or result from their depression.
- Cognitive/behavioral therapists help clients to change the negative styles of thinking and behaving that are often associated with depression.

Medication

- Selective serotonin reuptake inhibitors (SSRIs)
- Tricyclic and tetracyclic antidepressants
- Monoamine oxidase inhibitors (MAOIs)
- Serotonin and norepinephrine reuptake inhibitors (SNRIs)

Electroconvulsive Therapy

Electroconvulsive therapy is used as a last resort when no other treatments have proven effective. It involves electrically inducing a seizure that causes physiological and biomechanical changes in the brain (NIMH, 2000).

OT EVALUATIONS

Observations, interviews, and history taking play a major role in evaluating depression (Cara, 2005). An occupational therapist will analyze a person's ability to perform relevant occupations (American Occupational Therapy Association, 2002). The following assessment instruments are also used when appropriate:

- Canadian Occupational Performance Measure (COPM)
- Kohlman Evaluation of Living Skills (KEHLS) (Kohlman Thompson, 1992)

◆ Scorable Self-Care Evaluation
◆ Beck Depression Inventory (Beck, 1978)

OT INTERVENTIONS

Occupational therapy often becomes involved with the depressed client in an attempt to assist in the remediation and treatment of symptoms. Group therapy is commonly used in mental health settings, and the focus of interventions may be on any number of following areas:

ADL/IADL

◆ Medication/time management
◆ Activities of daily living
◆ Community mobility/reentry
◆ Reestablishing normal routines

Social

◆ Expressive activities
◆ Social integration
◆ Functional behavior training
◆ Focuses on restoring motor and cognitive functioning

PERFORMANCE SKILLS/WORK

◆ Stress management (relaxation training, attention to stressors, biofeedback)
◆ Lifestyle alterations
◆ Judgment skills
◆ Work to increase self-esteem with attainable goals
◆ Instructing the individual on setting realistic goals
◆ Psychoeducation concerning symptoms and precursors to symptom exacerbation

OCCUPATIONAL THERAPY AND THE EVIDENCE

For children and adolescents with depression, cognitive-behavioral therapy (CBT), interpersonal psychotherapy, psychosocial intervention, antidepressants, or a combination of pharmacological options is an effective first-line treatment (Dopheide, 2006). Occupational therapists are among the many professionals who can be qualified to use CBT and interpersonal psychotherapy during interventions (Dopheide, 2006). CBT, used in conjunction with pharmacotherapy, has been observed to reduce negative thinking associated with depression, lessen residual symptoms of depression, and decrease the possibility for relapse (Beevers & Miller, 2005; Fava et al., 2004; Hensley,

Nadiga, & Uhlenhuth, 2004). Current evidence also suggests leisure activity, including exercise, cards, bingo, and church attendance, as a valuable tool for decreasing depression. Occupational therapists have experience using activity as a part of intervention to treat a variety of conditions. Therefore, using leisure activity as a modality to decrease depression would be an appropriate occupational therapy approach. Keeping a holistic approach in mind, occupational therapists not only treat the condition itself, but also seek to improve the individual's functioning and overall well-being (Babyak et al., 2000; Fine, 2000).

CAREGIVER/FAMILY CONCERNS

Having a loved one with depression can be very stressful. Individuals with mood disorders, such as depression, have a very high rate of divorce (Long, 1998). Family therapy may be beneficial when (1) the depression appears to be seriously jeopardizing the client's marriage and family functioning or (2) a client's depression appears to be promoted and maintained by marital and family interaction patterns (Long, 1998).

DEVELOPMENTAL COORDINATION DISORDER

Kimberly Fletcher

The *Diagnostic and Statistical Manual-IV* describes developmental coordination disorder (DCD) as "a marked impairment in the development of motor coordination that must significantly interfere with academic achievement or activities of daily living, not be due to a general medical condition or pervasive developmental disorder and if mental retardation is present the motor difficulties must be in excess of those usually associated with it" (American Psychiatric Association, 2000, p. 56). DCD has been discussed in the literature under a number of different names, including *minimal brain dysfunction, perceptual motor dysfunction, physical awkwardness, clumsy child syndrome,* and *developmental dyspraxia* (Miller, Polatajko, Missiuna, Mandich, & Macnab, 2001).

INCIDENCE

- Six percent of school-age children are estimated to have some degree of DCD (Dilley, 2004).

CHARACTERISTICS

Many, but not all, children with DCD have the following characteristics:

- Born prematurely or having low birth weight
- Delayed motor milestones
- Comorbid attentional problems or learning disabilities

COURSE

- Potential etiologies include brain damage, genetic predisposition, or impairment in information processing.
- DCD is typically diagnosed at school age when children begin to have difficulties keeping up with classroom tasks (Cermak & Larkin, 2002).
- There is strong empirical evidence that the motor problems associated with DCD persist into adulthood (Miller, Missiuna, et al., 2001).

SYMPTOMS

At Home

- Late reaching motor milestones
- Difficulty walking up and down stairs
- Difficulty with dressing
- Falls often
- Difficulty with puzzles and sorting (http://dyspraxia foundation.org.uk/an_overview.htm)

At School

- Avoids physical education and games
- Might not run, hop, catch, or kick like peers
- Poor pencil grip
- Immature artwork
- Might have trouble with math
- Difficulty copying from board (http://dyspraxiafounda tion.org.uk/an_overview.htm)
- Handwriting is extremely effortful
- Difficulty on the playground
- Reduced participation in unstructured physical activities
- Academic problems
- Organization problems
- Task completion problems (Miller, Missiuna, et al., 2001)
- Difficulty keeping friends

POTENTIAL RISKS

- DCD can lead to the development of secondary mental health and educational issues, including poor social competence, academic problems, behavioral problems, and low self-esteem (Miller, Missiuna, et al., 2001)
- Children with DCD tend to be less successful than other children in sports and other physical activities and games, resulting in a tendency to avoid physical activities. This withdrawal has negative effects on the

musculoskeletal and cardiopulmonary systems (Cermak & Larkin, 2002).

OT EVALUATIONS

Occupational Performance Based

- Perceived Efficacy and Goal Setting System (PEGS)
- The School Function Assessment (SFA)
- The Movement Assessment Battery for Children Checklist (M-ABC Checklist)
- Developmental Coordination Disorder Questionnaire
- The Pediatric Interest Profiles (PIP)
- The Child Routine Inventory
- The Children's Assessment of Participation and Enjoyment (CAPE)

Motor Skills Assessments

1. Movement Assessment Battery for Children (M-MABC)
2. Bruininks Oseretsky Test of Motor Proficiency

OT INTERVENTIONS

- *Cognitive strategies:* A well supported example of this approach is the CO-OP approach. The CO-OP approach is an individualized, child-centered treatment that focuses on identifying cognitive strategies for successful task performance (Miller, Polatajko, Missiuna, Mandich, & Macnab, 2001).
- *Neuromotor Task Training (NTT):* NTT is an approach based in motor learning theory. NTT involves direct teaching of the task to be learned, through analysis and training of motor control processes. NTT has demonstrated positive effects on handwriting and fine and gross motor skills (Niemeijer, Smits-Engelsman, Reynders, & Shoemaker, 2003).
- *Parent and teacher training:* Training parents and teachers to work with children around developing specific skills using a cognitive motor approach has been found to be effective for some children (Sugden & Chambers, 2003).
- *Activity analysis/consultation:* It is important to consider the features of an activity; for example, in intervening to increase a child's participation in the community, one would consider the amount of hand-eye coordination involved in baseball versus swimming (Chen & Cohn, 2003).

OT AND THE EVIDENCE

A small randomized clinical trial comparing the CO-OP approach to a contemporary treatment approach (including neuromuscular, multisensory and biomechanical treat-ments), found the CO-OP approach to be most effective (Miller, Polatajko et al., 2001).

Additionally, Polatajko, Mandich, Miller, and Macnab (2001) analyzed five studies of the effectiveness of the CO-OP approach in children with DCD. They found that all five studies supported the use of the CO-OP approach with children with DCD. Three of the five studies indicated that the effect of the CO-OP treatment was reproducible across therapists, children, and a variety of activities.

CAREGIVER CONCERNS

Caregivers of children with DCD often have the following concerns:

- Their child's social development and whether their child can participate in activities that are typical for the child's peer group (Chen & Cohn, 2003).
- The possibility that the family unit could be limited in its participation within their community and involvement in leisure activities as a result of difficulties experienced by the child with DCD (Chen & Cohn, 2003).

DOWN SYNDROME

Alisa Jordan

Down syndrome is a genetic condition that is caused by a chromosomal mutation resulting in a third chromosome 21 (trisomy 21) in 95% of cases. It can also be caused by an unbalanced translocation of genetic material or mosaicism, in which one cell line is typical and one displays trisomy 21. Down syndrome can be diagnosed through prenatal testing or shortly after birth (American Academy of Pediatrics, 2001).

INCIDENCE

Down syndrome occurs in 1 in 800 births in the United States and 1 in 400 births for women over 35 years of age. (National Institute of Child Health & Human Development, 2006).

CHARACTERISTICS

People with Down syndrome have a wide variety of physical and functional abilities. The phenotype (physical appearance) of Down syndrome typically includes the following:

◆ Sloping forehead
◆ Flat nasal bridge
◆ Upslanting openings between the upper and lower eyelids
◆ Tongue protrusion
◆ Broad hands with short fifth fingers
◆ Small head, ears, and mouth (AAP, 2001; Roizen & Patterson, 2003)

The behavioral/cognitive phenotype of people with Down syndrome has been described as follows:

◆ Mental retardation (of varying degrees)
◆ Deficits in grammar skills, expressive language, auditory memory, intelligible speech
◆ Strengths in receptive language, visual-spatial memory, and interest in social interactions (Chapman & Hesketh, 2001)

PRECAUTIONS AND RELATED CONDITIONS

◆ Congenital heart disease
◆ Hypotonia
◆ Neck joint instability or subluxation
◆ Hearing loss
◆ Vision problems
◆ Hypothyroidism and obesity

◆ Celiac disease (gluten allergy)
◆ Respiratory tract infections
◆ Seizures
◆ Alzheimer's disease after the age of 40 years (AAP, 2001; Roizen & Patterson, 2003)

COURSE AND LIFE EXPECTANCY

◆ Life expectancy for people with Down syndrome is currently over 50 years (Roizen & Patterson, 2003).
◆ Over 80% of children born with Down syndrome survive to the age of 5 years (Dastgiri, Gilmour, & Stone, 2003).
◆ With services and support, many children and young adults with Down syndrome are able to participate in inclusive classrooms and progress with academic and self-care skills (Turner & Alborz, 2003).
◆ After transition from school services, many individuals with Down syndrome are able to live and work in the community, either independently or, commonly, with support from family or a group home environment (Roizen & Patterson, 2003).
◆ Later in life, approximately 75% of adults over 60 years with Down syndrome show signs and symptoms of Alzheimer's disease (Roizen & Patterson, 2003).

INTERDISCIPLINARY INTERVENTIONS

Traditional medical specialties consulted may include the following:

◆ Developmental pediatrics
◆ Neurology
◆ Gastroenterology
◆ Cardiology
◆ Orthopedics
◆ Endocrinology
◆ Ophthalmology
◆ Audiology (Leshin, 2002)

Therapies and support services are often an integral part in the lives and development of individuals with Down syndrome. In addition to occupational therapy, individuals may receive the following:

◆ Physical therapy
◆ Speech therapy
◆ Nutritional counseling
◆ Special education
◆ Vocational support
◆ Residential/community living support
◆ Dementia/Alzheimer's-related services (Leshin, 2002)

Alternative therapies may also be used in treatment for individuals with Down syndrome. Research supporting these interventions in reducing the related conditions of Down syndrome is limited or nonexistent. These therapies include the following:

◆ Cell therapy
◆ Nootropics ("smart drugs")
◆ Nutritional supplements
◆ Plastic surgery (Leshin, 2002)

OT EVALUATION

Pediatric

ADL and Adaptive Behavior

◆ Pediatric Evaluation of Disability Inventory (PEDI)
◆ Vineland Adaptive Behavior Scales (VABS)
◆ Functional Independence Measure for Children (WeeFIM)

School Participation and Functioning

◆ School Function Assessment (SFA)
◆ Occupational Therapy Psychosocial Assessment of Learning (OTPAL)

Play/Leisure

◆ Test of Playfulness

Adolescent/Adult

ADL

◆ Functional Independence Measure (FIM)

Transition Services

◆ Transition Planning Inventory (TPI)

Occupational Needs, Interests, and Environmental Fit

◆ The Volitional Questionnaire Assessment (VQ)
◆ Canadian Occupational Performance Measure (COPM)

Other Client Performance Areas

◆ Fine and gross motor skills
◆ Praxis
◆ Visual-motor and perceptual skills
◆ Sensory processing
◆ Muscle tone
◆ Cognition and safety awareness
◆ Assistive technology needs

Caregivers of Adults with Down Syndrome and Alzheimer's Issues and Needs

◆ Caregiver Activity Survey-Intellectual Disability (CAS-ID)

OT INTERVENTION

Occupational therapy can be beneficial to individuals with Down syndrome throughout the life course. Because of the variability in functional strengths and limitations in this population, client-centered services are especially essential to effectiveness.

Early Intervention for Ages 0–3 Years

Possible Client Challenges

- Developmental delays in many areas, especially praxis and prehension
- Poor motivation and poor ability to explore and learn from the environment (Duff & Charles, 2004; Fidler, Hepburn, Mankin, & Rogers, 2005; Niccols, Atkinson, & Pepler, 2003)

Possible Interventions

- Efficient physical, cognitive, communication, social-emotional, and adaptive skill development
- Facilitation of participation in environment and family routines
- Maintenance of development rate
- Environmental adaptation (American Occupational Therapy Association, 2004; Lebeer & Rijke, 2003; Mahoney, Robinson, & Fewell, 2001)

Important Considerations

- Most children with Down syndrome take about twice as long as typical children to reach developmental milestones (Palisano et al., 2001).
- No one particular frame of reference commonly used by occupational therapists in early intervention (neurodevelopmental treatment, sensory integration, etc.) has been found to be more effective than others and should be used in conjunction to address all client needs (Mahoney et al., 2001; Uyanik, Bumin, & Kayihan, 2003).

Characteristics of Effective Intervention

- Natural environment
- Involvement and education of parents and caregivers
- Promotion of positive caregiver-child interactions (Lebeer & Rijke, 2003; Mahoney et al., 2001; Uyanik et al., 2003)

School Services for Ages 3–22 Years

Possible Client Challenges

- Toilet training
- Complex fine motor tasks
- Peer play and interactions

- Few severe functional limitations (Dolva, Coster, & Lilja, 2004; Leonard, Msall, Bower, Tremont, & Leonard, 2002)

Possible Interventions

- IEP consultation
- Elimination of barriers to learning and inclusion through environmental modification
- Supports for behavioral, social skills and ADL development
- Educating teachers, professionals, and parents about school-age issues related to Down syndrome
- Integration of outpatient and school services (AOTA, 2004; Cross, Traub, Hutter-Pishgahi, & Shelton, 2004; Wolpert, 2001)

Transitioning Out of School Services

At this stage, important tasks are development of supports and planning for optimal performance after exit from school in areas including the following:

- ADL, IADL, related assistive technology
- Prevocational and vocational skills
- Social skills and leisure participation
- Environmental modification (Kardos & White, 2005; Spencer, Emery, & Schneck, 2003)

Supported Employment and Community Living for Ages 18 Years and Older

Possible Client Challenges

- Limited independent living skills
- Aggressive or agitation behaviors, potentially due to exposure to negative life events, such as the constant shift in staff or location of group homes, relationship difficulties, or illness (Owen et al., 2004)

Possible Interventions

- Environmental adaptation for just-right fit
- Cognitive, problem solving, and social skill training
- ADL training and adaptation
- Adaptive equipment
- Sensory and occupation-based aggressive behavior management
- Self-advocacy and effective communication training (Chan, Fung, Tong, & Thompson, 2005; LaVigna, Christian, Liberman, Camacho, & Willis, 2002; Siporin & Lysack, 2004)

Characteristics of Effective Intervention

- Foster the client's feelings of being respected
- Promote the client's autonomy and choice
- Maximize the client's competence and productivity
- Use concrete, simple, repetitive, and multisensory teaching approaches (LaVigna et al., 2002; Siporin & Lysack, 2004)

OT AND THE EVIDENCE

The collaboration between therapist and parent(s) has been seen as a positive, effective, and valued part of intervention by all parties involved (Hanson, 2003; Hinojosa, Sproat, Mankhetwit & Anderson, 2002; Mayer, White, Ward, & Barnaby, 2002). While the strongest therapist-parent collaboration is typically during early intervention services, continued relationships have the potential to continue to provide benefit throughout the life course.

Research suggests that benefits for parents who are involved in their child's therapy include the following:

◆ Feeling more engaged in the system
◆ Receiving more education and information about their child
◆ Improved ability to see the strengths and progress made by their child
◆ Increased parental compliance and carryover of intervention strategies
◆ Increased developmental gains in relation to positive parent-child interaction (Mahoney et al., 2001; Mahoney, Wheeden, & Perales, 2004)

CAREGIVER CONCERNS

Being a caregiver for an individual with Down syndrome is often a lifelong role. Parents may benefit from the following:

◆ Education for parents to understand and take care of their children and themselves
◆ Early fostering of positive parent-child relationships and interactions in service provision
◆ Increased support for parents as services for the child decrease after they leave school
◆ Interventions to address negative or aggressive behaviors
◆ Respite services, especially if adult children still reside at home
◆ Encouragement to advocate for children and family's needs throughout the life course (Abbeduto et al., 2004; Ben-Zur, Duvdevany, & Lury, 2005; Hanson, 2004)

FRAGILE X SYNDROME

Laurie Dossett and Kate-Lyn Stone

Fragile X syndrome, also known simply as *fragile X,* is the most common inherited form of mental retardation. It results from a change, or mutation, in a single gene (the Fragile X Mental Retardation 1, or FMR1, gene) on the X chromosome (March of Dimes, 2003; National Institute of Child Health & Human Development, 2005). This mutation can be passed from one generation to the next. The name comes from the place on the X chromosome where the mutation appears and the fact that the affected portion looks fragile (March of Dimes, 2003).

INCIDENCE AND PREVALENCE

Fragile X affects approximately 1 in 4,000 males and about 1 in 8,000 females and occurs across all ethnic and racial groups (March of Dimes, 2003).

CAUSE

Fragile X syndrome occurs when the mutated gene cannot produce enough of a protein (fragile X mental retardation protein, or FMRP) that is needed by the body's cells, especially cells in the brain, to develop and function normally (NICHD, 2005; National Fragile X Foundation, 2006). Usually, females with fragile X either do not have the common characteristics that are seen in males or have the characteristics in a milder form (NFXF, 2006). This difference may be due to the fact that females have two X chromosomes and therefore have two sets of instructions for making FMRP, so affected females can often make enough to fill most of the body's needs (NFXF, 2006). Because males only have one X chromosome, they do not produce enough FMRP for their bodies. Mothers of affected boys are carriers of the gene.

SYMPTOMS AND CHARACTERISTICS

Young children with fragile X often have delays in developmental milestones. Many clinicians refer to some signs of fragile X as "autistic-like" (March of Dimes, 2003).

Intelligence and Learning

The most common effect of fragile X is on intelligence, more than 80% of affected males having an IQ of 75 or less, with more variable effects in females (NICHD, 2005). Some females have mental impairment, some have learning disabilities, and some have a normal IQ. Adults and children with fragile X may have varying degrees of mental retardation or learning disabilities (March of Dimes, 2003; NICHD, 2005).

Physical

Many infants and young children show no typical characteristics of fragile X, but as they enter puberty, some characteristics become more evident (NICHD, 2005). Some of these include a long, narrow face or jaw; large ears; flat feet; a high, arched palate; and hyperflexible joints (especially metatarsophalangeal joints), and children with fragile X might not be as tall as their peers (March of Dimes, 2003; NICHD, 2005). Males with fragile X may also develop enlarged testicles, a condition called macro-orchidism (NICHD, 2005). Girls with fragile X have fewer or less severe characteristics, but many do have large ears.

Social/Behavioral/Emotional

Many children who have been diagnosed with fragile X experience behavior problems, anxiety, possible depression, difficulties paying attention, and poor eye contact. They do not react well to new situations, and during adolescence, boys may exhibit aggressive behavior (March of Dimes, 2003; NFXF, 2006; NICHD, 2005). Behaviors such as hand flapping and chewing on skin, clothes, or objects are often seen in boys (March of Dimes, 2003; NFXF, 2006).

Sensory

Many children and adults with fragile X are very sensitive to certain sensations in their environments (NICHD, 2005). Sensory disorders in people with fragile X often include hyperarousal or hypoarousal, sensory over-reactivity and sensory underreactivity, including motor planning issues and fine motor weaknesses, and tactile defensiveness (NFXF, 2006). Children with fragile X may also have problems with balance, coordination, and connective tissue, which cause difficulties for them as they learn to sit, stand, and walk or, later, to ride a bicycle (NICHD, 2005).

Speech and Language

Many children with fragile X begin talking later than expected; most begin to use words around age 4, but some might not talk until age 6 or 7 (NICHD, 2006). Language difficulties in children who have fragile X range from mild stuttering to more severe problems with basic language skills, boys typically have more problems and girls rarely experience severe problems (NFXF, 2006; NICHD, 2005).

DIAGNOSIS

A blood test can identify people who either have fragile X syndrome or are carriers of the disorder (March of Dimes, 2003). Prenatal tests using amniocentesis or chorionic villus sampling can determine whether a baby of a carrier mother has inherited the full mutation, but this test cannot always determine whether the baby will have mental retardation (March of Dimes, 2003).

AFFILIATED CONDITIONS

Most people with fragile X do not have serious medical problems and have a normal life expectancy, though about 20% of people with fragile X will develop seizures, which are usually controlled with medication (March of Dimes, 2003). Children with fragile X may also be at an increased risk for autism, inner ear problems, sleep distur-

bances, ADD/ADHD, vision problems, digestive disorders, connective tissue problems, and premature ovarian failure in females (March of Dimes, 2003; NICHD, 2005).

TREATMENT

At this time, there is no cure for fragile X syndrome. It is possible, however, that through appropriate medications and education, the potential for each person can be maximized and signs can be minimized (Fragile X Research Foundation, 2005; NICHD, 2005).

Education

Most children with fragile X will qualify for special education services (because of mental retardation) in their school, where an individualized education plan (IEP) will be designed for the child (NICHD, 2005). These services will be provided from ages 3 to 21 years (or until they graduate from high school) through the Individuals with Disabilities Education Act (IDEA), which provides for a free, appropriate, individualized education in the least restrictive environment (Fragile X Research Foundation, 2005). As students get older, vocational assessment is a related service that should be part of the IEP from the middle school or early high school level (Fragile X Research Foundation, 2005). These assessments are provided to students in middle or high school who are beginning to plan their lives after graduation and are designed to assess the adolescent's aptitudes and interests as they relate to careers. When students leave high school, IDEA requires a plan that includes a coordinated set of activities based on the individual student's needs and interests (Fragile X Research Foundation, 2005). This helps during the transition period and helps these individuals and their families to decide what vocational education or postsecondary education options are appropriate, what supported employment might be needed, and the level of independence that is needed for living arrangements and community participation (Fragile X Research Foundation, 2005).

Medication

Medications are sometimes used to treat symptoms of fragile X or affiliated problems. They are usually most effective when used in conjunction with therapeutic interventions (NICHD, 2005).

Therapeutic Options

Many children (and some adults) with fragile X will find participation in services such as speech-language therapy, occupational therapy, behavioral therapy, and physical therapy beneficial to improve functioning in many areas (NICHD, 2005).

OCCUPATIONAL THERAPY EVALUATIONS

Occupational therapists may observe chewing and swallowing; grasp; states of alertness and overload; reactions to sound, light, and touch; and other sensorimotor and fine motor areas (NFXF, 2006). Occupational therapists will often use standard assessments to test for development and functional abilities. Some of these assessments may include the following:

◆ Infant-Toddler Developmental Assessment (birth to 36 months)
◆ Hawaii Early Learning Profile (0–36 months) (HELP)
◆ Miller Assessment for Preschoolers (2 years, 9 months to 5 years, 8 months) (MAP)
◆ Bayley Scale of Infant Development (1–42 months)
◆ Sensory Integration and Praxis Tests (4 years to 8 years, 11 months) (SIPT)
◆ Peabody Developmental Motor Scales-2 (1 month to 6 years) (PDMS)
◆ Bruininks-Oseretsky Test of Motor Proficiency (4.5–14.5 years) (BOT-2)

OCCUPATIONAL THERAPY INTERVENTION

Occupational therapists can work with people of all ages with fragile X to make necessary modifications in tasks or environments to ensure maximum functional performance (NICHD, 2005). This may include making changes in someone's home or school environment or finding appropriate assistive devices and equipment. As children grow older, an OT in a high school may work with students to match interests and abilities to find employment or volunteer work or to develop new skills (NICHD, 2005). Occupational therapy may be provided in early intervention, early childhood, and school programs; in work settings; and through private agencies (Fragile X Research Foundation, 2005).

Early Intervention Services

The Early Intervention for Infants and Toddlers with Disabilities and Their Families program is an amendment to IDEA to encourage states to set up programs for very young children and their families. Services are jointly selected by parents and service providers and may be offered in the home, school, hospital, or center.

Occupational therapists may work with families to adjust when they bring their newborn home and teach caregivers calming strategies, massage, deep pressure, and other supportive techniques for soothing an overstimulated baby (Fragile X Research Foundation, 2005).

School System

Younger school-aged children may receive occupational therapy services involving sensory integration and assistance with fine motor skills for activities such as writing or using a computer keyboard (Fragile X Research Foundation, 2005). As students get older, occupational therapists may evaluate workplaces and provide services to help both work skills and the work environment; and when vocational planning takes place, the OT plays a role in considering what type of work would be a good match for an individual (Fragile X Research Foundation, 2005).

OT AND THE EVIDENCE

Much of the research on fragile X syndrome (FXS), which is closely linked to other types of developmental disorders, discusses the importance of early identification of FXS. Early identification allows for early intervention, which provides important services for newborns and their families. High-quality early intervention has been shown to have beneficial effects on the progress of children with developmental disabilities secondary to FXS (Bailey, 2004; Bailey, Skinner, & Sparkman, 2003). Current research also directs attention to the importance of taking the environment into consideration when planning intervention for children with FXS (Baker & Donnelly, 2001; Mirrett, Roberts & Price, 2003). Mirrett, Roberts, and Price (2003) suggest that intervention accommodations should include providing visually based learning (photographs, picture symbols, or communication books); providing stable routines for transitions; making modifications for limited attention span; and adjusting, as necessary, during treatment for sensory processing difficulties. Shaaf and Miller (2005) found occupational therapy incorporating sensory integration to be particularly helpful in guiding intervention for children with FXS who have sensory processing difficulties.

CAREGIVER/FAMILY CONCERNS

Caregivers of children with special needs have common concerns for their children and their entire families. The process of getting a diagnosis can be long and trying for many families, leading to incredible stress.

RESOURCES

Organizations

◆ FRAXA (The Fragile X Research Foundation)
45 Pleasant Street
Newburyport, MA 01950

Telephone: 978-462-1866
Fax: 978-463-9985
Website: www.fraxa.org
Run by parents, relatives, and friends of those with fragile X, as well as by medical professionals. Promotes and funds scientific research aimed at the treatment and cure of fragile X.

◆ National Fragile X Foundation
P.O. Box 190488
San Francisco, CA 94119-0488
Telephone: 800-688-8765
Fax: 925-938-9315
Website: www.fragilex.org
Provides information and support to individuals with fragile X, their families, educators, and health professionals.

Books

◆ Schopmeyer, B. B. & Lowe, F. (1992). *The fragile X child.* San Diego: Singular Publishing Group.
A book covering what fragile X syndrome is, intervention options (including occupational therapy), and case studies.

◆ Webber, J. D. (2000). *Children with fragile X syndrome: A parent's guide.* Bethesda, MD: Woodbine House.
Written by leading professionals in the field and experienced parents, the guide is both helpful and supportive. Information helps families to adjust, understand their child's strengths and weaknesses, and know where to seek further help and expertise.

◆ Griffin, E. (2004). *Fragile X, fragile hope: Finding joy in parenting a special needs child.* Bethesda, MD: Woodbine House.
Provides a complete, sensitive introduction to fragile X syndrome, written by renowned professionals and experienced parents, who offer an in-depth look at the issues and concerns affecting children and their families. It covers diagnosis, parental emotions, therapies and medications, development, early intervention, education, daily care, legal rights, and advocacy.

◆ Icon Health Publications. (2005). *The official parent's sourcebook on fragile X syndrome: A directory for the internet age.* San Diego: Icon Group International.
This book was created for parents who have decided to make education and research an integral part of the treatment process; it tells parents where and how to look for information covering virtually all topics related to fragile X syndrome.

◆ Busby, M., & Massey, M. (2006). *Dear Megan: Letters on life, love and fragile X.* Sterling, VA: Capital Books.
In the form of intimate letters over the years between two mothers of different generations, this book is about dealing with the tragedy of having two mentally retarded

children as well as the privilege of joining the crusade to cure fragile X.

Websites

HIP AND KNEE REPLACEMENTS

Jennifer Keller and Kate-Lyn Stone

DESCRIPTION OF CONDITION

Knee Replacements (Total Knee Arthroplasty)

The largest joint in the body is the knee. Nearly normal knee joint function is vital to the performance of several routine daily activities. Disease or injury can compromise the function of the knee. Knee replacements are generally performed to decrease pain and muscle weakness and to improve limited function secondary to arthritis (the leading cause of knee pain and loss of function) or injury (American Academy of Orthopedic Surgeons, 2006b). Mezey (2001) states that knee replacements involve replacing the joint with an implant attaching to the tibia and femur. The surfaces are prepared by cutting the bones and flattening the surfaces prior to attaching the implant.

Hip Replacements (Total Hip Arthroplasty)

One of the largest weight-bearing joints in the body is the hip (AAOS, 2006a). When medications, changes in activities, and walking aids are no longer decreasing hip pain and stiffness secondary to arthritis, injury, or fracture, total hip replacements may be the next reasonable solution (AAOS, 2006). Total hip replacements are the most common hip procedure (Gann, 2001). Fagerson (1998) notes that total hip replacements are frequently performed on individuals who have rheumatoid arthritis and osteoarthritis. In this procedure, the joint is removed and replaced with an implant. Recovery after surgery can last anywhere from 6 to 12 weeks (Fagerson, 1998).

INCIDENCE AND PREVALENCE

◆ More than 300,000 knee replacements are performed each year in the United States (Mayo Clinic, 2006).
◆ More than 193,000 total hip replacements are performed each year in the United States (AAOS, 2006a).
◆ Approximately 85–97% of patients experience no pain after having a total hip replacement (Daniel & Strickland, 1992).

SEQUENCE OF CARE

Hip Replacement/Knee Replacement

Physicians conduct an initial assessment of the injury, including pain level and ability to function, and collect information regarding medical history and current health status (AAOS, 2006a). A physical examination is used to evaluate joint strength, stability, and range of motion. X-rays, CT scans, or MRIs are used to determine the specific diagnosis. Surgery is conducted to stabilize the joint and structures (Merck, 2005).

SYMPTOMS

The following symptoms may indicate a need for knee replacement:

- Severe pain that limits participation in everyday activities
- Moderate pain while at rest
- Inflammation and swelling that does not improve with medication
- Knee deformity
- Limited range of motion, knee stiffness
- Limited function
- Limited ability to perform ADL

The following symptoms may indicate a need for hip replacement:

- Hip pain that limits activities such as walking and bending
- Pain that continues even when not in use
- Stiffness
- Limited function
- Limited range of motion
- Limited mobility and strength
- Limited weight bearing
- Limited ability to perform ADL

GENERAL PRECAUTIONS AND CONSIDERATIONS

These general precautions and considerations are taken immediately following joint replacement surgery:

- *Medical status:* Each day, the client must be assessed by the physician, whose orders determine the course of therapy (Daniel & Strickland, 1992).
- *Cardiac/respiratory:* Watch for risks related to anesthesia, including heart attack, stroke, pneumonia, and blood clots. Blood clots can occur in the legs, but usually appear a few days after surgery. These can be dangerous because they may move from the leg to the lungs causing shortness of breath, chest pain, and even death. It is recommended that a patient get out of bed shortly after surgery to decrease the risk of forming blood clots (The Patient Education Institute, 2004).
- *Fall prevention:* Provide supervision when the client is performing tasks. The client needs to follow all precautions to prevent further injury or damage to the repaired or replaced joint (Bear-Lehman, 2002).
- *Skin integrity:* Watch for signs of skin breakdown, especially if the client is bed-bound for long periods. Frequent weight shifts will prevent bedsores. Follow wound care protocol for incisions (Daniel & Strickland, 1992).
- *Muscle stiffness:* Range of motion frequently is limited because of periods of immobility. PROM/AROM will

minimize the stiffness and increase range in the muscles (Bear-Lehman, 2002).
- *Safety concerns:* The client needs to be safe within his or her environment. Frequently, these clients need assistance when maneuvering in the environment (Bear-Lehman, 2002).

PRECAUTIONS

Always consider incision management and weight-bearing status for all orthopedic conditions of the lower extremity as prescribed by the physician's order.

Knee precautions for the first six to eight weeks after surgery include the following (AAOS, 2006b):

- Follow the physician's orders.
- Follow range of motion guidelines.
- Avoid high-impact activities, such as running.
- Avoid excessive activity or weight gain, as this may hasten normal wear.

Hip precautions for the first six to eight weeks after surgery include the following (Dolhi, Leibold, & Schreiber, 2003):

- Follow the physician's orders.
- Avoid extreme hip internal or external rotation.
- Avoid hip adduction.
- No hip flexion beyond 90 degrees.
- No crossing legs, knees, or ankles
- No lying or rolling on the affected side.

Long-term precautions for joint replacement surgeries include the following (Huddleston, 2005):

- Prophylactic antibiotic use prior to dental work or other medical procedures or surgeries.
- Being cautious of infection. After a joint replacement, if an individual gets an infection in the body, it can travel through the bloodstream to the replaced joint. This can eventually lead to a systemic infection.

POSTSURGICAL MEDICAL INTERVENTIONS

Following are typical postsurgical medical interventions for knee and hip replacements (Fagerson, 1998; Paul & Orchanian, 2003; WebMD, 2006):

- Surgery to repair, replace, or remove the joint. The surgeon removes the diseased tissue and cartilage from the joint and replaces the removed parts with new, artificial parts
- Pain medications for pain management
- Antibiotics to prevent infection
- Anticoagulants to prevent blood clots

◆ Catheter for urination
◆ Compression stockings or a compression pump to maintain circulation
◆ Impatient and outpatient rehabilitation

TYPICAL OT EVALUATIONS

Following are typical occupational therapy evaluations for knee and hip replacements (Paul & Orchanian, 2003):

Comprehensive Assessments

◆ Functional Independence Measure (FIM)
◆ Assessment of Motor and Process Skills (AMPS)
◆ Barthel Index
◆ Katz ADL
◆ Berg Balance Test

Quality of Life or Life Satisfaction Assessments

◆ Canadian Occupational Performance Measure (COPM)
◆ Role/interest Checklist
◆ Short Form-36 Health Survey (SF-36)
◆ Worker Role Inventory

Psychosocial Assessments

◆ Peiers-Harris Coping Inventory
◆ Geriatric Depression Scale

Other Assessments

◆ Manual muscle testing
◆ Range-of-motion testing using a goniometer
◆ Pain scales
◆ Home assessment

TYPICAL OT INTERVENTION

◆ The primary goal is to restore functional status to the client (Bear-Lehman, 2002).
◆ When the client is cleared medically, the therapist needs to conduct a careful analysis of functional activities (Bear-Lehman, 2002).
◆ Follow protocols for wound care (Dolhi et al., 2003). Avoid soaking the wound in water until the incision has thoroughly sealed and dried (AAOS, 2006a, 2006b).
◆ In treatment, consider weight-bearing status and precautions (Bear-Lehman, 2002).

OT INTERVENTIONS

◆ ADLs
◆ Energy conservation techniques
◆ Strengthening exercises
◆ Pain management
◆ Assistive technology
◆ Adapt environment
◆ Adaptive equipment
◆ IADL
◆ Safety, hip and other precautions, and fall prevention
◆ Patient and family education
◆ Home planning, including installing grab bars in showers, handrails in stairways, a toilet seat riser, and a shower bench; removing loose carpets; and preparing a temporary living space on the ground floor if possible

OT AND EVIDENCE

Novalis, Messenger, and Morris (2000) examined critical pathways regarding hip injuries. The researchers obtained eight critical pathways from various rehabilitation facilities. The pathways included functional transfers, adaptive equipment, and length of patient stay. Benchmarks differed depending on the facility. It was found that the array of occupational therapy benchmarks suggests a broad scope for the role of occupational therapists in enhancing clients' functional outcomes (Novalis et al., 2000).

Coudeyre and colleagues (2007) found that a preoperative rehabilitation program consisting of education and preparation was effective in contributing to a decrease in length of hospital stay following total hip and knee replacements. It is suggested that the program consist of a multidisciplinary approach of at least physical therapy, education, and occupational therapy home visits. Crowe and Henderson (2003) discovered similar results with their preoperative, individually tailored rehabilitation program with an interdisciplinary approach that helped to reduce average length of stay following surgery.

CAREGIVER ISSUES

Hip and knee replacements engender the following issues among family members and caregivers (Merck, 2005):

◆ The patient is vulnerable to secondary complications due to surgery.
◆ Swelling, pressure sores, stiffness, and functional changes affect the patient.
◆ Patients often are reliant on caregivers for assistance with ADL and IADL.

HIV/AIDS

Alyssa Wells Arnold and Kate-Lyn Stone

DIAGNOSIS

Acquired immunodeficiency syndrome (AIDS) is caused by the human immunodeficiency virus (HIV) (National Institutes of Health, 2005). The diagnosis of HIV is determined by testing blood for the presence of antibodies (disease-fighting proteins) to HIV by using two different types of antibody tests: ELISA and Western blot. HIV antibodies generally do not reach noticeable levels in the blood for one to three months following infection (NIH, 2005). HIV progressively destroys the body's ability to fight infections and certain cancers by damaging and killing the T helper cells (T4 cells) that are responsible for fighting diseases in the body's immune system. Individuals with a T4 level count below 200 are diagnosed with an AIDS-defining opportunistic infection (Copperman, Forwell, & Hugos, 2002).

PREVALENCE

The Centers for Disease Control and Prevention (2005) estimates the prevalence of HIV/AIDS in the United States at the end of 2003 to be 1,039,000–1,185,000. Of these, approximately 25% of HIV-positive individuals remain unaware of their HIV infection (Glynn & Rhodes, 2005). The CDC has estimated that approximately 40,000 people in the United States become infected with HIV each year. HIV can affect both males and females; however, in 2004, almost three quarters of HIV/AIDS diagnoses were for male adolescents and adults. Females make up 27% of new HIV diagnoses (CDC, 2005). HIV can affect all ethnicities; however, in 2004, half the people in the United States who were diagnosed with HIV/AIDS were African Americans. Caucasians make up 30%, Hispanics 18%, and Asian/Pacific Islander and Native American/Alaskan Native 2% of the HIV/AIDS population (CDC, 2005).

TYPICAL COURSE AND SYMPTOMS

According to NIH (2005), individuals begin to present with flulike symptoms within one to two months after exposure to HIV/AIDS. During this period, people are very infectious, and HIV is present in large quantities in genital fluids. More persistent or severe symptoms might not appear for 10 years or more after HIV first enters the body in adults or within two years in children who are born HIV-positive (NIH, 2005). As the immune system deteri-

orates, the first signs of infection occur in the large lymph nodes. According to the NIH, the most prevalent symptoms prior to the onset of AIDS include the following:

◆ Lack of energy
◆ Weight loss
◆ Frequent fevers and sweats
◆ Persistent or frequent yeast infections (oral or vaginal)
◆ Persistent skin rashes or flaky skin
◆ Pelvic inflammatory disease in women that does not respond to treatment
◆ Short-term memory loss

According to the NIH (2005), symptoms related to the onset of opportunistic illness include the following:

◆ Coughing and shortness of breath
◆ Seizures and lack of coordination
◆ Difficult or painful swallowing
◆ Mental symptoms such as confusion and forgetfulness
◆ Severe and persistent diarrhea, nausea, abdominal cramps, and vomiting
◆ Vision loss
◆ Weight loss and extreme fatigue
◆ Severe headaches
◆ Coma

CAUSE AND ETIOLOGY

HIV is most commonly transmitted through sexual contact. HIV can also be transmitted through the use of contaminated needles or blood transfusions and prenatally from mother to fetus (NIH, 2005).

AFFILIATED PROBLEMS

Depression is very common among individuals with HIV/AIDS and should be considered in the treatment plan (Copperman et al., 2002). HIV is also associated with many neurological complications, such as cognitive and motor changes (Copperman, 2003), which can affect an individual's ability to complete activities of daily living. Alcohol use increases the risk of developing some infections that can occur as complications of AIDS. Tuberculosis, pneumonia caused by *Streptococcus pneumoniae,* and hepatitis C are three infections that are associated with both alcohol and AIDS. Alcohol may also exacerbate damage to the brain caused by AIDS (National Institute on Alcohol Abuse and Alcoholism, 2002).

INTERVENTIONS

Medications

Health care providers must use a combination of medications to effectively suppress HIV. When the multiple drugs (three or more) are used in combination, this type of treatment is referred to as highly active antiretroviral therapy (HAART). HAART is the most common form of treatment for individuals with HIV or AIDS. HAART is not a cure for AIDS; however, it has greatly improved the health of many people with AIDS, and it reduces the amount of virus circulating in the blood to nearly undetectable levels (NIH, 2005).

Psychoeducation

Teaching individuals with HIV/AIDS and their families about the disease and how to prevent transmission is extremely important. This includes avoiding behaviors that put a person at risk of infection, such as sharing needles and having unprotected sex (NIH, 2005).

OT EVALUATIONS

Basic and Instrumental Activity of Daily Living Skills

- Kohlman Evaluation of Living Skills (KELS)
- Assessment of Motor and Process Skills (AMPS)
- Functional Independence Measure (FIM)
- Klein-Bell Activities of Daily Living Scale (Klein-Bell)
- Satisfaction With Performance Scaled Questionnaire (SPSQ)

Psychosocial Skills

- Mini-Mental State (MMSE)

Self-Perception

- The Canadian Occupational Performance Measure (COPM)
- The Role Checklist

Somatic Sensory Evaluations

- Primary somatic system
  1. Light touch
  2. Pain
  3. Temperature
- Discriminative somatic system
  1. Tactile localization
  2. Two-point discrimination
  3. Stereognosis
  4. Proprioception
  5. Kinesthesia

OT INTERVENTIONS

- ADL
- Energy conservation techniques
- Strengthening exercises
- Assistive technology
- IADL
- Patient and family education
- Dietary concerns regarding weight management
- Medication management, including scheduling
- Prevention education
- Group therapy
- Coping

OT AND THE EVIDENCE

Group therapy can be beneficial for individuals with HIV/AIDS. Group therapy has been applied to concepts such as symptom management, self-management and coping skills, psychoeducational support, and cognitive behavioral psychotherapy (Chiou et al., 2004; Inouye, Flannelly, & Flannelly, 2001; Nokes, Chew, & Altman 2003; Rousaud et al., 2007). Nokes, Chew, and Altman (2003) found that group therapy enables individuals with HIV/AIDS to develop connections with other individuals who are coping with the same illness.

Exercise is also a key management strategy to address impairments, limitations, and restrictions in individuals with HIV/AIDS. O'Brien, Nixon, Glazier, and Tynan (2004) found progressive resistive exercise to have several benefits, including increases in body weight and composition, improvements in cardiopulmonary fitness, and improvements in psychological status. Constant or interval aerobic exercise or a combination of aerobic exercise and progressive resistive exercise has been found to lead to significant reductions in depression and improvements in cardiopulmonary fitness (Nixon, O'Brien, Glazier, & Tynan, 2007). Overall, exercise as an intervention strategy appears to be safe and beneficial for individuals with HIV/AIDS.

JUVENILE RHEUMATOID ARTHRITIS

Kate-Lyn Stone

The information that is presented in this resource sheet is specific to juvenile rheumatoid arthritis (JRA). For general information on rheumatoid arthritis and additional information regarding JRA, please refer to the resource sheet for rheumatoid arthritis.

DESCRIPTION

Juvenile rheumatoid arthritis (JRA) is the most common type of arthritis in children. JRA causes joint stiffness or inflammation in children aged 16 years old or younger. According to the definition of JRA provided by the National Institute of Arthritis and Musculoskeletal and Skin Diseases (2001), the joint inflammation and stiffness that lead to a diagnosis of JRA last for at least six weeks. There are three types of JRA: pauciartricular (four or fewer joints involved), polyarticular (five or more joints involved), and systemic onset (at least one joint involved as well as inflammation in internal organs). JRA has no known cause or cure (Arthritis Foundation, 2007). In terms of etiology, some researchers are considering a two-step process as a cause. The researchers speculate that something in the child's genetics leads to the tendency to develop JRA, and an environmental factor triggers the JRA to emerge (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2001).

INCIDENCE AND PREVALENCE

- Approximately 300,000 children in the United States have some form of arthritis (Nemours Foundation, 2005).
- The most prevalent form of arthritis in children is JRA, which affects approximately 50,000 children in the United States (Nemours Foundation, 2005).

SIGNS

The four most common symptoms of JRA are as follows (Arthritis Foundation, 2007):

- Joint inflammation
- Joint contracture
- Joint damage
- Alteration/change in growth most evident by impaired mandibular growth resulting in altered morphology and position of the facial skeleton

Other signs of JRA can include the following:

- Stiffness, especially after rest or decreased activity level (also called gelling)
- Weakness in muscles surrounding the involved joints
- Skin erythema and rash

Symptoms include the following:

◆ Pain
◆ Fatigue

An important fact to remember about signs and symptoms is that they are different for each child and can vary from day to day in the same child.

TYPES OF JRA

Pauciartricular JRA

About half of all children with JRA have the pauciartricular type. The literal meaning of pauciartricular is "few joints." Knees, ankles, and elbows are the most commonly involved joints in this type of JRA. Rather than being a symmetrical arthritis like adult RA, pauciartricular JRA generally affects a joint on only one side of the body (Arthritis Foundation, 2007).

Polyartricular JRA

About 30% of children with JRA have this type (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2001). Girls are more commonly affected than boys by polyartricular (meaning "many joints") JRA. Generally, the small joints of the fingers and hands are affected, but JRA can also affect weight-bearing joints such as the ankles, knees, and hips. The neck and jaw can also be affected. Polyartricular JRA is a symmetrical arthritis, meaning that joints on both sides of the body are involved. Signs of JRA can include fever; a positive blood test for rheumatoid factor; nodules on points of the body that receive pressure from chairs, shoes, or other objects; and anemia. Children with polyartricular JRA are at risk for developing damage to joints, which can influence how they grow (Arthritis Foundation, 2007).

Systemic Onset JRA

Systemic onset JRA is the least common form of JRA, only 20% of all children with JRA being affected (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2001). Boys and girls have equal chances of developing this form of JRA, which is a systemic illness that can affect the child's entire body. Signs of systemic onset JRA include high fevers; rash; arthritis (joint pain and inflammation); inflammation of internal organs; anemia; high white blood cell and platelet counts; and enlarged lymph nodes, liver, or spleen. The disease seems to disappear about one year after onset for about 50% of children with systemic onset JRA (Arthritis Foundation, 2007).

MULTIPLE SCLEROSIS

Jennifer Keller and Kate-Lyn Stone

Multiple sclerosis (MS) is a progressive neurological condition that is characterized by patches of demyelination of nerves in areas of the brain and the spinal cord, which result in distorted or interrupted transmission of nerve impulses to and from the brain (Beers & Berkow, 1999). MS is considered to be an autoimmune disease. The body's own defense system attacks the myelin sheath that surrounds and protects the nerve fibers of the CNS. The sites where myelin is lost appear as hardened sclerotic (scarred) areas in the CNS and cause a variety of physical and neurological symptoms (Reed, 2001).

PREVALENCE/INCIDENCE

Approximately 400,000 Americans have MS, and every week, about 200 people are diagnosed. Worldwide, MS may affect 2.5 million individuals. Most people with MS are diagnosed between the ages of 20 and 50 years. It affects twice as many women as men.

COURSE

People with MS can expect one of four clinical courses of disease, each of which might be mild, moderate, or severe (National Multiple Sclerosis Society, 2004).

Relapsing-Remitting

In the relapsing-remitting course, the person experiences clearly defined exacerbations (relapses) and episodes of acute worsening of neurological function that are followed by partial or complete recovery periods (remissions) free of disease progression. This is the most common form of MS at time of initial diagnosis (~85%).

Primary-Progressive

In the primary-progressive course, the person experiences a slow but nearly continuous worsening of the disease from the onset, with no distinct relapses or remissions. However, there are variations in rates of progression over time, occasional plateaus, and temporary minor improvements. This course is relatively rare (~10%).

Secondary-Progressive

In the secondary-progressive course, the person experiences an initial period of relapsing-remitting disease followed by a steadily worsening, unpredictable disease course. About 50% of people with relapsing-remitting MS developed this form of the disease within 10 years of their initial diagnosis. However, there is preliminary research to suggest that disease-modifying treatments may significantly delay this progression.

Progressive-Relapsing

In the progressive-relapsing course, the person experiences a steadily worsening disease from the onset but also has clear acute relapses, with or without recovery. In contrast to relapsing-remitting MS, the periods between relapses are characterized by continuing disease progression. This course is relatively rare (~5%).

PROGNOSIS

According to Dirette (2007), approximately 60% of individuals with MS can continue to be fully functional for up to 10 years following their first exacerbation. In addition to this, approximately 30% of individuals with MS continue to be able to function 30 years after their first exacerbation. The fact that an individual is diagnosed with MS does not mean that his or her life expectancy is significantly decreased. There are some individuals, however, who do become quite disabled secondary to MS, and some even die prematurely from infections or complications (Dirette, 2007).

SYMPTOMS

Primary Signs as a Result of Demyelination of the CNS

◆ Muscle stiffness (spasticity) or weakness
◆ Tremulousness in extremities
◆ Paresthesias, numbness, and blunting of sensation (e.g., reduced pain or temperature sense, disturbances of vibratory or position sense)

- Partial or complete paralysis of extremities
- Visual deficits (vision loss, blurred or double vision)
- Extended periods of fatigue
- Interruptions in sexual functioning
- Problems with memory, concentration, information processing, or rapid problem-solving skills
- Visual-spatial deficits
- Difficulty articulating speech
- Fluctuation in mood/depression
- Emotional lability

Secondary Signs

- Pain
- Staggering gait and/or loss of balance
- Poor coordination
- Loss of bladder or bowel control; frequent urinary tract infections
- Anxiety and sleep disturbances
- Contractures and pressure sores
- Decreased ADL skills

Tertiary Signs

- Shift in roles, changing responsibilities
- Social isolation
- Divorce
- Loss of independence
- Stigma of disability (Shapiro, 2003)

INTERDISCIPLINARY TREATMENT

Medications

- Corticosteroids are used to shorten acute attacks, reduce inflammation, and ease symptoms.
- Disease-modifying treatment with injections of the protein interferon-beta reduces the frequency of relapses in MS and might help to delay eventual disability. These medications have shown effectiveness in modifying the natural course of relapsing MS by altering the rate and/or extent of disease progression. Medication management with these "disease modifiers" is recommended as early as possible for individuals with a relapsing course.
- More potent medications are being developed that are effective in slowing down MS that is rapidly worsening or becoming progressive (Beers & Berkow, 1999).

Rehabilitation

- *Physical therapy:* Physical therapy focuses primarily on mobility and the use of mobility aids, spasticity of the muscles, and physical fitness. Personalized exercise programs may help people recover muscle control and

strength after an exacerbation. There is significant evidence associating aerobic exercise with improved quality of life, mobility, endurance, and reduction in fatigue (Mostert & Kesselring, 2002). Hydrotherapy is a popular form of aerobic exercise that addresses the fatigue and weakness experienced by individuals with MS.

- *Occupational therapy:* Occupational therapy focuses on strength, coordination, and fine motor control of the upper extremities. Fatigue and pain management techniques have been well supported as a means to improve occupational performance and satisfaction. Psychosocial intervention is embedded in the treatment plan to address cognitive, emotional, and self-concept issues.
- *Speech therapy:* In progressive forms of MS, problems with speech or swallowing due to muscle weakness or a lack of coordination may need to be addressed.
- *Psychosocial support/counseling:* Individual or group therapy can help individuals with MS and their families to deal with depression, anxiety, and the unpredictability of the disease process. Evidence suggests that a personalized psychosocial rehabilitation program encourages active participation, increased autonomy, and improved quality of life (Ferriani et al., 2002).

OCCUPATIONAL THERAPY EVALUATIONS

Comprehensive Evaluations

- The Functional Assessment of Multiple Sclerosis (FAMS)
- Functional Independence Measure (FIM)
- Multiple Sclerosis Impact Scale (MSIS-29)

ADL Evaluations

- Assessment of Motor and Process Skills (AMPS)
- Barthel Index (BI)

Fatigue Evaluations

- Fatigue Severity Scale (FSS)
- Modified Fatigue Impact Scale (MFIS)

Psychosocial Evaluations

- Beck Depression Inventory (BDI)
- Self-Perceived Burden Scale (SPBS)
- Ways of Coping Checklist (WCC)

Quality of Life/Life Satisfaction Evaluations

- Canadian Occupational Therapy Performance Measure (COPM)
- Health Status Questionnaire (SF-36)

- Multiple Sclerosis QOL Inventory (MSQLI)
- Multiple Sclerosis Quality of Life-54 (MSQOL-54)
- Occupational Performance History Interview (OPHI)

Other Areas to Address

- Balance and coordination
- Caregiver adjustment
- Cognition and memory
- Coping skills
- Daily living skills
- Driving skills
- Environmental barriers
- Fine motor skills
- Leisure interests
- Locus of control
- Muscle strength and spasticity
- Pain and sensation
- Self-concept
- Sexuality
- Vision and perception

OT INTERVENTIONS

- ADL training
- Assistive technology
- Cognitive retraining
- Employment modifications
- Energy conservation
- Environmental modifications
- Home management
- Pain treatment
- ROM/endurance/strengthening for functional activity
- Safety awareness
- Splinting
- Stress management

OT AND THE EVIDENCE

Meta-analysis suggests that occupational therapy–related treatments are effective in treating the deficits associated with MS, particularly for outcomes in the capacity and ability (e.g., muscle strength, ROM, mood) and task and activity (e.g., dressing, bathing, ambulation) levels of performance. The effect sizes for the capacities and abilities outcomes were generally large for studies that examined a specific intervention method, such as exercise, fatigue management, cooling, and transcutaneous electrical nerve stimulator application for pain. A smaller effect size has been shown for emotional and cognitive outcomes, such as stress management, skills training in socialization, and attention training (Baker & Tickle-Degnen, 2001). Alternative therapies including acupuncture, massage,

yoga, meditation, and dietary modifications have shown encouraging results as part of the treatment program for individuals with MS (MS Australia, 2001).

Fatigue is one of the most common targets of OT intervention. It impedes an affected person's ability to fully engage in desired occupational performance and roles. There is significant evidence to support the use of energy conservation education within both community-based and inpatient rehabilitation settings to reduce the impact of fatigue among people with MS and possible positive change associated with peer support (Vanage, Gilbertson, & Mathiowetz, 2003). Energy conservation courses, including education about rest and delegation of tasks to others, have been found to be effective interventions (Holberg & Finlayson, 2007; Matuska, Mathiowetz, & Finlayson, 2007; Vanage et al., 2006).

Coping involves cognitive and behavioral efforts to master, reduce or tolerate an external or internal demand created by a stressful situation. Certain types of coping strategies have been shown to be associated with better or worse adjustment in MS. Many studies in the chronic illness literature have demonstrated that high levels of increasing feelings of self-efficacy, improving quality of life, and lower levels of depression are associated with emotion-focused coping. In contrast, problem-focused coping has been shown to be associated with lower levels of depression and higher levels of adjustment. OT intervention should involve teaching successful coping and integrating it into daily life (Artnett, Higginson, Voss, Randolph, & Grandey, 2002).

CAREGIVER CONCERNS

MS affects people in their most productive years: young adults readying themselves to leave home in pursuit of academic, vocational, or social goals; men and women starting their careers and families of their own; and those in middle age who are enjoying their productive years and planning for retirement. In each of these age groups, the diagnosis of MS has a significant impact on the individual and the family members and/or loved ones in his or her life. Challenges to family coping include the following:

- Individual needs and coping styles
- Disruption in family rhythm
- Disruption in family communication
- Uncertainty and anxiety
- Adaptation and adjustment
- Impact of cognitive changes

Approximately 100,000 people who have MS require help with daily activities or personal care. They receive most of their help from spouses, who typically have major additional responsibilities, including employment and

child care. Caregiver burnout has many different causes, including physical strain and emotional stress. Some ways to address these issues include the following:

- Effective communication
- Relieving pressures of caregiving
- Planning and decision making for the future (Kalb, 1998)

MYOCARDIAL INFARCTION

Kate-Lyn Stone

DIAGNOSIS

Myocardial infarction (MI) is also referred to as *heart attack, acute MI, acute coronary syndrome, coronary thrombosis,* or *coronary occlusion* (National Heart Lung and Blood Institute, 2007). It occurs when the heart is starved of oxygen because of a lack of blood supply. This causes the heart muscle to die or to become permanently damaged (Weinrauch, 2007). The most common site of a myocardial infarction is the left ventricle (American Heart Association, 2007).

INCIDENCE AND PREVALENCE

◆ Approximately one of every five deaths in the United States is caused by a heart attack (Weinrauch, 2007).
◆ In the United States, about 1.1 million people have a heart attack each year, and about 50% of these people die (National Heart Lung and Blood Institute, 2007).

ETIOLOGY

The coronary arteries are the arteries that are responsible for bringing blood, and thus oxygen, to the heart. When a coronary artery becomes blocked by a blood clot, blood cannot get to the heart. This starves the heart of oxygen, and a myocardial infarction is generally the result (Weinrauch, 2007). The most common underlying cause of myocardial infarction is atherosclerotic heart disease (American Heart Association, 2007).

Risk factors for myocardial infarction include the following (Weinrauch, 2007):

◆ Hereditary factors
◆ Gender, males being more likely to suffer a heart attack
◆ Diabetes
◆ Aging
◆ High blood pressure
◆ Smoking
◆ Poor eating habits
◆ High LDL cholesterol levels
◆ Abnormally high levels of homocysteine (an amino acid), C-reactive protein (related to inflammation), and fibrinogen (involved in blood clotting)
◆ In some cases, extremely high levels of stress can lead to a heart attack

SIGNS AND SYMPTOMS

Symptoms of a myocardial infarction include the following (Weinrauch, 2007):

◆ Chest pain, usually lasting longer than 20 minutes; can be mild or severe and can feel like heavy pressure, squeezing, or bad indigestion
◆ Shortness of breath
◆ Nausea
◆ Anxiety

◆ Dizziness
◆ Palpations in the heart

   Signs of a myocardial infarction include the following:

◆ Sweating
◆ Fainting
◆ Cough

SEQUENCE OF CARE

A myocardial infarction is a medical emergency that can result in death if health care is not sought immediately once symptoms begin to appear. Individuals have the best prognosis if they begin to receive treatment within the first hour after symptoms occur (National Heart Lung and Blood Institute, 2007). On admission, the physician will conduct a physical examination, including examination of the client's heart and lungs. Pulse and blood pressure may also be monitored. Tests that look specifically at the heart are then administered. Such tests include coronary angiography, CT scan, echocardiography, electrocardiogram, MRI, and nuclear ventriculography. Blood tests may also be used to look for substances that are indicative of heart tissue damage (Weinrauch, 2007).

   If diagnosed with a heart attack, the individual will need to stay in the hospital. Oxygen will be administered, regardless of whether levels are normal or abnormal, to decrease cardiac load. Some clients will receive thrombolytic therapy, which involves giving the clients blood thinners within the first 12 hours of the onset of chest pain. Thrombolytic therapy is not appropriate for all clients, especially women who are pregnant, people who have had a stroke or head injury in the past three months, people with high blood pressure, or people with a history of using blood thinners. Angioplasty, a surgery to open blocked arteries, may be used instead of thrombolytic therapy. Other medicines that are used for myocardial infarction include nitroglycerin (to decrease chest pain), antiplatelet medicines (to prevent clot formations), beta-blockers (to reduce strain on the heart), and ACE inhibitors (to prevent heat failure). In some cases, the patient might need emergency coronary artery bypass surgery (Weinrauch, 2007).

PREVENTION

There are several ways in which people can decrease their chances of having a myocardial infarction, or heart attack. These include the following (Weinrauch, 2007):

◆ Maintain good blood pressure and cholesterol levels.
◆ Do not smoke.
◆ Eat a well-balanced, low-fat diet.
◆ Exercise consistently.
◆ If overweight, lose weight safely, but consult your health care provider before doing so.
◆ Use aspirin therapy, but consult your physician before beginning this on your own.

ROLE OF OT

See the resource list sheet in cardiac conditions.

RESOURCES

Please refer to the resource sheet on cardiac conditions for further information on resources for myocardial infarction.

OPPOSITIONAL DEFIANT DISORDER

Karen Marticello

Oppositional defiant disorder (ODD) is a recurrent pattern of negativistic, defiant, disobedient, and hostile behavior toward authority figures that persists for at least six months (American Psychiatric Association, 2000).

PREVALENCE

The prevalence rate of ODD is 2–16%. After puberty, this condition is as prevalent in girls as in boys (Prairienet Community Resources, 2005).

ETIOLOGY AND RISK FACTORS

Biological factors have been supported by the demonstration of genetic correlations, atypical frontal lobe activation patterns, and underarousal of the physiological factors, such as lower heart rate. Child functional factors including temperament and intensity of reactions to negative stimuli may contribute to ODD. Psychosocial factors include family instability, economic stress, parental mental illness, harsh punitive behaviors, inconsistent parenting practices, multiple moves, and divorce (Burke, Loeber, & Birmaher, 2002).

COURSE AND SYMPTOMS

The course of ODD is different in different people. It is a disorder of childhood and adolescence that usually begins by age 8, if not earlier. Symptoms include the following:

◆ Losing one's temper
◆ Arguing with adults
◆ Actively defying requests
◆ Refusing to follow rules
◆ Deliberately annoying other people
◆ Blaming others for one's mistakes
◆ Being touchy, easily angered or annoyed, resentful, spiteful, or vindictive (American Psychiatric Association, 2000).

Symptoms may change. Younger children are likely to engage in defiant behaviors, and older children are likely to engage in covert behavior such as stealing. In some children, ODD evolves into a conduct disorder or mood disorder. Later in life, this condition may evolve into antisocial personality disorder.

COMORBID CONDITIONS

Diagnosis is complicated by relatively high rates of co-morbid disruptive behavior disorders. Some symptoms of attention-deficit/hyperactivity (ADHD) disorder and conduct disorder overlap. In some children, ODD may be the developmental precursor for conduct disorder. Comorbidity of ODD with ADHD has been reported to occur in 50–65% of children with ODD. ODD commonly occurs with anxiety and depressive disorders, as well as with learning disabilities and academic difficulties (Greene et al., 2002). ODD is often misdiagnosed in children with a history of trauma whose behaviors are related to neural disorders, that is, sensory-processing disorders (B. Atchison, personal communication, July 28, 2007).

PRECAUTIONS

In problem situations, children with ODD are more likely to react with aggressive physical actions than verbal ones. Professionals should be aware of their own safety and the safety of those around them (eMedicine, 2005).

INTERDISCIPLINARY TREATMENT

Multidimensional Intervention Foster Care

A broad based-intervention that targets many family and extrafamilial factors while the child is on out-of-home placement. This intervention involves placing a child or adolescent in the home of a foster parent who has been trained in behavior management skills. The foster parent establishes an individualized plan to reinforce desired self-management, academic, and social behaviors (Woolfenden, Williams, & Peat, 2005).

Pharmacotherapy

Medication treatment alone appears to be an ineffective method of treating ODD. However, it can be effective for treating some symptoms of comorbid disorders.

OT INTERVENTION

Intervention for ODD is complex and challenging. Children with ODD are frequently uncooperative and experience feelings of fear and mistrust toward authority. Intervention involves a multimodal, psychosocial approach that includes parent training, social skills training, and group therapy.

Interventions with the Child

Social Skills Training, Problem Solving, and Anger Management

Children with ODD and conduct problems show cognitive and behavioral deficits with peers. These children often have limited social and conflict resolution skills, loneliness and negative attributions, inability to empathize or understand others' perspectives, and limited use of feeling language.

Cognitive behavioral intervention activities may include the following:

- Videotape modeling and role-plays to provide opportunities to reenact conflict situations using coping skills and acceptable solutions.
- Read and discuss stories depicting children solving social problems and then sharing feelings about the stories.
- Strategies to strengthen motivation, hold attention, and reinforce key concepts and newly acquired skills (Webster-Stratton, Reid, & Hammond, 2001).

Child-Centered Intervention

The child initiates activities while the therapist creates a positive environment. This intervention is useful for building rapport.

Interest Groups

Interest groups assist the child in developing interests that can be used during frustrating times or for practicing social skills.

Socratic Questioning

This intervention involves asking questions to guide a child through a problem situation, such as "Why did you choose to do that?" (Garlikov, 2003).

Behavior Management

Use of behavior-recording charts, a time-out process, and alternating liked and disliked activities.

Interventions with Parents

Behavioral Parent Training

This intervention is based on the assumption that the child's behavior is related to past and current interactions with significant others and that the behavior of these significant people must be changed to change the child's behavior (Nixon, 2002).

Intervention strategies include the following:

- Teaching parents to attend to and praise their child's appropriate behaviors through the use of techniques such as providing simple and clear commands and using time-outs.
- Labeled praise involves describing enthusiastically what the child is doing whenever possible to inform the child of what is clearly appropriate behavior.
- Role-playing of techniques to generalize strategies to different environments (e.g., going to the grocery store or visiting friends).

Stress Management

- Coping skills training provides resources for parent support groups and instruction in time management instruction, cognitive restructuring, and social skills and assertive training.
- Other stress management techniques include exercise, deep breathing, meditation, verbalization, and exploration of leisure interests and participation (Mindtools, 2005).

Interventions in the Environment

A sensory integration approach adapts aspects of the environment to promote self-regulation and attention (i.e., limit distractions) and to decrease hyperactivity. This approach also includes developing structure and routines as well as successful transitions within home and school activities.

OT AND THE EVIDENCE

The occupational therapy literature does not contain recent and relevant evidence regarding this topic; therefore, evidence from other peer-reviewed journals is presented here.

Results from a social skills and problem-solving training group indicate that this intervention was successful in producing clinically and statistically significant improvements in child conduct problems (i.e., aggression) and in children's cognitive social problem-solving

strategies after treatment. Parent and teacher reports and independent observations indicated that these changes were produced both at home and in the classroom, suggesting generalized improvements across settings (Webster-Stratton, Reid, & Hammond, 2001).

CAREGIVER CONCERNS

ODD can have a negative effect on the family environment, leading to less cohesion, more conflict, and increased parental stress. However, this relationship is reciprocal, since many parental factors have been identified as risk factors for ODD. Parental mental illness (including substance abuse, depression, and antisocial personality disorder), physical punishment, marital discord and divorce, and socioeconomic status have all been correlated with ODD. Therefore, effective treatment of ODD may include services for the parents such as mental health services, vocational and money management skills training, and education regarding community resources to address these concerns (Burke et al., 2002; eMedicine, 2005).

OSTEOARTHRITIS

Kate-Lyn Stone

Osteoarthritis (OA) is the most common form of arthritis. It is also the oldest form; evidence of the disease has been found in Ice Age skeletons (Arthritis Foundation, 2007). OA can also be referred to as *degenerative joint disease, hypertrophic arthritis,* and *degenerative arthritis.* OA is a chronic condition that is commonly known as "wear-and-tear" arthritis because of the breakdown of the cartilage in the joints. When the cartilage wears away in this fashion, the bones of the joint rub together, causing stiffness and pain. The cause of OA is still unknown, and there is no cure (Arthritis Foundation, 2007).

There are two types of OA: primary and secondary. Primary OA is the "wear-and-tear" arthritis that is generally associated with aging. Secondary OA classifies all osteoarthritis that is not associated with aging. With secondary OA, there is an evident cause such as injury, heredity, or obesity.

INCIDENCE AND PREVALENCE

- Twenty-one million Americans live with OA (Arthritis Foundation, 2007).
- The incidence of OA increases with age; in other words, the older a person is, the more likely he or she is to develop OA.
- Under age 55, men are more likely to get OA than women are. Over age 55, women are more likely to have the condition (Arthritis Foundation, 2007).
- OA is the number one cause of disability in industrialized nations (Medline Plus, 2005).

TYPICAL COURSE OF DISEASE

There are several stages of OA including the following (Arthritis Foundation, 2007):

- The cartilage begins to break down and lose elasticity. It becomes more easily damaged by injury or overuse.
- The bone lying beneath the cartilage begins to change because of the breakdown of the cartilage. The bone may thicken, cysts may form, or bony growths known as spurs may appear at the end of the bone.
- Small pieces of bone or cartilage may detach from the joint and float loosely in the joint space.
- The synovium (the joint lining) becomes inflamed, causing inflammation proteins, known as cytokines, to further damage the already worn cartilage.

The knees, lower back, hips, fingers, and neck are the most common areas of the body to develop OA. The base of the thumb and the big toe can also be affected by OA.

SEQUENCE OF CARE

The primary care physician will begin by taking the individual's medical history and completing a thorough physical examination. During the physical exam, the physician looks for common signs of OA, such as joint swelling or tenderness, decreased range of motion, and joint damage. The physician may choose to have X-rays taken to confirm a diagnosis of OA. Joint aspiration, or draining fluid from the joint to look for crystals, is another tool that is used to rule out other conditions or diseases. Once the diagnosis has been confirmed, the patient may be referred to a rheumatologist, a doctor who specializes in arthritis, depending on the severity of the case.

Goals of a plan to treat OA include decreasing pain, increasing the ability to function on a day-to-day basis, and decreasing the speed at which the disease is progressing. A drug regime may be prescribed to begin combating OA, but ultimately, it is the lifestyle changes that the individual makes that determine how well he or she lives with the condition. Treatment plans may also include exercise, diet

modification for weight control, joint protection, physical therapy, and occupational therapy. Surgery may be considered for severe cases that do not seem to be improving with other interventions (Arthritis Foundation, 2007).

SYMPTOMS

Several or all of the following symptoms may occur for an individual with OA. It is important to remember that each individual is affected by the disease differently, so symptoms will vary. The most common symptoms of OA are as follows:

- Soreness, especially after inactivity or overuse
- Stiffness
- Morning stiffness, which generally goes away within half an hour
- Pain, which is usually caused by the weakening of the muscles surrounding the joint secondary to inactivity
- Pain in the joint that generally increases over the course of the day because of the day's activities
- Irritation
- Grating of the joint
- Decreased ability of the joints to absorb shock
- Limited use of joint
- Limited range of motion
- Decreased coordination, poor posture, and difficulty walking because of pain and stiffness

For more detailed information about symptoms in each area of the body, refer to the Arthritis Foundation's Website (http://www.arthritis.org/).

ETIOLOGY

The cause of OA is unknown. There are, however, several risk factors that are thought to play a role in whether or not an individual develops OA, including age, obesity, genetics, muscle weakness, overuse of the joint, injury, other disease, or forms of arthritis. For more information on how each factor relates to the risk of developing OA, refer to http://www.arthritis.org/. An individual could acquire OA as a result of two or several of these factors combined (Arthritis Foundation, 2007). Knowing and understanding what the risk factors are can help to decrease the chances of developing this chronic condition.

INTERVENTIONS

There are several treatment options that may be beneficial in slowing the progress of OA, decreasing pain, and increasing function. These interventions include the following (Arthritis Foundation. 2007):

- Medications, generally nonsteroidal, anti-inflammatory drugs (NSAIDs)
- Physical therapy
- Occupational therapy
- Chiropractic services
- Surgery
- Glucosamine, an amino sugar, and chondroitin sulfate, part of a protein (both dietary supplements), for pain relief
- Vitamins to help ease some symptoms
- Exercise to reduce pain, increase muscle strength, and improve movement
- Weight control to reduce stress on joints
- Education about self-management for OA, including information about taking breaks, pacing oneself, keeping active, using proper body mechanics, and setting realistic goals

PREVENTION

Primary Prevention: Stop OA Before It Develops

Maintaining a healthy weight reduces the risk of an individual's developing osteoarthritis, especially in the knees. Keeping active in general reduces the risk for obesity, which in turn lessens the stress on joints and keeps them healthy (Sacks & Sniezek, 2003).

Secondary Prevention: Early Diagnosis and Good Management

By diagnosing OA early, an individual can begin to take appropriate medication to positively affect the course of the disease. Medications can also decrease pain (Sacks & Sniezek, 2003).

Tertiary Prevention: Increase Self-Management

Self-management education, weight control, and physical activity all help an individual who has been diagnosed with OA have a better sense of control over his or her life. This improves overall quality of life while one is living with OA (Sacks & Sniezek, 2003).

TYPICAL OT EVALUATION

Comprehensive Assessments

- Functional Independence Measure (FIM)
- Assessment of Motor and Process Skills (AMPS)

Quality of Life/Life Satisfaction Assessments

- Canadian Occupational Performance Measure (COPM)
- Role Interest Checklist

- Short Form-36 Health Survey (SF-36)
- Worker Role Inventory

Psychosocial Assessments

- Geriatric Depression Scale

Other Assessments

- Manual muscle testing
- Range-of-motion testing
- Pain scales
- Home assessment

TYPICAL OT INTERVENTION

Because each individual is affected by OA differently, the occupational therapist should take a top-down approach to ensure focus on each client's unique needs (Mallinson et al., 2005). This means that there is a focus on a broad range of barriers to functioning versus a focus on specific symptoms that are blocking function.

Occupational therapy programs for treating OA generally focus on the following:

- ADL
- Energy conservation techniques
- Strengthening exercises
- Pain management
- Assistive technology
- Adapt environment
- Adaptive equipment
- Patient and family education
- Home planning
- Splinting to support limbs
- Education about self-management, including learning techniques to reduce pain, proper exercise, weight management, and joint protection (National Center for Chronic Disease Prevention and Health Promotion, 2007)

OT AND EVIDENCE

Egan and Brousseau (2007) found splinting to be an effective intervention for decreasing pain and increasing function in individuals with carpometacarpal OA. They did not find one splint to be superior to the other for providing pain relief other than in terms of patient preference. Because of this, the researchers suggest taking a client-centered approach when choosing a splint for a client with OA.

Lorig, Ritter, and Plant (2005) compared the disease-specific Arthritis Self-Management Program (ASMP) with the generalized Chronic Disease Self-Management Program (CDSMP) for individuals with arthritis. They found that the ASMP should be considered as a first choice of self-management programs, since individ-

uals with arthritis at four months showed improvements in conditions. At one year, there was no difference between the ASMP and the CDSMP, suggesting that both programs are effective in improving the quality of life for individuals with arthritis.

Programs

- Arthritis Foundation Self-Help Program (AFSHP)
  This six-week program helps individuals with arthritis learn how to manage their condition on a day-to-day basis. It was developed by Dr. Kate Lorig of Stanford University. Studies done on this intervention report that participants experience a 20% decrease in pain and a 40% decrease in doctors' visits. As of 2007, there were 36 CDC-funded state arthritis programs.
- Chronic Disease Self-Management Program (CDSMP).
  This six-week program teaches self-management education for individuals with chronic diseases or conditions, including arthritis, diabetes, heart disease, and lung disease. This program was created and developed at Stan-

ford University. As of 2007, there were 36 CDC-funded state chronic disease programs.

◆ Arthritis Foundation Exercise Program (AFEP)
This program, developed by the Arthritis Foundation, is a community-based, recreational program that focuses on range of motion exercises, endurance building, stress management, relaxation techniques, and other topics related to health. This program is unique in that it can be tailored to meet each participant's individual needs.

◆ Arthritis Foundation Aquatic Program (AFAP)
This exercise program, developed by the Arthritis Foundation, is an aquatic program that works to increase flexibility, endurance, and range of motion while decreasing pain because there is less impact on the joints in the water environment.

◆ EnhanceFitness
Formerly known as Lifetime Fitness, this program is an evidence-based, community exercise program. It has been proven to increase strength and activity levels in individuals with arthritis.

OSTEOPOROSIS

Stephanie Grant

Osteoporosis is a disease that involves low bone mass and microarchitectural deterioration of bone tissue that leads to bone fragility and increased fracture risk particularly at the hip, spine, and wrist (Osteoporosis, 2005).

INCIDENCE AND PREVALENCE

Osteoporosis is a major public health threat for 44 million Americans, with more than 200 million people affected worldwide (International Osteoporosis Foundation, 2007; National Osteoporosis Foundation, 2007). It is estimated that 50% of women and 20% of men over 50 in the United States will have an osteoporosis related fracture during their lifetime (NOF, 2007). Risk for osteoporosis increases with age but can affect any age group. Osteoporotic fractures are associated with significant morbidity and disability leading to substantial burden on the individual, the person's family, and society (Hallberg, 2004).

DIAGNOSTIC CRITERIA, SIGNS AND SYMPTOMS

Osteoporosis is classified as either primary or secondary. Primary osteoporosis, the most common form of the disease, is the loss of bone mineral density because of altered bone remodeling that occurs within the bone itself and appears to be influenced by total bone accrual at the time of peak bone density and, in women, estrogen decline (IOF, 2007; NOF, 2007). Secondary osteoporosis is bone loss due to another cause outside of the skeletal system, such as medication-induced bone loss (including corticosteroids, anticonvulsants, or cancer therapies), rheumatoid arthritis or malabsorption syndromes (IOF, 2007; NOF, 2007).

In 1994, the World Health Organization published the WHO Diagnostic Criteria for Osteoporosis (World Health Organization Study Group, 1994):

◆ *Normal:* Bone mineral density (BMD) value within 1 standard deviation (S.D.) of the young-adult mean (T-score at or above –1)
◆ *Osteopenia:* BMD value between 1 and 2.5 S.D. below the young-adult mean (T-score between –1 and –2.5)
◆ *Osteoporosis:* BMD value at least 2.5 S.D. below the young adult mean (T-score at or below –2.5)
◆ *Severe osteoporosis:* BMD value at least 2.5 S.D. below the young adult mean and presence of fracture

While these criteria remain an important diagnostic element, research in the field has indicated that the T-score is one of many factors contributing to fracture risk, so a thorough assessment of fracture risk is important in making a diagnosis.

Fracture risk assessment is critical for individuals over the age of 65 and should include a thorough history to determine whether the individual has the following risks: is on medications that cause bone loss, smokes, sustained a fracture after age 50, has a family history of osteoporosis or parental hip fracture. Next, fracture risk assessment should examine risk to fall, low body weight or low body mass index, and inability to stand from a seated position without help or the use of the hands (Black et al., 2001; Kanis et al., 2005).

COURSE AND PROGNOSIS

Osteoporosis is not a disease of aging. In fact, it is a geriatric disease with an adolescent onset. Peak bone mass occurs in early adulthood. Therefore, accrual of bone and prevention of bone loss are essential in childhood and adolescence. This process can be negatively affected by many childhood nutrition and activity habits as well as by diseases such as anorexia nervosa, cancer, and cystic fibrosis (Bachrach, 2001).

The early stage of this disease is typically silent in nature, with few, if any, symptoms. Often, the first symptom of osteoporosis is a fracture. Early diagnosis can lead to a significantly reduced risk for fracture and loss of independence. In later stages, osteoporosis can be associated with or cause loss of height; postural changes, including kyphosis; muscle weakness, pain, particularly at the back; balance impairment; decreased health-related quality of life; and eventual loss of independence (NOF, 2007).

MEDICAL TREATMENT

Medical intervention for osteoporosis is targeted at reducing fracture risk. Increasing bone density and improving bone microarchitecture can be addressed with pharmacotherapy such as antiresorptives or anabolic agents. Antiresorptives assist in preventing additional bone loss and come in the form of bisphosphonates, selective estrogen receptor modulators, calcitonin, and estrogens. The anabolic agent teriparitide assists the body to rebuild bone. All individuals with low bone density should be counseled to take calcium (1,500 mg/day) and vitamin D (800 IU/day). In some cases, individuals may have such low vitamin D levels that they need to have vitamin D injections before beginning a pharmacotherapy regimen (NOF, 2007).

OT EVALUATION

Because osteoporosis affects so many areas of physical functioning, occupational therapists have used many assessment tools with this population.

◆ Canadian Occupational Performance Measure (COPM) (Law et al., 1990)
Semistructured interview. A client-centered outcome measure that examines a client's perceptions with regard to an occupation's importance as well as performance and satisfaction with occupations. This is an effective assessment tool to use with individuals who have severe osteoporosis and related physical symptoms but has been found to have a ceiling effect in individuals with the disease who have few or no symptoms (Edwards, Baptiste, Stratford, & Law, 2007; Randles, Randolph, Schell, & Grant, 2004).
◆ The FRACTURE Index (Black et al., 2001)
Evaluates and predicts an individual's fracture risk at the spine, hip, and other nonvertebral areas over the next five years.
◆ The Mini-Osteoporosis Quality of Life Questionnaire (Mini-OQLQ) (Ioannidis, Adachi, & Guyatt, 1999)

Self-administered and quickly completed. Examines five domains: symptoms, physical function, activities of daily living, emotional function, and leisure.

◆ The Bone Safety Evaluation (Recknor et al., 2005) A comprehensive assessment and an osteoporosis database registry. Qualitatively and quantitatively evaluates a client's risk for fracture. A physical functional performance measure that analyzes spinal compression forces, balance, strength, flexibility, and physical symptoms with valued activities and quality of life. Calculates musculoskeletal functioning with health-related quality of life.

Occupational therapists who work with children can help to identify children who are at risk for bone loss and design intervention strategies to optimize nutrition and weight-bearing activity.

OT INTERVENTION

Occupational therapy intervention in this population focuses on rehabilitating individuals who have sustained a fracture and on fracture risk reduction for these clients as well as for individuals who are not currently coping with a new fracture. Because rehabilitation of specific fractures is beyond the scope of this resource sheet, the reader is referred to the Resources section below for where to locate this information. Occupational therapy should aim to maximize an individual's occupational performance as it relates to the person's current elevated fracture risk state. The occupational therapist should determine the activities that both are highly valued by the client and pose a risk for fracture.

◆ *Education:* Education on the osteoporosis condition to build awareness is important because this disease begins silently (Munch & Shapiro, 2006).
◆ *Safe movement:* The occupational therapist should focus on occupation-specific instruction in safe movement patterns to reduce spinal compression forces during daily activities (Meeks, 1999; NOF, 2007). Clients can learn about the safety precautions associated with osteoporosis by reading a fact sheet but are often unsure how to apply these precautions to daily activity without the help of an occupational therapist (Randles et al., 2004).
◆ *Quality of life:* When the osteoporosis condition is more severe, a client is likely to present with back pain, weakness, unsteadiness, dizziness, and fatigue (Ioannidis, Gordon, & Adachi, 2001).

The occupational therapist should address these conditions in light of their influence on the client's quality of life. Offering compensatory strategies, adaptive equipment, and alternative methods for accomplishing daily activity can significantly improve quality of life and motivate a client to engage in treatment.

◆ *Fall risk and balance:* Fall risk should be addressed and should include interventions for both intrinsic and extrinsic factors. Because fall is a leading cause of fracture, clients who present with balance impairment should be treated for the underlying cause, such as vestibular dysfunction, decreased proximal muscle strength, or postural changes (Meeks, 1999; NOF, 2007).
◆ *Posture:* Clients can benefit from postural correction techniques to minimize kyphosis and improve lordotic curve. Techniques include interventions such as weighted kyphosis bracing, visual feedback with mirrors, and use of exercise balls or air cushions (Meeks, 1999; NOF, 2007; Pfeifer et al., 2004).
◆ *Strength and flexibility:* Paraspinal, scapular, and lower body strengthening exercises as well as flexibility programs can help to reduce back pain and the risk of vertebral fracture (Meeks, 1999; NOF, 2007; Sinaki et al., 2002).
◆ *Function and occupational performance:* Adults with osteoporosis may benefit from occupational therapy for remediation or modification of basic or IADL because of disease-related physical impairments. (Hagsten, Svensson, & Gardulf, 2006). Alternatively, in the early stages of the disease, a customized blend of exercise and occupation paired with disease awareness education is an effective method (Randles et al., 2004). The unique approach that occupational therapists have with this population is to both improve physical functional performance and modify performance for fracture risk reduction as it relates to a client's occupations.

OT AND THE EVIDENCE

Although occupational therapists have treated clients with this disease concurrently with other impairments for decades, specific focus on osteoporosis as a primary disease is new in recent years.

◆ Two randomized, controlled trials found that balance training improves functional and static balance and mobility and reduces fall frequency in elderly women and in elderly women with osteoporosis (Madureira et al., 2007; Steadman, Donaldson, & Kalra, 2003).
◆ A randomized, controlled trial found that low-intensity back-strengthening exercise improves quality of life and back extensor strength in patients with osteoporosis (Hongo et al., 2007).
◆ A randomized controlled trial found that strengthened back muscles significantly reduce incidence of vertebral fractures in estrogen-deficient women (Sinaki et al., 2002).
◆ A randomized, controlled trial found that individualized occupational therapy improved the ability to perform

instrumental activities of daily living and health-related quality of life in patients with hip fracture (Hagsten et al., 2006).

PARKINSON'S DISEASE

Kayoko Takahashi and Pai-Chuan Huang

Parkinson's disease (PD) is an idiopathic, slowly progressive, degenerative disorder of the basal ganglia in the central nervous system. It is the second most common neurodegenerative disease. Symptoms usually appear after the age of 50 years.

INCIDENCE

Incidence increases with age from 0.3–8.3 per 1,000 of the population in age 55–79 years in Western countries. Although perhaps less frequent in China and Africa, the disease is seen worldwide. Men seem to have a higher risk than women for PD (de Lau et al., 2004).

DIAGNOSIS, SYMPTOMS, AND AFFILIATED PROBLEMS

The cause of PD remains unknown. Diagnosis is based on clinical signs, including tremor, cogwheel rigidity, bradykinesia (slowness of movement), hypokinesia (reduction of movement), akinesia (loss of movement), and postural abnormalities. The criteria are: bradykinesia plus one of the following: a classic resting tremor, unilateral onset, progressive persistent asymmetry, and excellent response to levodopa (>70%), levodopa-induced dyskinesia, and continued response to levodopa for at least five years (Marsden, 1994). Problems affiliated with PD include insomnia, depression, and medication fluctuations ("on-off" state).

HOEHN AND YAHR STAGING OF PARKINSON'S DISEASE

- *Stage I:* Unilateral; no or minimal functional impairment; resting tremor
- *Stage II:* Midline or bilateral; mild functional impairment related to trunk mobility and postural reflexes
- *Stage III:* Impairment of balance; mild to moderate functional impairment
- *Stage IV:* Increased impairment of balance but still able to walk; functional impairment increased, especially difficulties with manipulation and dexterity, which interfere with eating, dressing, and washing
- *Stage V:* Confined to a wheelchair or bed (Hoehn & Yahr, 1967)

OT EVALUATIONS

PD reduces control of muscular movements, strength, endurance, cognitive, speech, and psychosocial functions and affects all ADL. PD-specific and some general OT assessments could be appropriate.

Participation Level

- Parkinson's Disease Quality of Life Questionnaire-39 Item Version (PDQ-39)
  Self-report that includes the following:
  - Five-point Likert scale, from "always" to "never" have a problem with ADL during the past 30 days because of PD.

- Eight subscales
  1. Mobility
  2. ADL
  3. Emotional well-being
  4. Stigma
  5. Social support
  6. Cognition
  7. Communication
  8. Bodily discomfort
- Higher scores characterize lower quality of life.
- Adequate reliability has been demonstrated cross-culturally (Jenkinson, Fitzpatrick, Norquist, Findley, & Hughes, 2003).
- Canadian Occupational Performance Measure (COPM)

Activity Level

- Unified Parkinson's Disease Rating Scale (UPDRS), a rating tool that follows the longitudinal course of PD. It includes these categories:
  - Mentation, behavior, and mood
  - ADL
  - Motor sections
- Functional Independence Measure (FIM)

Client Factor Level

- Hoehn and Yahr staging of PD
- Unified Parkinson's Disease Rating Scale Balance Test
- Range-of-motion test
- Manual muscle testing
- Rigidity testing
- Cognitive tests
- Geriatric Depression Scale (GDS)

INTERVENTIONS FOR PARKINSON'S DISEASE

Medications

The following current therapies aim to replace dopamine and decrease the symptoms of PD:

- L-dopa (levodopa)
- Dopamine agonists

Surgery

Surgical interventions include the following (Clinical Neuroscience, 2005):

- Pallidotomy
- Thalamotomy
- Deep brain stimulation
- Tissue transplants

Therapies

- *Physical therapy:* Improve ADL, stride length, and walking speed (de Goede, Samyra, Kwakkel, & Wagennar, 2001; Ellis et al., 2005).
- *Speech therapy:* Improve voice and speech function (de Swart, Willemse, Maassen, & Horstink, 2003; Schulz & Grant, 2002).

OT INTERVENTION

Intervention focuses on accommodative, remedial, compensatory, preventive, and environmental adaptation approaches, involving learning to identify the fluctuation in the symptoms and adjusting or grading activities accordingly.

Self-Care

- Teach adaptive techniques and tools to reduce the effect of tremors (Lyons, 2003; Montgomery, Lieberman, Singh, & Fries, 1994).
- Provide strategies to assist with medication routines.
- Encourage maximum functional level in all activities of daily living as long as possible.

Sensorimotor

- Maintain range of motion, prevent contractures by stretching.
- Improve motor planning and increase speed by adding cues, such as music with beats (Majsak, Kaminski, Gentile, & Flanagan, 1998; Marchese, Diverio, Zucchi, Lentino, & Abbruzzese, 2000; McIntosh, Brown, Rice, & Thaut, 1997).
- Encourage the client to increase voice volume through speaking and singing activities (Pacchetti et al., 2000).

Psychosocial

- Group approach to achieve therapy objectives, especially exercise and teaching groups to improve mood and socialization (Gauthier, Dalziel, & Gauthier, 1987).
- Educate in self-management skills, such as how to respond to changing symptom displays and when to seek medical help and how to improve self-efficacy in believing that the person can control their symptoms (Lyons, 2003).
- Encourage continuation of productive activities and leisure with suitable challenges (Sunvisson & Ekman, 2001).
- Encourage the person to discuss roles within the family and living unit.

◆ Educate the family to understand how the social inter-action is affected by PD, such as facial masking and oral rigidity (Lyons & Tickle-Degnen, 2003).

Environment

◆ Change the home or work environment to reduce the impact of immobility, such as a barstool for sitting and a striped pattern floor for the visual cue.
◆ Encourage the person and family to participate in a self-help or support group.
◆ Help the person and family to explore the community for resources.

OT AND THE EVIDENCE

◆ Meta-analysis found that 37% of clients had positive results without therapy but that 67% had positive results with OT-related intervention, particularly with respect to improving basic abilities and ADL (Murphy & Tickle-Degnen, 2001).
◆ Health education and exercise promotion for PD (six months) improved significantly on ADL and self-efficacy in believing that they could control their symptoms (Montgomery et al., 1994).
◆ Group occupational therapy is effective as an adjunct to drug treatment with people who have PD. At one-year follow-up, the participants who had not received the therapy had experienced a significant decline. By contrast, those who had received the therapy had maintained their functional status (Gauthier et al., 1987).

PRENATAL DRUG EXPOSURE

Laurie Dossett and Kate-Lyn Stone

Prenatal drug exposure results from a woman using illicit drugs such as cocaine, heroin, marijuana, methamphetamines, and ecstasy (MDMA) during pregnancy. This exposure can affect a developing fetus as well as the health and development of children after birth (U.S. Department of Health and Human Services, 1994). Some effects of prenatal drug exposure are severe, while others are more subtle (National Institute on Drug Abuse, 1998).

INCIDENCE AND PREVALENCE

Although the actual number of children born each year with prenatal drug exposure can be difficult to determine, it is known that exposure occurs in all racial, ethnic, and socioeconomic groups. It is estimated that approximately 3% of pregnant women use illicit drugs (March of Dimes, 2004).

DIAGNOSIS

It can be difficult to determine whether problems experienced by some children are caused by prenatal drug exposure or result from other factors such as poor prenatal and/or postnatal care, poor nutrition or poverty (NIDA, 1998). Also, because many women who use illicit drugs during pregnancy also use tobacco products and consume alcohol, it can be difficult to determine whether problems were specifically caused by the illicit drugs (March of Dimes, 2004). Newborns who were prenatally exposed to different illicit drugs are more likely to be born prematurely, with microcephaly and low height and weight measures, than other infants who were not exposed (NIDA, 1998).

SIGNS

Note that symptoms are not applicable to infants.

Infancy (0–15 months)

- Unpredictable sleeping patterns
- Feeding difficulties
- Irritability
- Atypical social interactions
- Delayed language development
- Increased muscle tone and poor fine motor development

Toddlerhood (15–36 months)

- Atypical social interactions
- Delayed language development
- Minimal play strategies (USDHHS, 1994)

SIGNS AND SYMPTOMS BASED ON SPECIFIC TYPE OF DRUG EXPOSURE

There are also signs and symptoms that are specific to the illicit drug to which a child was exposed in the womb (March of Dimes, 2004):

Cocaine

- Increased risk of urinary tract and heart defects
- May be jittery or irritable (as infants)
- Not easily consolable (as infants)
- Behavior problems: inability to control emotions
- Learning problems: difficulty paying attention

Marijuana

- Postnatal withdrawal symptoms such as excessive crying and trembling (with regular exposure during the pregnancy)
- Subtle effects on attention abilities and solving visual problems

Ecstasy (and Other Amphetamines)

- Possible increase in congenital heart defects and club-foot (in females only)
- Postnatal: possible jitteriness, drowsiness and breathing problems

Methamphetamines

- Increased risk of birth defects such as cleft palate and heart and limb defects
- Postnatal: possible jitteriness, drowsiness, and breathing problems

Heroin

- Most babies who were exposed to heroin experience postnatal withdrawal signs, including fever, sneezing, trembling, irritability, diarrhea, vomiting, continual crying, and occasionally seizures
- May be at risk for low IQ and serious behavior problems

CAUSE

Prenatal drug exposure is caused by the use of illicit drugs by a woman during pregnancy.

AFFILIATED PROBLEMS

Other than medical problems, many children with prenatal exposure to drugs can have learning difficulties, along with trouble paying attention and staying focused (NIDA, 1998). There are also indications that these children can have difficulties in social interactions and emotional regulation (NIDA, 1998).

PRECAUTIONS

Infants who were exposed to opiates in utero may exhibit postnatal withdrawal signs, and those who were exposed to cocaine may experience increased tone, hyperexcitability, and tremors (Agency for Healthcare Research and Quality, n.d.). Children who were exposed to drugs in the womb are more likely to be vulnerable to substance abuse themselves, especially in the adolescent years (NIDA, 2004).

TREATMENT

Treatment for these children will begin at birth, especially since many drug-exposed babies will be born prematurely and might need treatment for some of the common issues associated with prematurity (March of Dimes, 2004). Sleep disturbances, difficulties in self-consoling, and feeding disorders can be treated in different ways, including teaching the caregiver to read behavioral cues, modifying the environment, and providing support for the infant's attempts at self-regulation (Cole, 1996).

OT EVALUATION

Many different assessments can be used to evaluate the development of infants and children with prenatal exposure to illicit drugs. These may include some of the common pediatric developmental screening and assessments such as the following:

- Infant-Toddler Developmental Assessment (birth to 36 months)
- Hawaii Early Learning Profile (0–36 months) (HELP)

- Miller Assessment for Preschoolers (2 years, 9 months to 5 years, 8 months) (MAP)
- Bayley Scale of Infant Development (1–42 months)
- Sensory Integration and Praxis Tests (4 years to 8 years, 11 months) (SIPT)
- Peabody Developmental Motor Scales–2 (1 month to 6 years)
- Neonatal Behavioral Assessment Scale (infants)

OT INTERVENTION

Neonatal Intensive Care Unit

- Family education and support
- Work with infants on nipple feeding to promote active suck reflex
- Infant sensory stimulation protocols (National Institutes of Health, 2004)

Early Intervention

- Feeding skills
- Sensory processing
- Motor development
- Play skills
- Adaptive behavior
- Environmental exploration
- Child-caregiver interactions (American Occupational Therapy Association, 2005)

School Systems

- Sensory integration
- Fine and gross motor development
- Classroom participation

OT AND THE EVIDENCE

Infants who have been exposed to substances while in utero have been found to have difficulty attending to books and toys, abnormalities in sleep cycles, trouble with pinpointing sound, problems with visually tracking an object, disruption in mother-infant interactions, and difficulty participating in social games (Osborn, Jeffery, & Cole, 2007; Singer et al., 2000). Early identification of such deficits is crucial in facilitating early intervention services as soon as possible to promote more normal development (Singer et al., 2000). Belcher, Butz, Hoon, Reeves, and Pulsifer (2005) found that early intervention can reduce the effects of maternal substance abuse on the exposed child. Early intervention can also have several positive benefits on the development of the child and family. Early intervention should be family-oriented, meaning that it should be directed at both the child and caregivers, as well as culturally relevant

in order to be most constructive (Dudek-Shriber, 2004). Brown, Bakeman, Coles, Platzman, and Lynch (2004) suggest that early intervention should carefully analyze and consider the effects of the caregiving environment on the development of the exposed infant.

CAREGIVER CONCERNS

Prenatal drug exposure often results in premature birth. This means that the baby will most likely spend a lot of time in the hospital, which can be very physically and emotionally stressful for caregivers. Many children will also have special needs, which will create whole new experiences for parents and other caregivers. Caregivers must also learn to be aware of subtle signs and symptoms to prevent hyperarousal and understand that often these infants are not easily consolable (Cole, 1996).

RHEUMATOID ARTHRITIS

Kate-Lyn Stone

DIAGNOSIS

Rheumatoid arthritis (RA) is a systemic, inflammatory, chronic condition. It is also considered an autoimmune disease because of the fact that people who have RA have an irregular immune response. Basically, this means that the immune system in people with RA attacks the body's healthy tissue as if the tissue were a foreign invader. RA is generally characterized by the inflammation of the synovium, or lining, of the joints (Arthritis Foundation, 2007). It generally occurs in a symmetrical way, meaning that if an individual has RA in his or her left hand, he or she is likely also to have RA in the right hand. The disease causes pain, swelling, discomfort, and loss of function in the joints (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2004). The cause of RA is unknown, and there is no cure.

INCIDENCE AND PREVALENCE

- 2.1 million Americans, approximately 1% of the population, are affected by RA (Arthritis Foundation, 2007).
- Women are two to three times more likely to develop RA than their male counterparts (Arthritis Foundation, 2007).

- Rheumatoid nodules appear in about 20% of the population with RA (Arthritis Foundation, 2007).
- People with RA generally begins to show symptoms during middle age; however, children and adolescents can also develop the disease (for more information on this condition, see the resource sheet for juvenile rheumatoid arthritis).

THE CAUSE AND ETIOLOGY

The cause of RA is unknown. There are several theories as to what could cause this disease, including theories involving the immune system, gender, genetics, or infection (Arthritis Foundation, 2007; NIAMS, 2004).

TYPICAL COURSE AND SYMPTOMS

Rheumatoid arthritis can affect any joint in the body, but it most commonly starts in the joints of the fingers, hands, and wrists. The disease process of RA generally has three stages:

1. The synovial lining begins to swell, which results in pain, stiffness, and swelling around the joint.
2. The synovium thickens because of the rapid division and growth of cells.

3. The inflamed cells in the joint begin to release enzymes that digest bone and cartilage. This often results in the joint's losing its shape and an increase in pain and loss of movement (Arthritis Foundation, 2007).

Signs include the following:

- Stiffness
- Weakness
- Flulike symptoms
- Rheumatoid nodules (bumps under the skin)
- Depression
- Weight loss
- Cold and/or sweaty hands and feet
- Decreased production of tears and saliva because of involvement of the glands that produce these secretions
- Deformity of joints
- Instability of joints
- Limited range of motion
- Decreased strength
- Decreased ability to function
- Anemia

Symptoms include the following:

- Pain
- Fatigue
- Loss of appetite

SEQUENCE OF CARE

Early diagnosis is critical in RA because it can lead to early intervention, which allows an individual with RA to continue living a productive and meaningful life. The physician makes a diagnosis based on medical history, physical examination, and X-rays and confirmed by lab tests (Arthritis Foundation, 2007). During the medical history, the physician will look for information, including, but not limited to, pain level, amount of stiffness and when the stiffness is most prevalent, and presence of fatigue. During the physical examination, the physician will look for the common signs of RA, such as swelling, tenderness, and misalignment. In addition to the medical history and the physical exam, the physician may choose to use lab tests to confirm the diagnosis. Possible lab tests include complete blood count (checking red blood cells, white blood cells, or platelets for abnormalities), erythrocyte sedimentation rate (to detect the amount of inflammation in the body), C-reactive protein (also to detect inflammation), and rheumatoid factor (the higher the amount of rheumatoid factor, the more severe the RA is). Imaging tests may also be used, such as X-rays, MRI, bone densitometry (measuring bone density), and joint ultrasound (Arthritis Foundation, 2007). Once RA has been diagnosed, appropriate treatment can begin. Refer to the following section for information on different types of treatment and the medical professionals who may be involved.

MEDICAL INTERVENTIONS

Aggressive treatment of RA can decrease the amount of damage that is done to the joint, which in turn leads to a decrease in pain and an increase in range of motion. Because each person is affected differently by RA, treatment methods differ from person to person. The overarching goals for treatment include decreasing pain, inflammation, and damage and increasing function (NIAMS, 2004). In general, treatment will include the following:

- Medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), analgesic drugs, glucocorticoids or prednisone, disease-modifying antirheumatic drugs (DMARDs), biologic response modifiers, and protein-A immunoadsorption therapy (Arthritis Foundation, 2007). For more information on these drugs, visit the Arthritis Foundation's website at http://www.arthritis.org/
- Physical therapy
- Occupational therapy
- Surgery
- Proper rest
- Joint care
- Stress management
- Exercise to reduce pain and improve movement
- Weight control to reduce stress on joints

Health professionals that may be involved in treating an individual with RA include a general practitioner, a rheumatologist, a physical therapist, an occupational therapist, a nurse, a psychologist/psychiatrist, an orthopedic surgeon, and a social worker (Arthritis Foundation, 2007).

OT EVALUATIONS

Basic and Instrumental Activity of Daily Living Skills

- Kohlman Evaluation of Living Skills (KELS)
- Assessment of Motor and Process Skills (AMPS)
- Functional Independence Measure (FIM)
- Klein-Bell Activities of Daily Living Scale (Klein-Bell)
- Satisfaction With Performance Scaled Questionnaire (SPSQ)

Psychosocial Skills

- The Assessment of Occupational Functioning (AOF)
- The Occupational Performance History Interview II (OPHI II)
- Geriatric Depression Scale

Self-Perception

- The Canadian Occupational Performance Measure (COPM)

- The Role Checklist
- Worker Role Inventory

Somatic Sensory Evaluations

- Primary somatic system
  - Light touch
  - Pain
  - Temperature
- Discriminative somatic system
  - Tactile localization
  - Two-point discrimination

Other Assessments

- Manual muscle testing
- Range-of-motion testing
- Pain scales
- Home assessment

OT INTERVENTIONS

- ADL
- Energy conservation techniques
- Strengthening exercises
- Pain management
- Assistive technology
- Adapt environment
- Adaptive equipment
- Patient and family education
- Home planning
- Splinting to support limbs
- Self-management education

OT AND THE EVIDENCE

Steultjens and colleagues (2004) found that instruction and education on joint protection as an occupational therapy intervention for individuals with RA improved their functional ability. These researchers also found that splinting the involved joints led to a decrease in pain both immediately and over time as well as an immediate improvement in grip strength following splinting. Hammond and Freeman (2004) found results similar to those of Steultjens and colleagues in that an OT-administered educational joint protection program improved functional ability and improved adherence to joint protection strategies for individuals with RA. Hammond and Freeman (2004) credit the success of their program to the applied educational, behavioral, and motor learning aspects of the training instilling the clients with a greater sense of self-efficacy. Kennedy (2006) looked into the effectiveness of aerobic exercise programs for individuals with RA. She found that the exercise programs did not increase the disease progression and aided in decreasing the loss of bone mineral in the hip joint. Overall, aerobic exercise programs seem to be safe and effective for individuals with RA.

RESOURCES

Programs

- Arthritis Foundation Self-Help Program (AFSHP) (Centers for Disease Control and Prevention, 2004) This six-week program helps individuals with arthritis learn how to manage their condition on a day-to-day basis. It was developed by Dr. Kate Lorig of Stanford University. Studies done on this intervention report that participants experience a 20% decrease in pain and a 40% decrease in doctors' visits. As of 2007, there were 36 CDC-funded state arthritis programs.
- Chronic Disease Self-Management Program (CDSMP) (Centers for Disease Control and Prevention, 2004) This six-week program teaches self-management education for individuals with chronic diseases or conditions, including arthritis, diabetes, heart disease, and lung disease. This program was created and developed at Stanford University. As of 2007, there were 36 CDC-funded state chronic disease programs.
- Arthritis Foundation Exercise Program (AFEP) This program, developed by the Arthritis Foundation, is a community-based, recreational program that focuses on range-of-motion exercises, endurance building, stress management, relaxation techniques, and other topics related to health. This program is unique in that it can be tailored to meet each participant's individual needs.
- Arthritis Foundation Aquatic Program (AFAP) This exercise program, developed by the Arthritis Foundation, is an aquatic program that works to increase flexibility, endurance, and range of motion while decreasing pain because there is less impact on the joints in the water environment.
- EnhanceFitness Formerly known as Lifetime Fitness, this program is an evidence-based, community exercise program. It has been proven to increase strength and activity levels in individuals with arthritis.

SCHIZOPHRENIA

Grace M. Trudeau

Schizophrenia is a psychotic disorder that typically occurs in late adolescence or adulthood and affects an individual's perceptions and behaviors in all facets of life. Disturbed thought patterns or psychotic symptoms leading to severe difficulties in social or occupational functioning must be present for a minimum of six months for diagnosis (American Psychiatric Association, 2000).

PREVALENCE

◆ Schizophrenia affects 1% of the world's population (National Institute of Mental Health, 2005a).
◆ Between one third and one half of Americans who are homeless have schizophrenia (PyschologyNet.org, 2003).

ETIOLOGY AND RISK FACTORS

The etiology of schizophrenia is unknown, but theories include organic or neurological causes, events during development, environmental factors, or genetics. It is possible that "schizophrenia" is actually a collection of different underlying causes that present similarly (NIMH, 2005b).

POTENTIAL SYMPTOMS

Symptoms can be divided into two categories: negative symptoms, resulting in trait "loss," and positive symptoms, which "add" traits.

Negative Symptoms

◆ Flat affect
◆ Inattention
◆ Lack of interest or energy
◆ Impoverished thought process
◆ Inability to experience pleasure

Positive Symptoms

◆ Hallucinations
◆ Delusions
◆ Disordered or disorganized thinking
◆ Language disturbances
◆ Self-neglect
◆ Paranoia
◆ Inappropriate emotion (NIMH, 2005a; Psychology Net.org, 2003)

Typical Course

Schizophrenia may progress in three typical courses:

◆ Single episode of symptoms with almost complete recovery
◆ Repeated episodes of symptoms with moderate recovery between
◆ Progressive slide into long-term disability (Stevens, 1997)

OT EVALUATION

Client, Caregiver, and Staff Perceptions of Impact

◆ Canadian Occupational Performance Measure (COPM)
◆ Client Assessment of Strengths, Interests, and Goals/ Staff Observations and Client Information (CASIG/ SOCI)

◆ Illness Perception Questionnaire for Schizophrenia/ Illness Perception Questionnaire for Schizophrenia– Relatives Version (IPQS/IPQS-Relatives)

Activities of Daily Living/Instrumental Activities of Daily Living (ADL/IADL)

◆ Global Assessment of Functioning (GAF) Scale
◆ Kohlman Evaluation of Living Skills (KELS)
◆ Milwaukee Evaluation of Daily Living Skills (MEDLS)
◆ The Test of Grocery Shopping Skills (TOG-SS)

Cognitive Assessment

◆ Allen's Cognitive Levels (ACL)
◆ Assessment of Motor and Process Skills (AMPS)

NON-OT TREATMENTS

Antipsychotic Medications

Antipsychotic medications are generally used as the first treatment of schizophrenia to help clients establish a stable base from which other treatments may be beneficial. However, while medications have been shown to be effective in preventing psychotic relapse, with the exception of clozapine, there is no evidence that they effect change in other domains (e.g., social functioning) (Bustillo, Lauriello, Horan, & Keith, 2001; Hargreaves, Gibson & Gibson, 2005; PsychologyNet.org, 2003).

Major Side Effects of Typical Antipsychotic Medication

◆ Chlorpromazine (anticholinergic, sedation, hypotension)
◆ Thioridazine (anticholinergic, sedation, hypotension)
◆ Trifluoperazine (extrapyramidal)
◆ Thiothixene (extrapyramidal)
◆ Fluphenazine (extrapyramidal)
◆ Haloperidol (extrapyramidal)

Major Side Effects of Atypical Antipsychotic Medication

◆ Risperidone (limited side effects)
◆ Olanzapine (limited side effects)
◆ Clozapine (anticholinergic, sedation, hypotension, risk of agranulocytosis)

Other Side Effects

◆ *Anticholinergic:* Dry mouth, constipation, blurred vision, urinary retention
◆ *Extrapyramidal:* Dystonia, parkinsonism, akathisisa, tardive dyskinesia
◆ With both typical and atypical antipsychotic medications, adverse reactions may include neuroleptic malignant syndrome, malignant hyperthermia, and tardive dyskinesia.

INTERVENTION

Assertive Community Treatment (ACT)

Rehabilitation teams provide comprehensive, 24-hour, 7-day-a-week case management and active treatment. Teams support individuals in ADL, work, and leisure activities. ACT has clear effects on the prevention of psychotic relapse and rehospitalization (Bustillo et al., 2001; Russell Teske, 2000).

Clubhouses and Supported Living

Clubhouses provide support as clients move through a continuum of dependency to independence. Although clubhouses vary from one program to the next, most offer a variety of self-help and skills programs. Likewise, supported living programs enable individuals to move from supervised to independent community living (Russell Teske, 2000).

Cognitive Behavioral Treatment

Cognitive behavioral therapy (CBT) treatments target changing thought patterns in order to change behavior and increase attention, memory, planning, and decision-making skills. Following CBT, some studies have shown decreases in delusional thinking and hallucinations (Bustillo et al., 2001; Russell Teske, 2000).

Family Therapy

When individuals are returned to their families following discharge, behavioral and psychoeducational interventions are employed with the whole family. Such interventions have been shown to be effective in preventing psychotic relapse and hospitalization (Bustillo et al., 2001).

Psychoeducation

In psychoeducation, which is sometimes termed *personal therapy,* therapists teach functional living skills, symptom management, health and safety awareness, and assertiveness training in individual treatment sessions. Preliminary research shows that psychoeducation may improve social functioning (Bustillo et al., 2001; MacRae, 2005).

Social Skills Training

In social skills training, training is provided in social adaptation, self-care, and interpersonal relationships using modeling, feedback, reinforcement, and role-play. Although it is not clear that effects generalize, improvements in social skills have been shown to last after one year. There is no effect on relapse prevention, psychopathology, or employment status (Bustillo et al., 2001; Russell Teske, 2000).

Supported Employment

Supported employment programs help individuals to obtain and maintain employment. Training is completed in searching for jobs and job skills, and support is provided throughout the job acquisition and employment processes. Employment may occur in a continuum from sheltered workshops to community settings. Best evidence shows that the place-and-train vocational model is most effective in obtaining competitive employment (Bustillo et al., 2000).

OT AND THE EVIDENCE

Family therapy and assertive community treatment have clear effects on the prevention of psychotic relapse and hospitalization but no consistent effects on other outcome measures. Social skills training has been shown to improve social skills but has not been shown to have a direct impact on other areas of outcome, including relapse or employment. Supportive employment programs that use place-and-train models demonstrate a positive effect on the obtainment of competitive employment. In some studies, cognitive behavior therapy has been shown to improve delusions and hallucinations (Bustillo et al., 2001).

SPINA BIFIDA AND NEURAL TUBE DEFECTS

Bridget A. Kane

Neural tube defects are malformations of the central nervous system that occur in utero within the first four weeks of gestation. There are three major forms of neural tube defects:

- Anencephaly is the absence of growth of the cerebral hemispheres. Newborns with this condition either are stillborn or die shortly after birth (Beers & Berkow, 1999).
- Encephalocele includes brain protrusion in the occipital region, often resulting in motor impairments, seizures, hydrocephalus, and mental retardation (Liptak, 1997).
- Spina bifida is a defect in the vertebral arches and the spinal column that occurs most commonly in the lower thoracic, lumbar, or sacral regions (Beers & Berkow, 1999).

The exact cause of spina bifida remains unknown. Genetics, environmental factors, certain medications, and maternal nutritional deficiency are suspected to influence neural tube development (National Institute of Neurological Disorders and Stroke, 2004; Spina Bifida Association of America, 2001).

INCIDENCE AND PREVALENCE

Spina bifida is reportedly "the most frequently occurring permanently disabling birth defect," affecting 1 in every 1,000 births in the United States. It is estimated that up to 70,000 people are living with spina bifida in the United States (SBAA, 2001, p. 1).

Prognosis

Approximately 90% of infants who are born with spina bifida will live into adulthood (SBAA, 2001). The cause of death for older individuals with spina bifida is usually loss of renal function and/or shunt complications (Beers & Berkow, 1999).

Common Characteristics

Signs vary based on the extent of the condition and may include the following:

- Paralysis, including sensory and motor impairments below the level of the lesion
- Hydrocephalus
- Cognitive impairments ranging from learning disabilities to mental retardation
- Sensory-processing and perceptual deficits
- Bladder and bowel dysfunction
- Psychosocial and sexual concerns
- Orthopedic conditions, including club foot, dislocated hip, scoliosis, kyphosis, and joint abnormalities due to overuse or muscle imbalance (Beers & Berkow, 1999; Brown, 2001; National Dissemination Center for Children with Disabilities, 2004; Simeonsson, McMillen, & Huntington, 2002; Snow, 1999; Wills, 1993)

HEALTH MANAGEMENT

Integrated, multidisciplinary services that are comprehensive, coordinated, and longitudinal are most effective in promoting health and participation in the community for individuals with spina bifida (Bent et al., 2002; Kinsman, Levey, Ruffing, Stone, & Warren, 2000). Interventions may include the following:

- Neurologic and orthopedic surgery
    - Surgical repair of open lesions is completed within 24 hours of birth to decrease the risk of infection and preserve existing spinal cord function.
    - Shunt implantation to manage hydrocephalus
    - Antibiotics and/or neurosurgical intervention to treat cerebrospinal fluid (CSF) abnormalities and meningeal or ventricular infection
- Urologic care with possible catheterization, along with bowel and bladder programs
- Radiographic imaging to monitor the integrity of spine, skull, hips, and lower extremities
- Orthotic and mobility interventions
- Screening for scoliosis, pathological fractures, and pressure sores
- Nutritional counseling (Beers & Berkow, 1999; Brown, 2001; NINDS, 2004)

PRECAUTIONS

Precautions involved in spina bifida include the following (Brown, 2001; Dias, 2003; McLone & Dias, 2001; Rekate, 2001; Scoggin & Parks, 1997):

- Contractures
- Joint protection
- Pressure sores and skin breakdown
- Seizures
- Latex sensitivity/allergy, with adverse reactions to latex that may include the following:
    - Itchy, watery eyes
    - Sneezing and coughing
    - Rash or hives
    - Swelling of trachea
    - Wheezing or shortness of breath
    - Anaphylactic shock
- Shunt malfunction: Signs of shunt malfunction include the following:
    - Headaches
    - Vomiting
    - Seizures
    - Behavioral and cognitive changes
    - Progressive decline in motor performance
    - Gagging or difficulty swallowing
    - Change in urinary or bowel function
    - "Setting sun" eyes
    - Increased head size
- Shunt infection, with signs that include those of shunt malfunction and the following:
    - Fever
    - Neck stiffness
    - Pain and tenderness
    - Skin redness
    - Abdominal pain
    - Drainage from shunt tract

OCCUPATIONAL THERAPY EVALUATION

Pediatric Evaluations

Daily Living Skills

- Functional Independence Measure for Children (WeeFIM)
- Hawaii Early Learning Profile (HELP)
- Pediatric Evaluation of Disability Inventory (PEDI)
- Vineland Adaptive Behavior Scales

School-Specific

- School Function Assessment (SFA)

Play/Leisure and Social Skills

- Children's Assessment of Participation and Enjoyment (CAPE)
- Play History
- Social Skills Rating System
- Test of Playfulness

Transition Planning and Goal Setting

- Canadian Occupational Performance Measure (COPM)
- Choosing Outcomes and Accommodations for Children (COACH)
- Making Action Plans (MAPS)
- Perceived Efficacy and Goal Setting (PEGS)
- Transition Planning Inventory

Additional assessments that target specific areas, including feeding, handwriting and academic performance, driving, and employment, may also be appropriate.

Adult Evaluations

Occupational Performance

- Canadian Occupational Performance Measure (COPM)
- Occupational Performance History Interview

Daily Living Skills

- Functional Independence Measure (FIM)

Additional assessments for adults may address employment, driving, accessing the community, IADL, and home safety.

Throughout the life course, body structure and function factors that can influence occupational performance should also be assessed. These factors can include range of motion, muscle strength and tone, postural deviations, sensation, visual perception, and sensory processing (Razma, 2001).

OT INTERVENTION

OT may address the physical, cognitive, neurological, social, and environmental factors that affect participation in daily activities for individuals with spina bifida. Changes in levels of dependence over time and the additional effects of aging support the need for continued assessment and intervention throughout the life course (Andren & Grimby, 2004; Brown, 2001; Klingbeil, Baer, & Wilson, 2004). Intervention may address accessibility, assistive technology and adaptive equipment, family and caregiver education and training, energy conservation and proper body mechanics, fitness and recreation, disability awareness, social skills, community integration, splinting and

orthotics, skin care, positioning, and, most important, transition planning.

OT AND THE EVIDENCE

- Children with developmental disabilities whose mothers participated in a one-hour intervention addressing caregiver-child interaction demonstrated significant improvement in playfulness, as measured by the Test of Playfulness, compared to children with developmental disabilities who participated in a one-hour neuro-developmental treatment session (Okimoto, Bundy, & Hanzlik, 2000). These results reinforce the importance of occupation-based and family-focused OT services to support improved participation in meaningful activities for children with disabilities.
- A 12-week psychoeducational group for children with spina bifida that focused on didactic teaching, personal goal setting, social interaction, and homework was found to be effective in improving self-care skills (Engelman, Loomis, & Kleiback, 1994).
- Participation in a short-term, inpatient rehabilitative program that provides interdisciplinary services can be effective in increasing independence in ADL for children and adolescents with spina bifida (Bolding & Llorens, 1991).
- The incorporation of leisure in the lives of individuals with congenital disabilities has been found to provide enjoyment; physical and mental health benefits; and opportunities to develop self-concept, self-worth, and friendships (Specht, King, Brown, & Foris, 2002).
- The use of word prediction programs have the potential to improve written production and task performance for school-aged children with spina bifida based on a consideration of individual skills and task requirements (Tam, Reid, Naumann, & O'Keefe, 2002).

There is a significant need to expand on the research that is currently available regarding occupational therapists' role in working with individuals with spina bifida and their families. The Spina Bifida Association of America identified a number of clinical questions that require further research (Liptak, 2003). Research priorities that relate to occupational therapy practice include independence, self-care, sexuality, education, employment, socialization, family functioning, mobility, behavioral and mental health, learning, orthopedics, and skin care.

FAMILY AND CAREGIVER CONCERNS

Family-centered and culturally competent care is essential in providing services for individuals with spina bifida. Because spina bifida is a chronic condition, lifelong planning is necessary for the individual and his or her family. The Needs Assessment Questionnaire developed

by Kennedy and colleagues (1998) may assist in identifying the needs for the individual with spina bifida and the individual's family. Needs are considered in the following areas:

- Transportation
- Accessibility
- Independence
- Finances
- Medical resources
- Communication
- Family and socialization
- Education of others
- School services
- Vocational training

Preliminary use of the Needs Assessment Questionnaire indicated that children with spina bifida and their families identified priorities and needs differently. Parents perceived greater needs than their children did (Buran, McDaniel, & Brei, 2002; Kennedy et al., 1998).

SPINAL CORD INJURY

Kirsten Protos, Kate-Lyn Stone, and Meredith Grinnell

DEFINITION

Spinal cord injury (SCI) involves damage to the spinal nerves through compression, bruising, or severing of the spinal cord, which results in paralysis and loss of sensory and motor function based on the level at which the injury occurs.

ETIOLOGY

SCI is most often caused by trauma, such as car accidents or gunshot wounds, but can also be the result of tumors or acquired diseases.

CLASSIFICATION

A *complete injury* indicates that there is no sensory or motor function below the level of injury. When there is some remaining sensory or motor function below the level of injury, it is considered an *incomplete injury.* SCI is categorized as tetraplegia or paraplegia. *Tetraplegia* involves a loss of function in both the upper and lower extremities; *paraplegia* involves a loss of function in the lower extremities only.

INCIDENCE AND PREVALENCE

There are approximately 250,000 people living with a SCI in the United States today, with 11,000 new cases

occurring each year. There is a higher incidence of SCI among people ages 18–25, males being at a significantly higher risk than females (National SCI Statistical Center, 2005; Reed, 2001; Spinal Cord Injury Resource Center, 2006b).

TYPICAL COURSE

Half of all people with SCI have associated injuries, especially if the injury was due to trauma. The length of stay in an acute care hospital depends on the severity of the SCI and the related injuries. When patients are medically stable, they are transferred to an inpatient rehabilitation hospital, where the average length of stay is about 44 days. Individuals with higher-level injuries often require longer and more intensive treatment than do individuals with lower-level injuries. After leaving inpatient rehab, most patients continue their therapy at an outpatient facility. Patients who survive the initial 24 hours after their injury have an 85% chance of surviving 10 years or more, younger survivors and those with lower and incomplete injuries having a better chance for survival (Shepherd Center, 2000; Spinal Cord Injury Recovery Center, 2006b).

SYMPTOMS AND COMPLICATIONS

Major Signs

- Paralysis: no motor function at and below the level of injury for individuals with complete SCIs; weakness and decreased range of motion in the partially affected muscles
- Paresis: impaired motor function at or below the level of injury for individuals with incomplete SCIs
- Sensory deficits: no sensory function at and below the level of injury for individuals with complete SCIs; impaired sensory function at or below level of injury for individuals with incomplete SCIs
- Spasticity: strong involuntary muscle spasms in the impaired limbs
- Respiratory dysfunction: loss of function or weakness in the respiratory muscles for individuals with high injury levels (C1–C3)
- Bladder and bowel dysfunction
- Orthostatic hypotension: drops in blood pressure on movement during the acute phase of the injury
- Pain
- Reproductive and sexual dysfunction

Complications

- Autonomic dysreflexia: a potentially fatal condition that causes blood pressure to rise dangerously high because of a noxious stimulus to the body below the level of injury
- Skin breakdown and pressure sores
- Pain
- Urinary tract infections
- Pneumonia
- Heterotopic ossification: abnormal bone growth at large joints
- Deep vein thrombosis
- Cardiovascular disease

(National Institute of Neurological Disorders and Stroke, 2003; Reed, 2001; Spinal Cord Injury Resource Center, 2006b)

TYPICAL INTERVENTIONS

- *Immobilization:* The spine and/or neck are immobilized to prevent further injury immediately following injury and surgery.
- *Medication:* In the first 24 hours following injury corticosteroid medications, such as methylprednisolone, are given to reduce swelling in the spinal cord. Medications are also used for pain management, because many patients with SCIs are in a great deal of pain during the acute period.
- *Surgery:* It is often necessary to perform surgery to remove or repair broken bones and ligaments of the spine caused by a traumatic injury. Fractured vertebrae are often fused or grafted to normal vertebrae by using metal rods or screws to prevent movement of the fractured vertebrae.
- *Rehabilitation:* In rehabilitation, a patient with a SCI will receive continuing medical care; physical, occupational, and recreational therapies; speech therapy if necessary; counseling services; and patient and caregiver education. The focus is on restoring strength and function and developing compensatory strategies to help the patient gain as much independence as possible. (Spinal Cord Injury Recovery Center, 2006a).

PROGNOSIS

Survivors of SCI will continue to live with functional limitations based on their level and type of injury. They may also continue to deal with pain and other secondary complications, depending on how they handle their daily care (NINDS, 2003). People with paraplegia and/or incomplete injuries tend to do better than those with tetraplegia and/or complete injuries. Advances in treatment, rehabilitation, and assistive technology have made it possible to improve some of the functional capabilities of people with SCIs.

PRECAUTIONS

◆ Monitor the patient's skin for redness or ulcers; individuals with SCI must perform pressure relief every 30 minutes to reduce the risk of skin breakdown.
◆ Monitor blood pressure and check for dizziness to prevent orthostatic hypotension.
◆ Observe body temperature; people with SCI, especially high level and in the acute phase, can have problems with temperature regulation.
◆ Watch for signs indicating autonomic dysreflexia (headache, sweating, congestion, hypertension, bradycardia); if these signs are observed, immediately place the patient in an upright position and remove any restricting materials or obvious noxious stimuli.
◆ Monitor the respiration of patients with a C1–C4 injury, especially if the patient is on a ventilator.
◆ Assess the patient for pain, spasticity, muscle stiffness/hypertonia, decreased range of motion, and subluxation to prevent further injury during treatment. (NINDS, 2003; Reed, 2001).

OCCUPATIONAL THERAPY EVALUATIONS

Motor and Sensory Function Evaluations

◆ American Spinal Injury Association (ASIA) Impairment Scale
◆ Manual muscle testing
◆ Range-of-motion testing using a goniometer

ADL and IADL Evaluations

◆ Functional Independence Measure (FIM)
◆ Barthel Index
◆ Klein-Bell ADL Scale
◆ Quadriplegic Index of Function (Reed, 2001)

OCCUPATIONAL THERAPY INTERVENTIONS

In rehabilitation of individuals with SCI, occupational therapists use a combination of biomechanical and rehabilitative (compensatory) treatment models.

◆ *Biomechanical model:* Used to help the patient improve strength, range of motion, endurance, balance, mobility, and energy conservation.
◆ *Rehabilitative model:* Used to improve the patient's functional performance to be as independent as possible; compensatory strategies and assistive technology are used to improve function in occupational performance areas such as ADL/IADL, leisure, and work and productivity.

◆ Occupational therapists also often address patients' cognitive and psychosocial needs in their intervention as well as providing patient and caregiver education and home modification suggestions (Dolhi, 2001; Reed, 2001).

FAMILY AND CAREGIVER CONCERNS

Caregivers have a responsibility to care for and perform the activities that their loved one with a SCI cannot do independently. Individuals with higher-level injuries require more work and diligence to prevent complications. Some concerns of caregivers can include the following:

◆ Financial coverage for medical bills, services, and equipment
◆ Physical and emotional support for caregivers— support groups are important
◆ Being able to perform the daily medical tasks to keep the loved one healthy
◆ Having a good quality of life

OCCUPATIONAL THERAPY AND THE EVIDENCE

Occupational therapists are the most appropriate service providers to address function in the performance areas of patients with SCI. According to the AOTA's practice guidelines for adults with spinal cord injury (Dolhi, 2001), occupational therapy intervention focuses on ADL, work, and leisure activities. Occupational therapists are also involved in education of family members and caregivers, environmental adaptation, assistive technology and equipment, and driving evaluation and training. Occupational therapists enable their clients to perform activities that are meaningful by building a trusting relationship with the client, being flexible and creative with resources and approaches to treatment, and adapting the environment (Guidetti & Tham, 2002).

Spinal cord injury has several different aspects that have been reviewed in current research. Functional electrical therapy, which is used to restore useful movements, has been found to be effective for both grasping exercises and gait training for individuals with spinal cord injury (Popovic et al., 2006; Thrasher, Flett, & Popovic, 2006). Kennedy, Duff, Evans, and Beedie (2003) found programs that use cognitive behavioral techniques in a group setting to be successful in reducing depression and anxiety associated with spinal cord injury. Participants found the shared problem solving among the group members to be particularly helpful. Guidetti and Tham (2002) addressed strategies that occupational therapists use in self-care training and suggested that

occupational therapists, through understanding each individual person, vary their strategies to meet the needs of each person's unique experience with spinal cord injury. Last, a weight management program involving education about nutrition, exercise, and behavior modification was effective for obese and overweight individuals with spinal cord injury to safely lose weight without compromising lean body mass and overall well-being (Chen, Henson, Jackson, & Richards, 2006).

TRAUMATIC BRAIN INJURY

Justina Hsu

A traumatic brain injury (TBI) is an insult to the brain that is not of a degenerative or congenital nature, but caused by an external physical force. A TBI may produce a diminished or altered state of consciousness that results in impairment of cognitive abilities or physical functioning as well as disturbances of behavioral or emotional function. These impairments may be either temporary or permanent and may cause partial or total functional disability or psychosocial maladjustment (Brain Injury Association of America).

TWO TYPES OF TRAUMATIC BRAIN INJURY:

- Penetrating or missile (open) injuries, which result from penetration of the skull
- Nonpenetrating, closed head injuries, which result from rapid acceleration or deceleration of the brain within the skull, causing damage at the point of impact (coup injuries) or at the opposite pole (contrecoup injuries)

INCIDENCE AND PREVALENCE

- Each year, an estimated 1.5 million Americans sustain a TBI.
- An estimated 5.3 million Americans currently live with disabilities resulting from a TBI.
- TBIs cause more death and disability than any other neurological condition before the age of 50 years.
- The majority of TBI is seen primarily in males between the ages of 18 and 25 years (Brain Injury Association of America).

PRIMARY CAUSES

The primary causes leading to TBI are motor vehicle, motorcycle, or off-road vehicle accidents; falls; sports-related accidents; objects falling on the head; and interpersonal violence.

TYPICAL COURSE/PROGNOSIS

No two brain injuries are exactly the same; the course of a TBI is complex and can vary greatly between individuals. Early prediction of outcome and prognosis is difficult because of the complex interaction of various factors, including the cause, location, and severity of injury; age; length of posttraumatic amnesia; increased intracranial pressure; and/or alteration of consciousness. Accurate prognosis requires repeated observations over weeks or months to predict the level of recovery.

POSSIBLE SYMPTOMS/DEFICITS

Depending on the location and severity of the injury, deficits may be present in the areas of cognitive, behavioral/emotional, physical, and/or sensory impairments.

RANCHO LOS AMIGOS LEVELS OF COGNITIVE FUNCTIONING SCALE

The Rancho Los Amigos Scale, a nonstandardized method of organizing and describing clinical observations of cognitive performance in individuals with TBI, allows for better assessment of recovery and improved communication with families. The Rancho Los Amigos Scale is a widely used tool that divides stages of recovery into 10 levels of cognitive functioning that are useful for documenting and assessing progress.

- Level I: No response
- Level II: Generalized response
- Level III: Localized response
- Level IV: Confused, agitated
- Level V: Confused, inappropriate
- Level VI: Confused, appropriate
- Level VII: Automatic, appropriate
- Level VIII: Purposeful, appropriate, with stand-by assistance

- Level IX: Purposeful, appropriate, with stand-by assistance on request
- Level X: Purposeful, appropriate, modified independence

OT EVALUATIONS

- Rancho Los Amigos Levels of Cognitive Functioning Scale

Acute Stages of Recovery

- Glasgow Coma Scale (GCS): Not administered by occupational therapists but important for quantifying level of consciousness and predicting recovery with early treatment and prognostic indicators.
- Western Neuro Sensory Stimulation Profile (WNSSP)
- Coma Recovery Scale

Inpatient Rehabilitation

- Functional Independence Measure (FIM)
- Functional Assessment Measure (FAM)
- Assessment of Motor and Process Skills (AMPS)
- Loewenstein Occupational Therapy Cognitive Assessment (LOTCA)
- Kitchen Task Assessment (KTA)

Postacute Rehabilitation

- Canadian Occupational Performance Measure (COPM)
- Safety Assessment of Function and the Environment for Rehabilitation (SAFER)
- Interest Checklist

OT INTERVENTION

Acute Stages of Recovery

- Positioning
- AROM, AAROM, PROM exercises
- Sensory stimulation
- Splinting and casting
- Patient and family education and support

Inpatient Rehabilitation

- Optimize gross and fine motor functioning and abilities through meaningful tasks and activities
- Optimize visual-perceptual functioning and abilities through environmental adaptations, compensatory techniques, and assistive devices such as low-vision aids
- Maximize cognitive functioning and abilities with compensatory or remedial strategies that optimize the areas of orientation, attention, and memory

- Increase independence in ADL and IADL
- Patient and family education and support

Postacute Rehabilitation

- Community reintegration
- Maximize cognitive abilities in natural environments by teaching compensatory and adaptive cognitive strategies
- Environmental modifications and adaptive equipment
- Restore competence in ADL and IADL
- Participation in previous or new leisure activities
- Patient and family education and support

OT AND THE EVIDENCE

Occupational therapy plays an integral role as a part of an interdisciplinary rehabilitation team for individuals with TBI in multiple settings, including inpatient, outpatient, and community settings. Evidence has shown occupational therapy to be effective in improving occupational performance through participation in functional tasks and activities for individuals with TBI. Trombly, Radomski, Trexel, and Burnett-Smith (2002) concluded that participation in goal-specific outpatient occupational therapy that focuses on teaching compensatory strategies is strongly associated with the achievement of self-identified goals and the reduction of disability in adults with mild to moderate brain injury. Trombly, Radomski and Davis (1998) found that people with TBI who participated in outpatient occupational therapy showed a significant achievement of self-identified goals, independence, and satisfaction with their tasks performance after treatment. A study by Neistadt (1994) concluded that functional activities may be more effective than tabletop activities in promoting fine motor coordination in persons with TBI. Dirette (2002) found that clients with brain injury slowly developed awareness of their deficits when they were in situations that enabled then to compare current performance to performance prior to brain injury.

CAREGIVER CONCERNS

Families and caregivers require education and support for the many behavioral, emotional, and personality changes that can occur in an individual following a TBI. A study by Groom, Shaw, O'Connor, Howard, and Pickens (1998) concluded that caregiver stress level is significantly related to the presence of the neurobehavioral symptoms of inappropriateness, depression, and indifference that are often seen in individuals with TBI. The possible issues caregivers may encounter during recovery with an individual following TBI include the following:

- Management of agitation
- Personality and behavioral changes following injury
- Difficulty with community reintegration and adaptation
- Lack of awareness of deficits/denial
- Deficits in higher-level cognitive functions, including orientation, attention, and memory
- Disinhibition of inappropriate behavior
- Depression
- Long-term need for assistance/care
- Change in family and societal roles
- Safety concerns/awareness

RESOURCES

Associations

- Brain Trauma Foundation
  523 East 72nd Street
  8th Floor
  New York, NY 10021
  Telephone: 212-772-0608
  Fax: 212-772-0357

First-Person Accounts

- Crimmins, C. (2001). *Where Is the Mango Princess?* New York: Random House.
  Crimmins tells her personal story of the victories and losses she endured as the caregiver of an individual recovering from a severe brain injury. She describes issues ranging from the frustrations of dealing with doctors and insurance plans to the pain of caregiver issues.
- Meili, T. (2003). *I am the Central Park jogger: A story of hope and possibility.* Waterville, ME: Thorndike Press.
  Meili tells her personal experience of recovery from a violence-related TBI following an attack in Central Park. She focuses her book on the rehabilitation process, how brain injury affected her personal and professional life, and her outlook on living with a brain injury.

- Osborn, C. (2000). *Over my head: A doctor's own story of head injury from the inside looking out.* Riverside, NJ: Andrews McMeel.
  Dr. Osborn chronicles her rehabilitation process following a brain injury from the struggle to remaster basic skills to the pain of parting with her old identity as a young doctor and the challenge of building a new life.

XVI

Occupational Therapy Resource Summaries: Practice Settings

Settings Providing Medical and Psychiatric Services

PAMELA ROBERTS AND MARY EVENSON

ACUTE MEDICAL/SURGICAL CARE

Persons Most Likely to Benefit from Type of Care

- Need for medical or surgical stabilization, 24-hour physician and nursing care
- Typical diagnoses include: cerebral palsy, stroke, brain injury, spinal cord injury, neurological disease, cardiac disease, pulmonary disease, orthopedics, and cancer

Requirements for Admission to Setting

- Need for medical or surgical diagnosis or intervention
- Admitted from emergency room, direct admission, or transfer from another facility

Typical Setting

- Private hospital
- Community hospital
- Veteran's Administration hospital
- Specialty hospital

Typical Length of Stay

- Varies based on diagnosis
- Diagnostic related groups (DRGs)
- Short term, usually 1–2 weeks or less

Typical Services

- Trauma services
- Intensive care unit

- Medical services
- Surgical services
- Consultations by allied health care providers

Type of Occupational Therapy Service

- Direct or consultation

Role of Occupational Therapy

- OT role for trauma services and ICU may be direct or consultation including positioning, range of motion, splinting/casting, and sensory stimulation
- OT role for medical and surgical services may be direct or consultation. Safety assessment; assessment of client's abilities, roles, habits and routines. Functional survival skills such as eating/dysphagia, grooming, dressing, bathing, and toileting, functional transfers and mobility
- Recommendations for continued services at next level of care
- Discharge planning

Typical Precautions

- Evaluation and monitoring of vital signs (respiratory, cardiac, neurological, gastrointestinal, and immune systems)
- Monitor and evaluate vital signs as indicated (heart rate, blood pressure, and respirations)
- Postsurgical protocols as applicable
- Dietary restrictions per individual needs
- Fall prevention protocols

Discharge Disposition

- Home
- Board and care
- Retirement home
- Assisted living
- Skilled nursing facility
- Hospice
- Inpatient rehabilitation unit or hospital
- Community discharge with home health
- Community discharge with outpatient rehabilitation

Legislation and Funding/Payment

- Prospective payment system
- Private insurance or self-pay
- Managed care (PPO or HMO)
- Indemnity
- Workers' compensation
- Medicare
- Medicaid

INPATIENT REHABILITATION

Persons Most Likely to Benefit from Type of Care

- People who require a comprehensive rehabilitation program
- 75% of clients must have a diagnosis within the Centers for Medicare and Medicaid Services (CMS) thirteen diagnostic groups. CMS-13 Diagnostic Groups include: (1) Stroke, (2) Spinal Cord Injury, (3) Congenital Deformity, (4) Amputation, (5) Major Multiple Trauma, (6) Fracture of Femur, (7) Brain Injury, (8) Neurological Disorders, (9) Burns, (10) Active Polyarticular Rheumatoid Arthritis, Psoriatic Arthritis, and Seronegative Arthropathies, (11) Systemic Vasculidities with Joint Inflammation, (12) Severe or Advanced Osteoarthritis, (13) Knee or Hip Replacement if one of the following conditions are met: (a) Patient underwent bilateral knee or bilateral hip joint replacement surgery immediately preceding the IRF admission, (b) patient is extremely obese with a body mass index of at least 50 at the time of admission to the IRF, and (c) patient is age 85 or older at the time of the admission to the IRF

Requirements for Admission to Setting

- Transfer from a hospital, nursing home, or home
- Must be able to tolerate intensive therapy for a minimum of 3 hours of therapy for 5 out of 7 days
- Must require care from a multidisciplinary team with at least two disciplines
- Must meet medical necessity
- Must require 24–7 rehabilitation nursing
- Must require close monitoring by a physician with training in rehabilitation

Typical Setting

- Free-standing rehabilitation center
- Unit within hospital
- Veteran's Administration rehabilitation unit

Typical Length of Stay

- 2–4 weeks
- Target length of stay by case mix groups (CMGs)

Typical Services

- Rehabilitation physician, rehabilitation nursing, physical therapy, occupational therapy, speech-language pathology, therapeutic recreation, neuropsychology or psychology, social services, respiratory therapy, dietary, pharmacy, and other services by consultation

Type of Occupational Therapy Service

◆ Direct

Role of Occupational Therapy

◆ Comprehensive evaluation
◆ Participation in functional outcomes such as the Inpatient Rehabilitation Facility Patient Assessment Instrument (IRF-PAI)
◆ Self-care skills
◆ Functional mobility
◆ Functional mobility during ADL
◆ Communication during ADL
◆ Cognition during ADL
◆ Home management skills
◆ Community reintegration
◆ Discharge planning
◆ Recommendations for continued services at next level of care

Typical Precautions

◆ Monitor and evaluate vital signs as indicated (heart rate, blood pressure, and respirations)
◆ Postsurgical protocols as applicable
◆ Dietary restrictions per individual needs
◆ Fall prevention protocols

Discharge Disposition

◆ Home
◆ Board and care
◆ Retirement home
◆ Assisted living
◆ Skilled nursing facility
◆ Hospice
◆ Community discharge with home health
◆ Community discharge with outpatient rehabilitation

Legislation and Funding/Payment

◆ Prospective payment system
◆ Private insurance or self-pay
◆ Managed care (PPO or HMO)
◆ Indemnity
◆ Workers' compensation
◆ Medicare
◆ Medicaid

SKILLED NURSING/ TRANSITIONAL CARE

Persons Most Likely to Benefit from Type of Care

◆ People who require special, 24-hour care for either a short or extended period of time
◆ Same diagnoses as acute medical/surgical care

Requirements for Admission to Setting

◆ Bridge the gap with another level of care
◆ Admitted from acute care hospital
◆ Skilled intervention such as intravenous medication, wound care, etc.
◆ Disability with a new functional deficit

Typical Setting

◆ Unit in a hospital
◆ Free-standing nursing home

Typical Length of Stay

◆ Short term: variable not to exceed 100 days
◆ Long term: indefinite or as needed

Typical Services

◆ Physician, nursing, social services, activity therapy and/ or therapeutic recreation
◆ Physical therapy, occupational therapy, speech-language pathology
◆ Other services by consultation

Type of Occupational Therapy Service

◆ Direct
◆ Consultation
◆ Participation in the Minimal Data Set (MDS)

Role of Occupational Therapy

◆ Short-term care is more intensive with specified frequency
◆ Long-term care is by consultation
◆ Self-care skills such as eating/dysphagia, grooming, upper and lower body dressing, bathing, and toileting
◆ Mobility skills during ADL such as bed, chair, wheelchair transfers, toilet and tub/shower transfers, and functional mobility
◆ Home management and community skills such as car transfers, kitchen activities, public dining, care of pets, etc.

Typical Precautions

◆ Monitor and evaluate vital signs as indicated (heart rate, blood pressure, and respirations)
◆ Post surgical protocols as applicable
◆ Dietary restrictions per individual needs
◆ Fall prevention protocols

Discharge Disposition

◆ Home
◆ Board and care

- Retirement home
- Assisted living
- Inpatient rehabilitation
- Hospice
- Community discharge with home health
- Community discharge with outpatient rehabilitation

Legislation and Funding/Payment

- Prospective payment system
- Private insurance or self-pay
- Managed care (PPO or HMO)
- Indemnity
- Workers' compensation
- Medicare
- Medicaid

OUTPATIENT REHABILITATION

Persons Most Likely to Benefit from Type of Care

- Children or adults who can benefit from rehabilitation services due to functional limitations that interfere with abilities to participate in social roles and activities

Requirements for Admission to Setting

- Need for medical or surgical diagnosis or need for skilled intervention
- Admitted from a variety of places including institutional care or home

Typical Setting

- May be part of free-standing rehabilitation center, unit within the hospital, or Veteran's Administration hospital
- May be a satellite clinic (affiliated with a health care institution) or an independent, privately owned clinic

Typical Length of Stay

- Need for skilled intervention
- Number of visits varies depending on skilled need

Typical Services

- Physician referral may be required
- Self-referral for self-pay services

Type of Occupational Therapy Service

- Direct

Role of Occupational Therapy

- Self-care skills such as eating/dysphagia, grooming, upper and lower body dressing, bathing, and toileting

- Home management, community skills, work skills, driving
- Social participation such as student, worker, caregiver roles
- Therapeutic activities/exercise to remediate body structure/body function impairments

Typical Precautions

- Varies based on diagnosis

Discharge Disposition

- Incorporation into home and community activities

Legislation and Funding/Payment

- Prospective payment system
- Private insurance or self-pay
- Managed care (PPO or HMO)
- Indemnity
- Workers' compensation
- Medicare
- Medicaid

INPATIENT PSYCHIATRY

Persons Most Likely to Benefit from Type of Care

- People who require special, 24-hour care for either a short or extended period of time
- Some typical diagnoses based on the *DSM IV-TR* include depression, schizoaffective disorders, mood disorders, obsessive-compulsive disorders, anxiety, eating, and phobic disorders, etc.

Requirements for Admission to Setting

- Need for psychiatric diagnosis or intervention
- Admitted from the emergency room
- Direct admit
- Transfer from another facility
- Person who requires 24-hour monitoring for safety
- May be court ordered as in the case of forensic cases in which client's require secured (locked) units due to safety risk to self or others

Typical Setting

- Free-standing hospital
- Private hospital
- Unit within hospital
- State hospital
- Veteran's Administration hospital

Typical Length of Stay

- 1–3 weeks

Typical Services

- Psychiatry
- Psychology
- Nursing
- Mental health workers
- Social services
- Occupational therapy
- Therapeutic recreation
- Art therapy
- Expressive or music therapy
- Behavior management
- Other services by consultation

Type of Occupational Therapy Service

- Direct
- Consultation

Role of Occupational Therapy

- Assessment of client's abilities, roles, habits, and routines
- Safety assessment
- May administer the Allen Assessment of Cognitive Levels
- Recommendations for continued services at next level of care; discharge planning
- Individual and/or group intervention
- Functional skills such as self-care, home and community function
- Reinforce behavioral or therapeutic plan as indicated

Typical Precautions

- Unit may be locked
- 'Sharps' precautions to prevent self-injury
- Individualized medication/prescription plans and dietary or nutritional care plans
- Suicide precautions as relevant
- Behavioral guidelines for program participation per institution procedures

Discharge Disposition

- Home
- Skilled nursing facility
- Community discharge with partial hospitalization
- Community discharge with home health
- Community discharge with outpatient
- Outpatient

Legislation and Funding/Payment

- Private insurance or self-pay
- Medicare
- Medicaid
- SSI

PARTIAL HOSPITALIZATION

Persons Most Likely to Benefit from Type of Care

- People who require episodic focused psychiatric intervention
- Same diagnoses as inpatient psychiatry

Requirements for Admission to Setting

- Transition from inpatient or as an alternative to acute psychiatric hospitalization
- Structured program

Typical Setting

- Free-standing hospital
- Private hospital
- Unit within hospital
- Veteran's Administration hospital

Typical Length of Stay

- Usually 1–3 months

Typical Services

- Psychiatry
- Psychology
- Mental health workers
- Social services
- Occupational therapy
- Therapeutic recreation

Type of Occupational Therapy Service

- Direct
- Consultation

Role of Occupational Therapy

- Assessment of client's abilities, roles, habits, and routines
- Continuity of care for self-management goals with emphasis on productive living for home, community, and work
- Individual and/or group treatment
- Recommendations for continued services at next level of care

Typical Precautions

- Behavioral guidelines for program participation per institution procedures
- Requirements might include mandatory attendance or remaining drug-free

Discharge Disposition

◆ Outpatient

Legislation and Funding/Payment

◆ Private insurance or self-pay
◆ Medicare
◆ Medicaid
◆ SSI

LONG-TERM CARE (PHYSICAL AND MENTAL HEALTH)

Persons Most Likely to Benefit from Type of Care

◆ For people who require special, 24-hour care for an indefinite period of time and for whom a functional recovery may not be possible or lack of resources to be safe at home
◆ Same diagnoses as acute medical/surgical and inpatient psychiatry plus mental retardation

Requirements for Admission to Setting

◆ Transfer from a hospital, nursing home, or home
◆ Bridge gap between inpatient setting and home versus determine need for permanent placement
◆ Person needs assistance with activities of daily living

Typical Setting

◆ Free-standing hospital
◆ Private hospital
◆ State hospital
◆ Veteran's Administration hospital
◆ Free-standing nursing home
◆ Private nursing home
◆ Custodial care such as eating/dysphagia, grooming and bathing

Typical Length of Stay

◆ Variable
◆ Indefinite

Typical Services

◆ Physician/psychiatrists
◆ Nursing
◆ Mental health workers
◆ Therapy consultation as indicated for safety assessment, self-care skills and routines, positioning, functional mobility during ADL, adaptations, and caregiver training.

Type of Occupational Therapy Service

◆ Direct
◆ Consultation

Role of Occupational Therapy

◆ Individual assessment and interventions as indicated
◆ Consultant to program for activities of daily living, environmental adaptations, and behavior management

Typical Precautions

◆ Unit may be locked
◆ 'Sharps' precautions to prevent self-injury
◆ Fall prevention protocols as indicated

Discharge Disposition

◆ Home
◆ Community-based placement such as group home

Legislation and Funding/Payment

◆ Medicare Part B
◆ Medicaid
◆ Private insurance or self-pay supplement

Community-Based Settings for Children

LOU ANN GRISWOLD, MARY EVENSON, AND PAMELA ROBERTS

EARLY INTERVENTION

Type of Setting

Services are provided in the child's natural environment, where the child spends most of his/her time, e.g., home or child-care. The therapist may be employed by a profit or not-for-profit agency or hospital.

Recipients of Service

Infants and toddlers, up to 3 years of age and their families

Eligibility

Children who

◆ Have developmental delay in one or more areas of development or have a diagnosis that is likely to result in developmental delay
◆ Have an identified disability or condition or are at risk for developing a disability
◆ Demonstrate atypical behaviors noted by family members and a qualified professional
◆ Have circumstances that place the child and/or parent that places the child at risk for developmental delay

Each state also has its own specific eligibility criteria.

Length of Services

Depending on when the child enters early intervention, services may last for up to 3 years, at which time the child transitions to another setting of services. Progress is monitored and goals are rewritten annually.

Focus of Services

A team approach to enable family members to promote early child development including sensory-motor development, gross and fine motor skills,

communication, cognitive, and social-emotional development for their child. Services not only address the child's needs, as identified in collaboration with the child's family, but also include support for family members, using a family-centered model for service delivery.

Model of Service Delivery

The OT may see the child directly or provide indirect services through consultation to another team member who provides direct services to a child and family, using a transdisciplinary model of service delivery.

Role of Occupational Therapy

Collaborate with family and other professional team members to provide services that address the family's needs in promoting the young child's development. OT focuses on promoting parent-child interaction, activities of daily living—particularly feeding and play skills—while enhancing all aspects of development. OT expertise includes sensory-motor development leading to gross and fine motor skills, self-help skills, and social-emotional development.

Intervention Approach

- Establish performance skills, performance patterns, and client factors using occupation-based activities
- Prevent disability

Discharge

Transition to a preschool program or from all supports and services occurs by the child's 3rd birthday. Transition planning is essential to ensure continuity of services.

Legislation and Funding

Individuals with Disabilities Education Act (IDEA) ensures that infants and young children who meet eligibility requirements receive services. IDEA specifies that services address families' needs through development of a Family Service Plan, and that services are provided in natural settings (e.g., home or child care). Early intervention services are primarily funded by federal (IDEA) and state money. Private insurance and Medicaid also fund services.

PRESCHOOL

Type of Setting

Preschool provided through the public school system or private child-care/preschool setting. The preschool may be for all children, including those with identified special needs, or a preschool that provides education and related services to children with special needs.

Recipients of Service

Children who are 3 years and older, until they enter elementary school. The child's preschool teacher, who is a colleague, may also be a secondary recipient of service as she or he learns new strategies to support a child in the classroom.

Eligibility

Children who have an identified disability that fits one of the categories specified under IDEA are eligible for special education. Eligibility is determined using multiple sources of evaluation information gathered by qualified examiners. Children are eligible for occupational therapy if services will assist the child to participate in preschool activities.

Length of Services

Depending on when the child enters preschool, services may last for up to 3 years, at which time the child transitions to another setting of services. Progress is monitored and goals are rewritten annually.

Focus of Services

In the natural environment of preschool, the focus of preschool education typically is on pre-academic skills and social-emotional development. Some preschool teachers also include gross motor development in their early childhood education curriculum.

Model of Service Delivery

- Direct individual or group services to support a child's education and development
- Direct services to the whole class so that all children benefit from developmentally appropriate activities
- Consultation to the teacher to provide strategies that support the child's performance in the preschool program

Role of Occupational Therapy

The OT supports the child's preschool education program by carrying out or suggesting activities that promote the child's overall development and ability to fully participate in preschool activities. Often the OT will work closely with the other members of the preschool team to determine activities that address multiple areas of development simultaneously, based on a theme of learning determined by the teacher (e.g., dinosaurs, oceans, seasons of the year). OT expertise includes sensory-motor development leading to gross and fine motor skills and social-emotional development.

Intervention Approach

- Establish performance skills, performance patterns, and client factors using occupation-based activities
- Promote development
- Modify the environment or activity demands for better occupational performance

Discharge

Preschool services end when a child transitions into kindergarten or elementary school.

Legislation and Funding

Individuals with Disabilities Education Act (IDEA) specifies that occupational therapy services remain educationally relevant and support the child's ability to participate in preschool activities. IDEA also mandates that all eligible children receive a free and appropriate education to meet their needs and that special education and services should be provided in the least restrictive environment. Medicaid funds may also help support services, particularly assistive technology, for qualified children.

SCHOOLS

Type of Setting

Public or private schools: kindergarten through elementary school; middle school or junior high; high school

Recipients of Service

The student is the primary recipient of OT services. The student's teacher, who is a colleague, may also be a secondary recipient of service as she or he learns new strategies to support a student in the classroom.

Eligibility

Students who have an identified disability that fits one of the categories specified under IDEA are eligible for special education. Eligibility is determined using multiple sources of evaluation information gathered by qualified examiners. Students are eligible for occupational therapy if services will assist the student benefit from the special education program. All eligibility and service decisions are made by a student's individual education program (IEP) team, of which the student's parents are part. Students in private schools are not entitled to services under IDEA. Special education is provided in accordance with the school's mission.

Length of Services

Students may receive OT services, as determined eligible, for any number of years, until they graduate from high school or turn 21 years of age. Need for service is monitored and goals are rewritten annually. Every 3 years, a student must be re-evaluated for eligibility for special education and all related services, including occupational therapy.

Focus of Services

Occupational therapy is a related service, that is, OT supports a student's special education program. Services may focus on performing schoolwork tasks, organizing the student's daily schedule and materials, negotiating the cafeteria, or participating in recess and physical education. As students reach the point of planning for transition out of the school system, the focus of their special education program and occupational therapy broadens to include independent living and community participation needs after high school such as education, vocational training, employment, and activities of daily living. Some school districts are using OT services to support population needs within the school to address broad existing student needs or to prevent future problems.

Model of Service Delivery

- Direct individual or group services to support a student's special education program
- Direct services to the whole class so that all students benefit from activities
- Consultation to teachers or staff to provide strategies that supports the student's performance in schoolwork tasks and in participating in school activities (lunch, recess, physical education)

Role of Occupational Therapy

The OT supports the student's education program by carrying out or suggesting activities that promote the student's performance throughout the school day and ability to fully participate in school activities. In addition to knowledge of development, OT expertise includes performance analysis and task analysis and modification of activity demands and the environment.

Intervention Approach

- Establish performance skills, performance patterns, and client factors using occupation-based activities
- Modify the environment or activity demands for better occupational performance

Discharge

School-based OT services end when a student is no longer eligible for services or special education or when he or she transitions to community living by graduating or turning 21 years old.

Legislation and Funding

Individuals with Disabilities Education Act (IDEA) specifies that occupational therapy services remain educationally relevant and support the student's ability to participate in educational activities. IDEA mandates that all eligible students receive a free and appropriate education to meet their needs and that special education and services should be provided in the least restrictive environment. No Child Left Behind (NCLB) legislation also requires schools to be accountable for students' outcomes, including those with disabilities, and requires evidence-based practices be used. Medicaid funds may also help support services, particularly assistive technology, for qualified students.

PRIVATE PRACTICE

Type of Setting

Private clinic

Recipients of Service

Children of all ages may receive private services. Typically private occupational therapists provide services to augment those provided by the school-based therapist to address needs that extend beyond those related to education. Children may have needs that do not impede education and consequently do not qualify for OT services in school, so parents may seek private services.

Eligibility

Decreased performance in daily tasks or desired activities; decreased body function, such as poor processing of sensory input, delayed gross or fine motor development, or low self-esteem. The payer of services may have specific eligibility requirements to include standard scores on assessments. Out-of-pocket payment for services does not have eligibility stipulations.

Length of Services

Determined by the payer of services and may be limited to the number of visits based on the diagnosis. Unlimited length of services for out-of-pocket payment. Services may last from six months to several years.

Focus of Services

In the clinic setting, the focus is typically on enhancing occupational performance related to play, engaging in household chores, and performing personal activities of daily living. Enhanced performance is most often addressed through improving body function such as improving sensory processing or motor development.

Model of Service Delivery

- Direct individual or small group services
- Consultation to the parents to provide strategies that support the child's performance at home

Role of Occupational Therapy

Occupational therapy addresses the child's needs that may not be met at school. OT expertise includes sensory-motor development leading to gross and fine motor skills and social-emotional development. In private practice, the OT may focus more on body functions such as sensory processing, motor planning, and visual perception that provide a foundation for skills needed in school, activities of daily living, and play.

Intervention Approach

- Establish performance skills, performance patterns, and client factors using occupation-based activities, purposeful activities, and preparatory methods
- Promote development
- Modify the environment or activity demands for better occupational performance

Discharge

Children may be discharged to school-based occupational therapy services or to extracurricular activities that will continue to address their needs such as tai-kwon-do, horseback riding, soccer, and gymnastics.

Legislation and Funding

Funding sources include Medicaid, health insurance, federal grants and private pay. Each funding source has its own regulations and policies for reimbursement, including the diagnostic code to be used, number of visits allowed, or a dollar cap for services.

Community-Based Settings for Adults

LOU ANN GRISWOLD, MARY EVENSON, AND PAMELA ROBERTS

ADULT DAY SERVICES (SOCIAL, MEDICAL, DEMENTIA)

Community-based settings are for adults living at home with the need for socialization and supervision, medical services, and/or dementia supports.

Setting

Usually free-standing, but may be associated with other community programs or health agencies such as senior centers, mental health centers, rehabilitation centers, nursing homes, or hospitals

Goals of Setting

◆ Provide social/medical programming to increase the quality of life and health status of day care participants via three different types of programs:
  ◆ **Social:** Day programs with social goals provide social/recreational activities, meals, and some health supports.
  ◆ **Medical:** Medical day programs provide rehabilitation and medical services to enhance health status and independence for people with more severe health problems. The goal is to provide sufficient supports to forestall nursing home placement.
  ◆ **Dementia:** Day programs designed to meet the needs for people with Alzheimer's disease and related disorders focus on providing programming with cognitive supports that improve the quality of life for program participants

Occupational Therapy Role

◆ Consultative services including assistance with modifying and adapting activity programming for all three types of day programs
◆ Direct service including assessment of individuals related to ADL, IADL, safety, cognitive function, etc. OT intervention may be provided in medical and dementia oriented day programs to maintain a person's skills and performance patterns.

- Educational services to staff and family members regarding ADL, IADL, safety, fall prevention, etc.

Legislation and Funding

Day programs are regulated by state governments and may be funded through federal, state, county, city, or town budgets. Some may be funded through churches or other charitable organizations. Medicaid may fund participants who meet financial guidelines and require medical or dementia services. Some long-term care policies provide reimbursement for day programs. Scholarships and sliding fees may also be available.

ASSISTED LIVING FACILITIES

Population

Assisted living facilities provide residential care for elders who can no longer live independently but do not require the medical services of a skilled nursing facility. They may experience difficulty with ADL, IADL, safety, etc. caused by dementia, neurological impairment, or other medical problem.

Setting

Assisted living facilities are residential in nature with single or double rooms, small suites, or apartments. Common areas for meals and social activities are provided. Typically these facilities are small with fewer than 50 residents.

Goals of Setting

- Improve quality of life by providing a safe, supportive environment that enhances autonomy and choice
- Provide supervision and support for self-care and instrumental ADL, as needed
- Provide activity programming to foster social engagement and participation

Occupational Therapy Role

- Consultation to activity program to assure that the program engages residents in occupations of their choice, assist facility personnel to modify the physical and social environment to promote safety and independence
- Direct services including evaluation and intervention to increase independence in ADL and IADL, prevent falls, and enhance participation in social activities by restoring performance skills and patterns or modifying the environment or task demands
- Education of direct service staff regarding issues related to aging, occupation, and health promotion

Legislation and Funding

Medicare and Medicaid may be available for people with dementia or certain medical conditions. Long-term care insurance may cover assisted living. Private pay.

COMMUNITY MENTAL HEALTH PROGRAMS

Population

Community mental health programs serve clients who have chronic mental illness such as schizophrenia, bipolar disorder, borderline personality, etc.

Setting

Day programs are usually free-standing but are sometimes part of a larger community health facility.

Goals of Setting

- Provide ongoing support and structure to people who have mental health diagnoses to live in the community by promoting daily routine, a sense of belonging to the program community as well as the community at large
- Participants may come and go based on program interests or may be expected to participate all day, for a certain number of days per week, as determined by the participant, a case manager, desired long-term goals, and the protocol of the setting.
- A variety of professionals provide daily programming to address participants' needs such as social workers, recreational therapists, art therapists, and dance movement therapists. Many programs focus on participants supporting one another.

Occupational Therapy Role

- Direct services to establish or restore performance skills for work, self-care, and leisure including coping strategies, interpersonal skills, time management, and decision-making. Services are often offered within a natural context of task expectations (e.g., using a budget to grocery shop), preparing a balanced meal, and cleaning up.
- Consultative role with other staff regarding strategies to support participants' behavior and ability to cope with challenges in social environments and adapt tasks for participant success

Legislation and Funding

Community mental health is primarily funded through state money and Medicaid.

GROUP HOMES

Population

Group homes serve adults with chronic mental illness, cognitive dysfunction, or developmental disabilities who need 24-hour residential care.

Setting

Small residential facilities (typically 3 to 10 residents) designed to create support, structure, and stability in a home-like setting. A full-time staff supervises and supports residents.

Goals of Setting

- Provide quality of life with maximum independence and autonomy
- Residents are involved in choices regarding their care, rehabilitation programs, work settings, leisure opportunities, etc. Residents are encouraged to take responsibility for their home, health, and hygiene.
- Group homes are designed to foster the development of social networks within the facility itself and in the community. Many residents work in sheltered workshops or supported employment during the day.

Occupational Therapy Role

- Consultative role with staff regarding behavioral management techniques, development of social and recreational programs in the home and facilitating independence in ADLs and IADLs by establishing performance patterns or modifying environment or activity demands.
- Direct services, primarily evaluation, to identify skills and develop behavioral plans and involvement in social, recreational, and work-related activities.

Legislation and Funding

Group homes are largely funded through Medicaid, state and local support.

SHELTERED WORKSHOPS AND VOCATIONAL TRAINING PROGRAMS

Population

Sheltered workshops and vocational training programs are for adults, usually who have developmental disability or cognitive limitation, who work together in a facility to complete work tasks obtained by facility staff.

Setting

Usually free-standing facility

Goals of Setting

- Provide support to workers as they perform work tasks such as parts assembly, packing, sorting, etc. Workers paid at percent of work output based on their performance in relation to typical work performance.
- Provide social opportunities for workers during the day and after work hours
- Goal setting and supports for transition to supported or independent employment in the community

Occupational Therapy Role

Evaluate workers' performance skills to match the activity demands of various possible jobs. For intervention, occupational therapists serve as consultants to other staff at the sheltered workshop or vocational training program to:

- Modify the work environment or activity demands for more efficient performance
- Establish performance patterns and new performance skills
- Maintain performance skills that workers have acquired

Legislation and Funding

Revenue primarily comes from the contracting company for which the work is being done. State funding and grants from nonprofit agencies may help support the programs.

SUPPORTED EMPLOYMENT

Population

Supported employment is for people with severe chronic mental illness, mental retardation, learning disabilities, traumatic brain injury, and other severe disabilities who desire to work but have disabilities sufficient to preclude their employment in traditional settings without ongoing support to perform their job.

Setting

Work environments in the community

Goals of Setting

Supported employment is designed to enable people with severe disabilities to work in work settings in their community by providing job coaches, assistive technology, job training, transportation, and supervision. By working in the community, people with disabilities are more effectively integrated in work, social networks, and community life.

Job coaches assist the employee to work effectively to meet the demands of the job and work environment. Natural supports from co-workers and supervisors further enable social integration. The employee is paid and receives the same benefits as other workers and receives ongoing support to maintain employment as long as this is necessary.

Occupational Therapy Role

- ◆ Consultation with work sites to assure integration of the employee and to provide education regarding adaptation of the work site environment and activity demands.
- ◆ Direct services in the role of job coach to assist the employee to adapt to the work site and to function effectively by learning job skills and interacting appropriately with other employees at the work site. May be involved in matching prospective worker to potential work sites.

Legislation and Funding

Funding varies from state to state via Vocational Rehabilitation, Division of Mental Health, and Medicaid

WORK-RELATED PROGRAMS

Population

Work-related programs serve people with acquired disability who require rehabilitation to return to the workforce, either to their previous job or a new one that better fits their current functional capacity. Common problems of clients relate to work-related injuries such as repetitive trauma disorders, shoulder, back, hand injuries, acquired brain injury, or stroke.

Setting

Work or vocational programs may be in free-standing or a part of other facilities such as a hospital, rehabilitation center, or community program.

Goals of Setting

Provide rehabilitation services to enable the client to return to work. Physical therapists, occupational therapists and employment specialists work together to achieve client-related goals. Referral for certified vocational evaluation may be appropriate.

Occupational Therapy Role

- ◆ Evaluation of work tolerance including medical history, worker interview, job description, pain assessment, physical assessment, lifting/carrying ability, pushing/pulling, stopping, bending, kneeling, crawling, sitting, and standing
- ◆ Intervention focuses on the development of work related skills primarily using purposeful activities such as work simulation, and preparatory methods, e.g., work conditioning, work hardening, and exercise programs
- ◆ Modification of job demands when necessary and possible to better match the current skills of the client

Legislation and Funding

Division of Vocational Rehabilitation at the state level, workers' compensation, income from litigation, and private insurance.

Classroom Observation Guide	Griswold, L.	Griswold, L. (1994). Ethnographic analysis: A study of classroom environments. *American Journal of Occupational Therapy, 48,* 397–402.	Children	Helps therapists understand classroom context	Activities of classroom settings; people in classroom settings; communication in classroom settings
Clinical Test of Sensory Integration and Balance (CTSIB)	Shumway-Cook, A., and Horak, F. B.	Shumway-Cook, A., & Horak, F. B. (1986). Assessing the influence of sensory interaction on balance: Suggestions from the field. *Physical Therapy, 66,* 1548–1550.	All	To assess a patient's ability to tolerate varied surfaces and sensory conditions	Balance; interaction of ocular, vestibular, and musculoskeletal systems
Cognitive Assessment of Minnesota (CAM)	Rustad, R. A., DeGroot, T. L., Jungkunz, M. L., Freeberg, K. S., Borowick, L. G., and Wanttie, A. M.	Harcourt Assessment, Inc. Attn: Customer Service P.O. Box 599700 San Antonio, TX 78259 (800)211-8378 Fax: (800) 232-1223	Adults	Screens a wide range of cognitive skills in order to identify general problem areas	Attention; memory; visual neglect; math; ability to follow directions; judgment
Cognitive Performance Test (CPT)	Burns, T.	Theressa Burns, OTR GRECC 11G Veterans Affairs Medical Center One Veterans Drive Minneapolis, MN 55417	Adults	Assesses how cognitive processing deficits affect performance of common activities	Cognitive processing
Community Adaptive Planning Assessment	Spencer, J., and Davidson, H.	Spencer, J. & Davidson, J. (1998). The Community Adaptive Planning Assessment: A clinical tool for documenting future planning with clients. *American Journal of Occupational Therapy, 52(1),* 19–30.	Adults	Examines major occupations of an individual at times of expected change	Activities involved in occupation; persons involved and their roles; physical setting; value of the occupation to self and others

Community Integration Measure	McColl, M. A., Davies, D., Carlson, P., Johnston, J., and Minnes, P.	McColl, M. A., Davies, D., Carlson, P., Johnston, J., & Minnes, P. (2001). The community integration measure: development and preliminary validation. *Archives of Physical Medicine and Rehabilitation, 82,* 429–34.	Adults	Appraise an individual's views about connecting to community	Integration into community
Community Integration Questionnaire	Willer, B., Rosenthal, M., Kreutzer, J., Gordon, W., and Rempel, R.	Centre for Research on Community Integration at the Ontario Brain Injury Association 3550 Schmon Parkway Thorold, Ontario L2V 4Y6, Canada	Adults	Helps clients examine the extent of their community participation	Household activities; shopping; errands; leisure activities; visiting friends; social events; productive activities
Competency Rating Scale	Prigatano, G.	Prigatano, G. P. *Neuropsychological rehabilitation after brain injury.* Baltimore, MD: Johns Hopkins University Press. 1986. For more information, contact: Tessa Hart, PhD. MossRehab TBI Model System Philadelphia, PA 215-456-5925.	Adult	Self-report instrument asks the client to rate his/her degree of difficulty in a variety of tasks and functions	Self-awareness following traumatic brain injury
Comprehensive Trail-Making Test (CTMT)	Reynolds, C. R.	PRO-ED, Inc. 8700 Shoal Creek Blvd. Austin, TX 78757 (800) 897-3202	11 to 74 years	To evaluate and diagnose of brain injury and other forms of central nervous system compromise	Visual search and sequencing; attention; concentration; resistance to distraction; and cognitive flexibility (or set-shifting)
Computer Attitude Scale	Loyd, B. H., and Gressard, C.	Loyd, B. H., & Gressard, C. (1984). The effects of sex, age, and computer experience on computer attitudes, *AEDS Journal, 18,* 67–77.	Adults	Assesses general attitudes toward computers	Computer anxiety: computer confidence; computer liking
Computer System Usability Questionnaire	Lewis, J.	Lewis, J. R. (1995) *IBM Computer Usability Satisfaction Questionnaires: Psychometric Evaluation and Instructions for Use. International Journal of Human-Computer Interaction, 7*(1), 57–78	All ages	Can be used to evaluate specific software programs for individuals	Usefulness; information quality; interface quality

Contextual Memory Test (CMT)	Toglia, J. P.	Harcourt Assessment, Inc. Attn: Customer Service P.O. Box 599700 San Antonio, TX 78259 (800)211-8378 Fax: (800) 232-1223	18 years and up	To assess awareness of memory capacity, use of strategy, and recall	Memory strategies for task completion
Coping Inventory	Zeitlin, S.	Scholastic Testing Service 480 Meyer Road Bensonville, IL 60106-1617 (800) 642-6787	Observation form for 3 to 16 years; self-rated form for 15 years to adult	To assess adaptive and maladaptive coping habits, skills, and behaviors	Coping with self; coping with environment; use of personal resources; initiation of activity
Cost of Care Index	Kosberg, J., and Cairl, R.	Kosberg, J. & Cairl, R. (1986). The cost of care index: A case management tool for screening informal care providers. *The Gerontological Society of America, 26, 273–278.*	Adults	Identifies concerns of families providing care to elders	Personal and social restrictions; physical and emotional health; value placed on caregiving; characteristics of care recipient; and economic costs
Craig Handicap Assessment and Report Technique (CHART)	Whiteneck, G., Charlifue, S., Gerhart, K., Overholser, J., and Richardson, G.	Craig Hospital Research Department 3425 S. Clarkson Street Englewood, Colorado 80113 (303) 789-8202 Dave Mellick, MA	Adult	Assess behaviors related to participation	Orientation; physical independence; mobility; occupation; social integration; economic self-sufficiency

Craig Hospital Inventory of Environmental Factors (CHIEF and CHIEF short form)	Craig Hospital	Harrison-Felix, C. (2001). The Craig Hospital Inventory of Environmental Factors. *The Center for Outcome Measurement in Brain Injury.* http://www.tbims.org/combi/chief http://www.craighospital.org/Research/Disability/CHIEF%20Manual.pdf	16 to 95 years	Designed to assess the frequency and magnitude of perceived physical, attitudinal, and policy barriers that keep people with disabilities from doing what they want or need to do	ADLs; IADLs
Crawford Small Parts Dexterity Test (CSPDT)	Crawford, J.	Harcourt Assessment, Inc. Attn: Customer Service P.O. Box 599700 San Antonio, TX 78259 (800)211-8378 Fax: (800) 232-1223	Adult	Assess dexterity and fine motor skills in handling small tools and parts; determine whether your applicant has the skills vital in positions requiring agility and strong dexterity	Eye-hand coordination; fine motor skills
Daily Activities Checklist	Brown, C., Hamera, E., and Long, C.	Brown, C., Hamera, E., & Long, C. (1996). The Daily Activities Checklist: A functional assessment for consumers with mental illness living in the community. *Occupational Therapy in Health Care, 10*(3), 33–44.	Adults	Examines engagement of persons with mental illness in social settings	ADLs; community living skills; socialization; quality of daily life
Daily Activities Questionnaire (DAQ)	Oakley, F., Sunderland, T., Hill, J. L., Phillips, S. L., Makahon, R., and Ebner, J. D.	Oakley, F., Sunderland, T., Hill, J. L., Phillips, S. L., Makahon, R., & Ebner, J. D. (1991). The Daily Activities Questionnaire: a functional assessment for people with Alzheimer's disease. *Physical and Occupational Therapy in Geriatrics, 10,* 67–81.	Adults	Assesses instrumental and self-care activities of daily living of people diagnosed with Alzheimer disease	ADLs; IADLs
Daily Activity Diary	Follick, M. J., Ahern, D. K., and Laser-Wolston, N.	Follick, M. J., Ahern, D. K., & Laser-Wolston, N. (1984). Evaluation of a daily activity diary for chronic pain patients. *Pain, 19,* 373–382.	Adults	To examine time use in relation to pain	Time spent sitting, standing, reclining and in productive activities
DeGangi-Berk Test of Sensory Integration	Berk, R. A., and DeGangi, G. A.	Western Psychological Services 12031 Wilshire Boulevard Los Angeles, CA 90025 800-648-8857	3 to 5 years	To measure sensory integration in preschoolers and to detect sensory integrative dysfunction	Postural control; bilateral motor integration; reflex integration

Motor-Free Visual Perception Test, 3rd Edition (MVPT-3)	Colarusso, R. P., and Hammill, D. D.	Academic Therapy Publications 20 Commercial Blvd. Novato, CA 94949 800-422-7249	4 to 11 years	To test visual perception without motor involvement	Spatial relationships; visual discrimination; visual figure ground; visual closure; and visual memory
Movement Assessment Battery for Children (Movement ABC)	Henderson, S. E., and Sugden, D. A.	Harcourt Assessment, Inc. Attn: Customer Service P.O. Box 599700 San Antonio, TX 78259 800-211-8378 fax: 800-232-1223	4 to 12 years	To assess children's motor skills in children with motor impairments	Static balance; dynamic balance; manual dexterity; speed of movement; eye-hand coordination; problem-solving skills
Movement Assessment for Infants (MAI)	Chandler, L., Andrews, M., Swanson, M., and Larson, A.	Chandler, L., Andrews, M., Swanson, M., & Larson, A. (1980). *Movement assessment of infants: A manual.* Rolling Bay, WA: Authors.	Birth to 12 months	To differentiate between normal variance among developing infants versus developmental delay	Motor function; neurological function
Multidimensional Functional Assessment Questionnaire	Duke University Center for the Study of Aging and Human Development	Duke University Center for the Study of Aging and Human Development. (1978). *Multidimensional functional assessment: The OARS methodology.* Durham, NC: Author.	Adults	Plan optimal community living arrangements	Functional level of individual; community service use and perceived need for services
Multiphasic Environmental Assessment Procedure—Architectural Features Checklist (MEAP)	Moos, R., and Lemke, S.	Moos, R. & Lemke, S. (1979). Multi-Phasic Environmental Assessment Procedures (MEAP): Preliminary Manual, Palo Alto, CA, *Social Ecology Laboratory,* Stanford University School of Medicine.	Older adults	To evaluate care settings for older adults	Accessibility; safety

Title	Author(s)	Reference / Contact	Age	Purpose	Domains
Multiple Errands Test	Shallice, T., and Burgess, P. W.	Shallice, T., & Burgess, P. W. (1991). Deficits in strategy application following frontal lobe damage in man. *Brain, 114,* 727–741.	Adolescents to adults	To assess the executive function that allows an individual to act on their own initiative and to solve problems in a relatively open ended situation	Executive function, initiation and problem solving involved in activities of daily living
Multiple Sclerosis Impact Scale (MSIS-29)	Fitzpatrick, R., Hobart, J., Lamping, D. L., Riazi, A. and Thompson, A.	Fitzpatrick, R., Hobart, J., Lamping, D., Riazi, A., & Thompson, A. (2001). The Multiple Sclerosis Impact Scale (MSIS-29): A new patient-based outcome measure. *Brain, 124,* 962–973.	Adults	To measure the physical and the psychological impact of multiple sclerosis from the patient's perspective	Disability/physical functioning; quality of life
Multiple Sclerosis Quality of Life—54 Instrument (MSQOL-54)	Vickrey, B. G., Hays, R. D., Harooni, R., Myers, L. W., and Ellison, G. W.	Dr. Barbara Vickrey Health Services Research Center UCLA Wilshire Center 10920 Wilshire Blvd., Suite 300 Los Angeles, CA 90024-6505 bvickrey@ucla.edu.	Adults	Measures quality of life in people diagnosed with multiple sclerosis	Physical function; role limitations-physical; role limitations-emotional; pain; emotional well-being; energy; health perceptions; social function; cognitive function; health distress; overall quality of life; sexual function
Multiple Sclerosis Quality of Life Inventory (MSQLI)	National Multiple Sclerosis Society Consortium of Multiple Sclerosis Centers	Director of Health Care Delivery and Policy Research National Multiple Sclerosis Society Nicholas LaRocca, PhD 733 Third Avenue 3rd floor New York, NY 10017 212.476.0414 nicholas.larocca@nmss.org http://www.nationalmssociety.org/docs/HOM/MSQLI_Manual_and_Forms.pdf	Adults	Measures quality of life in adults with multiple sclerosis	Quality of life

Assessment Title	Author(s)	Publisher and/or Contact Information	Ages	Stated Purpose	Areas Assessed
Sensory Processing Measure (SPM) Home Form	Parham, L. D. and Ecker, C.	Western Psychological Services 12031 Wilshire Boulevard Los Angeles, CA 90025 800-648-8857	5 to 12 years	To provide a complete picture of a child's sensory processing difficulties in the home	Visual; auditory; tactile; proprioceptive; vestibular
Sensory Processing Measure (SPM) School Form	Miller-Kuhaneck, H., Henry, D., and Glennon, T.	Western Psychological Services 12031 Wilshire Boulevard Los Angeles, CA 90025 800-648-8857	5 to 12 years	To provide a complete picture of a child's sensory processing difficulties at school	Visual; auditory; tactile; proprioceptive; vestibular
Sensory Profile; Adolescent/Adult Sensory Profile; Infant/Toddler Sensory Profile	Dunn, W.	Harcourt Assessment, Inc. Attn: Customer Service P.O. Box 599700 San Antonio, TX 78259 800-211-8378 fax: 800-232-1223	Sensory Profile: 3 to 10 years; Adolescent/Adult: 10 years and up; Infant/Toddler: 0 to 36 months	To determine how well a subject processes sensory information in everyday situations and to profile the sensory system's effect on functional performance	Sensory processing, modulation, and behavioral and emotional responses
Short Child Occupational Profile (SCOPE)	Bowyer, P., Ross, M., Schwartz, O., Kielhofner, G., & Kramer, J	www.moho.uic.edu	2 to 21 years	To assess a child's capacity for occupational functioning	Volition; habituation; motor skills; and environment
Skills Assessment Module (SAM)	Rosinek, M.	Rosinek, M. (1985). *Skills Assessment Module.* Athens, GA: Piney Mountain Press.	Adults	To attain a baseline of a client's ability to perform job-simulated tasks	Motor and process skills in relation to job tasks
Social Interaction Scale (SIS)	Trower, P., Bryant, B, and Argyle, M.	Trower, P., Bryant, B., & Argyle, M. (1978). *Social skills and mental health.* London: Methuen.	Adults	To rate social behavior that is exhibited during a semi-structured interview	Social competence; voice quality; nonverbal communication; conversation

Social Skills Rating System	Gresham, F. M., and Elliot, S. N.	Pearson Assessments P.O. Box 1416 Minneapolis, MN 55440 800-627-7271	3 to 18 years	Rates social behaviors believed to affect areas such as teacher-student relationships, peer acceptance, and academic performance	Social skills (cooperation, assertion, responsibility, empathy, and self-control); problem behaviors; and academic competence (teacher ratings of reading, math performance, general cognitive functioning, motivation, and parental support)
Sociospatial Support Inventory	Rowles, G.	Rowles, G. (1983). Geographical dimensions of social support in rural Appalachia (pp. 111–130). In G. Rowles & R. Ohta (Eds.), *Aging and milieu: Environmental perspectives on growing old.* New York: Academic Press.	Adults	Catalyst for examining how an individual can evaluate alternative ways to manage community living support arrangements	Perception of support in environment
Source Book	Kelly, C., and Snell, K.	Kelly, C. & Snell, K. (1989). *The source book: Architectural guidelines for barrier free design.* Toronto, ON: Barrier-Free Design Centre.	Adults	To identify architectural barriers in the home, work, and community	Home, work, community environments
Spinal Functions Sort	Matheson, L. N., and Matheson, M. L.	EPIC 188 Woodlands Place Court St. Charles, MO 63303 636-724-4556 fax: 636-898-0954	Adult	To quantify the subject's perception of ability to perform work tasks that involve the spine	Perception of work tasks
Spiritual Well-Being Scale	Bufford, R., Paloutzian, R., and Ellison, C.	Ellsion, C. (1983). Spiritual well-being: Conceptualization and measurement. *Journal of Psychology and Technology, 11*(4), 330–340. http://www.lifeadvance.com/	All ages	Catalyst to explore various forms of spirituality	Spirituality

Glossary
The following definitions are drawn from the chapters in this book and are intended as a resource for understanding. Chapter numbers appear in parentheses at the end of each definition so that readers can refer to the cited chapters for concepts and definitions listed here. The Glossary also includes definitions from the draft Occupational Therapy Practice Framework. These definitions are indicated by the abbreviation OTPF-II. Readers should cite the appropriate chapter authors or original citations when referring to these constructs.

Accreditation Council of Occupational Therapy Education of the American Occupational Therapy Association (ACOTE)   Maintains standards and accredits occupational therapy education programs primarily in the United States.

Active Range of Motion (AROM)   Arc of motion through which the joint passes when moved by muscles acting on the joint (54).

Activities of Daily Living (ADL)   Activities oriented toward taking care of one's own body, also is referred to as basic activities of daily living (BADLs)/ and /personal activities of daily living (PADLs); activities are essential for survival and well-being (OTPF-II).

Activity   Abstract idea about the kinds of things individuals do and the way they typically do them in a given culture (35).

Activity Analysis   Analysis of how an activity is perceived to be typically done in the relevant culture, identifying typical demands and performance skills for an activity (35).

Activity Choices   Activities that are engaged in during play and leisure. Activities that individuals or groups select to enact (52).

Activity Interests   Affective responses to play and leisure activities and perceptions and awareness of self and environments in relation to play and leisure activities. Affective and intellectual responses to options for engagement (52).

Adaptation   Changing task demands so they are consistent with the individual's ability level; may involve modification by reducing demands, use of assistive devices, or changes in the physical or social environment (35). Internal change in the functional state of the person as a result of increased relative mastery over occupational challenges (45). A change in response approach that the client makes when encountering an occupational challenge (OTPF-II).

Adaptation Gestalt   Relative balance of sensorimotor, cognitive, and psychosocial functioning that the individual creates internally in order to carry out an adaptive response (45).

Adaptive Capacity   Apparent capability of the individual to perceive the need for change and draw from a repertoire of adaptive responses that will enable him or her to experience mastery over the environment (45).

Adaptive Response or Adaptive Interaction   An appropriate action in which the individual responds successfully to some environmental demand; interactions between an individual and the environment in which the individual meets the demands of the task (59).

Adaptive Response Subprocess   Internal process through which an individual generates, evaluates, and integrates new adaptations into his or her person (45).

Adaptiveness   Ability the individual demonstrates in response to challenging, novel situations that call for an adaptive response (45).

Adequacy   Measure of performance indicating the efficiency of the action or process used to execute tasks and the acceptability of the outcome or product of that action (46).

Administration   Process of guiding an organization through the authoritative control of others completed by the governing body of the organization (67).

Administrative Controls   Changes in the nature of work such as scheduling, worker rotation, or assignment of work tasks (51).

Administrative Supervision Aspect of supervision directed toward managing the day-to-day work performance and process; includes tasks such as scheduling, monitoring performance, and delegating (68).

Adrenal glands Organs resting on top of the kidneys that produce the majority of hormones in the body linked to stress responses and arousal, including epinephrine, norepinephrine, and cortisol (56).

Advocacy Active support or pursuit of public policy and resource allocation decisions within political, economic, and social systems and institutions to directly affect people's lives (OTPF-II).

Ageism Stereotypic and often negative bias against older adults; a form of discrimination based on age (7).

Agnosia Inability to recognize familiar objects in spite of intact sensory capacities (57).

Allostasis (allostatic) A state of change and refers to active body responses and adaptations to environmental demands; the human stress response is an example of allostasis (56).

Allostatic Load (See also *Stress.*) A state of chronic stress (chronic allostasis) (56).

Alpha-Amylase Digestive enzyme, linked with sympathetic nervous system/sympathetic adrenomedullary system (SNS/SAM) activation (56).

American Occupational Therapy Association (AOTA) National professional association for occupational therapy with voluntary membership that represents and promotes members' interests.

American Occupational Therapy Foundation (AOTF) Nonprofit organization dedicated to expanding and refining the knowledge base of occupational therapy; provides support to research and education through grants and scholarships.

Antigroup Destructive forces in groups with potential for creative resolution (37).

Apraxia Inability to perform motor activities although sensory motor function is intact and the individual understands the requirements of the task (57).

Arena Place in which activities occur (35).

Arousal Level of alertness and responsiveness to stimuli (59).

Assessment Specific method, tool, or strategy that is utilized as part of the evaluation process (48, 50).

Assessment Evidence Research findings that test the quality of clinical assessment procedures (30).

Attention The cognitive ability to focus on a task, issue, or object (57).

Auditory Scanning Method of scanning used for a person who cannot see in which each option is announced aloud prior to selection (61).

Autonomic Nervous System (ANS) Portion of the nervous system that regulates smooth muscle activity, including heart and other organ functions, as well as both allostatic and homeostatic activities, including breathing, cardiac activity, cell repair, digestion, sleep, metabolic activity, and stress responding. The ANS has two branches, sympathetic and parasympathetic, that generally exert opposite effects on body organs and systems (56).

Aversion to Movement A type of sensory modulation dysfunction characterized by autonomic nervous system reactions to movements that most individuals would consider nonnoxious; thought to be the result of poor processing of vestibular information (59).

Balance Ability to maintain the body in equilibrium (synonym: *Stability*) (55).

Balance of Excitation and Inhibition Mediates input and output in the brain. Too much excitation leads to overreaction; too much inhibition leads to failure to notice and respond to the world. At each synapse and within neuron systems, there is a continuous negotiation between the excitation and inhibition messages that are available. There has to be enough excitation to override the inhibition in order to get an action (58).

Being in Place Sense of comfort and belonging stemming from the totality of physical, cognitive, emotional, imaginative, and historical habitation of an environment (8).

Beliefs Any cognitive content that an individual holds as true (OTPF-II).

Bilateral Motor Coordination Using both sides of the body in a smooth, coordinated way (59).

Biofeedback Use of instruments that help individuals to recognize how their bodies are working and teach them how to control patterns of physiological functioning (56).

Biological Needs Things that are essential to individual and species survival, including sustenance, self-care, shelter, and safety (5).

Biomarker Biologic or physiologic characteristic that can be objectively measured by using specialized machines (e.g., PET scanners) or assay procedures (e.g., salivary cortisol); assumed to be a window into the structural and physiological processes of a functioning body (56).

Blocked Practice Rote schedule of practice that involves repetition of one task before the next task is introduced (54).

Body Functions Physiological processes of the body (53).

Body Scheme Unconscious mechanism underlying spatial motor coordination that provides the central nervous system with information abut the relationship of the body and its parts to environmental space (59).

Body Structures Anatomical parts of the body such as bones and organs (53).

Boundary Crossing Ways in which people who come from different lived worlds and have different life experiences find commonalities and areas of mutual interest, bridge differences, negotiate multiple and diverse perspectives, develop understandings, and respect multiple and, at times, divergent perspectives (4).

Capacities Grounded in the biological features of *Homo sapiens* shaped by genetic heritage and occupational history; include strength, speed, dexterity, agility, gracefulness, cardiovascular fitness, insight, cunning, know-how, wisdom, thoughtfulness, tenderness, and so on (5). Generic abilities (e.g., attention, proprioception, joint mobility) inherent to people and task-specific skills such as dressing, meal preparation, Website designing, and playing wheelchair basketball (46).

Case Management Collaborative process of assessing, planning, implementing, coordinating, monitoring, and evaluating options and services to meet an individual's health needs through communication and available resources to promote high-quality cost effective outcomes (51).

Catecholamines Epinephrine (also known as adrenaline), norepinephrine (also known as noradrenaline), and dopamine; also known as biogenic amines, a type of amino acid, catecholamines are hormones produced by the adrenal glands, sympathetic nervous system, and brain; exert effects on organs and structures throughout the body and brain (56).

Centers for Disease Control (CDC) Principal agency in the U.S. government for protecting the health and safety of all Americans and for providing essential human services, especially for those people who are least able to help themselves (17).

Centers for Medicaid and Medicare Services (CMS) U.S. government agency whose mission is to ensure effective, up-to-date health care and coverage and to promote quality care for beneficiaries (17).

Central Tendency Average or majority attribute (e.g., mean, median, mode) among individuals in a population (30).

Centrifugal Control Most basic central nervous system operation; the brain's ability to regulate its own input; accomplished suppression, divergence, and convergence (58).

Class Ranking of people into a hierarchy within a culture, arising from interdependent economic relationships such as "middle class," "upper class," or "lower class" (7).

Client Individual, agency, organization, or government entity that contract with the consultant for a specific scope of work (70). Recipients of service may include individuals and other people relevant to the individual's life, including family, caregivers, teachers, employers, and others who may also help or be served indirectly; organizations such as business, industries, or agencies; and populations within a community (OTPF-II).

Client-Centered Philosophy of service committed to respect for and partnership with people receiving services (18). Emphasizes the individual recipient of service and a focus on developing, restoring, or adapting the individual's skills and organizing and using assistance available in natural supports from family and friends (19).

Clinical Reasoning Process used by practitioners to plan, direct, perform, and reflect on client care. See *Professional Reasoning* for a term that is considered to be broader (32).

Clinical Supervision (synonym: *Supervision*) (68).

Clinical Utility Ease and efficiency in the use of a test and the clinical relevance and meaning of the information that it provides (47).

Clonus Movement disorder characterized by rapid successive contractions and relaxations (55).

Closed Skills Stereotypical tasks with little trial variability and low information processing demands (55).

Coaching Providing verbal expectations and support to help an individual engage in therapy and sustain growth or changes (35).

Cognition Mental processes including attention, memory, motivation, emotional control, motor control, sensory processing, and thinking (55). Ability to think and reason to solve problems (57).

Collaboration Process through which practitioners and clients discuss client priorities, set goals, make decisions about intervention options, and work together in mutual effort and partnership toward goals (33).

Collaborative Supervision Involves one or more supervisors working with multiple students with all participants viewed as more equal partners in the learning process (26).

Collusion Working with others in a closed or secretive fashion, often to avoid a perceived negative consequence (37).

Community Sharing of an area, interests, and interactions, as well as a sense of shared identity (19).

Community Based Emphasizes delivery of services in locations within a client's local places or environments of community living (19).

Community Centered Emphasizes the community as a recipient of intervention and a focus on accessibility and acceptance within physical, social, and cultural environments (19).

Community Development Community consultation, deliberation, and action to promote individual, family, and communitywide responsibility for self-sustaining development, health, and well-being (18).

Community Supervision (synonym: *supervision*) (68).

Competence Developed and maintained practitioner knowledge, critical reasoning, interpersonal abilities, performance skills, and ethical reasoning (70).

Competencies Explicit statements that define specific areas of practitioner expertise and are related to effective or superior performance in a job (25).

Competency Characteristics Intrinsic to the practitioner; include such aspects as expert knowledge and skills, motivation to change performance, positive self-concept to become proficient, attitudes conducive to learning, and valuing of learning (25).

Competent Successfully performing a behavior or task as measured according to a specific criterion (25).

Conditioning Designing situations that increase or decrease the likelihood of a behavior being performed (36).

Construction Ability Ability to perform the sequences of movement involved in producing two- or three-dimensional representations as in drawing or assembling tasks (59).

Consultant Individual retained by an individual, group, agency, organization, or government entity to provide expert advice and recommendations according to an established agreement between two parties (70).

Consultation Process Type of intervention in which practitioners use their knowledge and expertise to collaborate with the client; involves identifying the problem, creating possible solutions, trying solutions, and altering them as necessary for greater effectiveness; consultant is not directly responsible for the outcome of the intervention (70).

Context Variety of interrelated conditions (cultural, physical, social, spiritual, temporal, and virtual) within and surrounding the client that influence performance (57, 70).

Contextual Features Cultural, physical, social, personal, spiritual, temporal, and virtual aspects of home, school, work, and community settings that facilitate or hinder participation (52).

Continuing Competence A practitioner's evolving or lifelong capacity to perform changing responsibilities as a part of professional role performance (25).

Continuing Competency Focuses on the regularity of meeting standards for current role performance regardless of the dynamic nature of professional practice (25).

Contract Agreement or promise to perform certain work (70).

Contraindications A therapeutic procedure that could potentially harm a client because of the client's condition or medications (39).

Control Enhancers Means of extending the capabilities of a client with an assistive device so as to preserve the ability to use a direct selection method (61).

Controlling Establishing performance standards, measuring, evaluating, and correcting performance (67).

Convergence Bringing input together from many sources; in the sensory systems, input from multiple sensory inputs converge so that the brain can create a more organized response (59).

Co-occupation Shared occupations in which participants are active agents (35).

Coordination An automatic response that is monitored primarily through proprioceptive sensory feedback (55).

Coordinative Structure Aggregate of subsystems organized around a specific goal directed movement (55).

Cortisol Corticosteroid hormone released from the adrenal glands via a complex system, the hypothalamic-pituitary-adrenal axis (HPA); sustains metabolic activity, increased vigilance, and increased blood pressure, among other processes, such that the individual can adapt to environmental challenges that last longer than a few minutes (56).

Countertransference Therapist's subjective and objective responses to group members (37).

Credentialing Process of authentication of qualifications in order to have the authority to perform a skilled service within specified limits (25).

Credentials Abbreviations after a person's name that designate that person's educational level and/or professional designation (39).

Cultural Myth Unfounded or poorly founded belief about a human group that is given uncritical acceptance by members of another group and that operates in support of existing or traditional practices and institutions (6).

Cultural Practices Familiar or repeated activities shared with others in a community; carry normative expectations and are given significance beyond the immediate goal of the activity (2). Familiar occupations carried out in similar ways by members of a community; occupations are given significance beyond their immediate outcome (3).

Cultural Relativism Perspective that holds that there is no single truth, yielding multiple truths and a situation-based ethic (27).

Cultural Stereotype Mental picture based on myth that leads people to associate a characteristic or set of characteristics with a particular group of others (6).

Degrees of Freedom The individual components (cells, tissues, organs, subsystems) of a system (e.g., human being) that can define that system and can be controlled and organized in any number of ways (55).

Descriptive Evidence Research findings that describe the experiences and needs of individuals in a clinical population (30).

Determinants of Health Range of personal, social, economic, and environmental factors that determine the health status of individuals or populations (18).

Developmental Model of Supervision Framework that outlines four different phases of the learner and supervisor relationship: directive, coaching, supportive, and delegation (26).

Dexterity Type of fine coordination that is mostly demonstrated in the use of the upper extremity (55).

Diagnostic Related Groups (DRGs) Classification system for Medicare Part A payments based on groups of diagnoses and procedures (69).

Direct Selection Selection from a set that contains all options as in a computer keyboard or a number pad (61).

Directing Providing guidance and leadership so that the work that is performed is congruent with goals (67).

Disability Impairments, limitations of activity and function, and activity restrictions (19, 55).

Discontinuation Summary Discharge summary; written at the termination of services to summarize the course of a client's intervention (39).

Discrete Tasks Actions that have a recognizable beginning and end (55).

Divergence Ability of the brain to transmit sensory input to many parts of the brain so that the input can affect multiple places at once; allows an entire muscle to work rather than one muscle fiber (59).

Dynamometer Instrument used to measure grip strength (54).

Dyspnea Shortness of breath (48).

Dyspraxia A developmental condition in which the ability to plan unfamiliar motor tasks is impaired (59).

Early Intervening Services Academic and behavior support to succeed in general education, not part of special education (50).

Effectiveness Evidence Research findings that evaluate the effectiveness of interventions (30).

Efficacy Expectations A person's belief about how successful or unsuccessful he or she will be at performing a skill or occupation (36).

Electrocardiogram (ECG/EKG) Test using attached wires (or wireless) to leads placed on the chest that document the pattern of electrical activity of the heart (56).

Electrodermal Response (EDR)/Galvanic Skin Response (GSR) Measurement of the electrical conductance of skin via skin-placed sensors designed to detect sweat gland activity (56).

Electroencephalograph (EEG) Noninvasive method of looking at electrical brain activity through wires and sensors that are placed on a person's head (56).

Electronic Aids to Daily Living (EADLs) Provide the user with control over appliances and other electronic devices (e.g., a door opener) within the environment; a wide variety of switches interface with EADLs to allow individuals with a variety of skills and impairments to use them (48).

Emergent Performance Combination of abilities put together in unpredictable ways to generate organized patterns of occupational behavior that is consistent with a particular situation (2). Investment of personal capacities put together in unpredictable ways to generate organized patterns of occupational behavior that fit the perceived affordances as well as children's reasons for doing the activity (3).

Empathic Competence Practitioner's emotional discernment to accurately perceive and respond to clients and their experiences in order to finely tune the therapy process (18).

Empathy Awareness of and insight into the feelings, emotions, and behavior of another person and their meaning and significance; not the same as sympathy, which is usually nonobjective and noncritical (33).

Endurance Ability to sustain a given activity over time (54).

Energy Conservation Modifying or adapting the environment or method of doing a task to increase efficiency and reduce stress on the respiratory system (54).

Engineering Controls Equipment and workplace designs or changes that reduce the human efforts needed (51).

Environment Physical, social, and cultural milieu that provides the stage on which lives are lived (8). Particular physical, social, cultural, economic, and political features within a person's context that affects the motivation, organization, and performance of occupation (44). The context for everyday living, including physical, social, cultural, economic, and institutional dimensions (60).

Environmental Affordance All action possibilities latent in the environment that within context invites or elicits interaction (59).

Environmental Demands Requirements that environments place on people during task performance (46).

Environmental Modifications Making minor or major alterations or changes to the environment to support the occupational performance of individuals or groups (60).

Environmental Press Demand characteristics of an environment that influence an individual's ability to perform an activity (60).

Epinephrine (adrenaline) Catecholamine produced by the adrenal glands that exerts effects on organs and structures throughout the body including the brain; primary purposes are to increase heart rate and blood pressure, facilitate efficient breathing, divert blood to large muscles, and mobilize blood sugars and fats so that an individual is prepared to respond to environmental challenges; acts as a neurotransmitter in the brain and as a hormone in blood circulation (56).

Ergonomics Scientific discipline concerned with the understanding of interactions among humans and other elements of a system; profession that applies theory, principles, data, and methods to design in order to optimize human well-being and overall system performance (51).

Essential Tasks Basic job duties that all employees must be able to perform with or without reasonable accommodation (51).

Ethnicity Socially constructed and potentially dynamic group membership based on subjective belief in common descent because of similarities of physical type and/or customs that may be self-selected or imposed from outside the group (6). Identification of a group (by group itself or others) on the basis of a boundary that distinguishes them from other groups—racial, cultural, linguistic, economic, religious, political—may be more or less porous; members of an ethnic group are often presumed to be culturally or biologically similar, although this is not necessarily the case (7).

Evaluation Process of gathering and interpreting qualitative and/or quantitative data to understand client needs and desires, describe function, predict future function, plan intervention, or measure outcome of OT intervention (39, 46, 47, 48, 50).

Evidence-Based Practice Use of research study findings, client values and practitioner expertise during clinical reasoning to support the process of making wise practice decisions (30).

Excitation Arousal of the nervous system (55).

Executive Function Ability to organize, problem-solve, and engage in independent behavior (57).

Exteroception Sensations from outside the body; information from touch, taste, sight, sound, and smell (59).

Facilitation Stimuli generated or information relayed following an action or interaction; often used to modify and refine future behavior (59).

Fading Systematic reduction of support (scaffold) to clients so that task demands increase; used when clients improve their skills (35).

Fair Testing Practice of determining potential sources of bias, irrelevant to the content of a test, that might negatively influence the performance of a person because of culture, age, disability, or some other trait and making modifications or accommodations to the test or test situation to minimize this bias without undue influence on reliability or validity (47).

Family-Centered Care Effective and compassionate attention to the concerns of family members; addressing the needs hopes of people and their families (4).

Fee for Service Retrospective reimbursement for medical services based on "reasonable and necessary" criteria (69).

Feedback Information that the learner receives about performance; critical for learning (54). Information arising from the response itself (productions feedback) or from changes that occur in the environment as a result of the response (outcome feedback) (59).

Fidelity Faithfulness of intervention to underlying therapeutic principles (59).

Fieldwork Work done or firsthand observations made in the field as opposed to those done or observed in a controlled environment (26).

Fine Coordination Smooth and harmonious action of groups of muscles working together to produce a desired finely controlled motion (55).

Formal Authority Right to issue orders or direct action by virtue of one's formal position (67).

Formal Theory Explanation of observable events or relationships by stating a series of abstract propositions or principles (42).

Fraud The act of intentionally being deceptive in relation to the provision of services; can include fabricating documentation for services that were not really rendered, billing for more services than were provided in a visit, or accepting bribes or kickbacks for referrals (39).

Free Appropriate Public Education (FAPE) Special education and related services provided at public expense that meets the standards of the state education agency (SEA) (50).

Function Processes, actions, and behavior of the various organs and systems of the body (55).

Functional Capacity Evaluation Measurement of an individual's abilities and/or limitations in the context of safe, productive work tasks (51).

Functional Group Group process procedure in which time and energy are used in purposeful action to promote adaptation through occupation (37).

Functional Supervision   Supervision over a specific aspect of work or job function (69).

Functioning   Extent to which people are able to engage in occupations, influenced by health conditions and the physical, social, and attitudinal context (5).

Gemeinschaft   Characterizes the relationships between individuals in community that are private and based on shared interests with kin or family, neighborhoods, and groups of friends (19).

General Education   Environment, curriculum, and activities available to all students (50).

General Schema   Implicit cognitive map of the world as known, which can be evoked and mentally constituted at diverse scales and in diverse manifestations that vary according to the circumstances in which it is invoked (8).

Generalization   Spontaneous ability to transfer what is learned in one situation to a different situation (57).

Genotype   Actual genetic inheritance of an individual; a collection of specific alleles (6).

Gesellschaft   Characterizes social actions in community that are a public expression or response to a duty or to an organization within society (19).

Goniometer   Instrument that is used to measure joint range of motion (54).

Grading   Sequentially increasing demands of an occupation to stimulate improved function or reducing the demands to respond to client difficulties in performance (35).

Gravitational Insecurity   Type of sensory modulation dysfunction that is thought to result from poor processing of vestibular and proprioceptive sensation; manifested as fear of moving, being out of the upright, or having one's feet off the ground that is out of proportion to any danger; also refers to any postural deficits the individual has (59).

Gross Coordination   The combined activity of many muscles into smooth patterns and sequences of motion; smooth, directed, and fluid actions supporting everyday activities (55).

Group Cohesiveness   Attraction of members for their group and for the other members; members of a cohesive group accept one another, provide support, and form meaningful relationships in the group; may be a significant factor in successful group therapy outcome (37).

Group Process   A complex set of interdependent variables acting on and within a group and its members (37).

Habits   Acquired tendencies to automatically respond and perform in certain, consistent ways in familiar environments or situations (44). Automatic behavior that is integrated into more complex patterns that enable people to function on a day-to-day basis; may be useful, dominating, or impoverished and either support or interfere with performance in areas of occupation (OTPF-II).

Habituation   Internalized readiness to exhibit consistent patterns of behavior guided by habits and roles and fitted to the characteristics of routine temporal, physical, and social environments (44).

Health   A state of being that is usually associated with the absence of illness or injury but increasingly is taken to mean the extent to which a person participates in age-appropriate mobility, self-care, domestic, educational, vocational, and community occupations (5). State of complete physical, mental, and social well-being and not merely the absence of disease or infirmity (18).

Health Disparities   Gaps in the quality of health and health care across racial and ethnic groups, population-specific differences in the presence of disease, health outcomes, or access to health care (7).

Health Maintenance Organization (HMO)   Managed care system in which health care providers are gatekeepers who oversee patient treatment within the system (69).

Health Promotion   Process of enabling people to increase control over and improve their health (18). Movement toward optimal health and high-level wellness (51).

Health Reimbursement Accounts (HRA)   Savings account used for medical bills that is not subject to income tax (synonym: *Health Savings Accounts*) (69).

Health Resources and Services Administration (HRSA)   Primary federal agency for improving access to health care services for people who are uninsured, isolated, or medically vulnerable (17).

Health Savings Account (HSA)   Savings account used for medical bills that is not subject to income tax (synonym: *Health Reimbursement Accounts*) (69).

Here-and-Now   Spontaneous action that focuses on the present (37).

Heterarchical Approach   Suggests that therapists consider a network of factors for clinical decision making instead of a hierarchy of levels (27).

Home   Abiding place of affection, provides a sense of centering, permanence, ownership, responsibility, control, self-expression, privacy, refuge, comfort (familiarity), emotional affiliation, and belonging (8).

Homeostasis   Maintenance of internal environment, describes periods in which the body grows and regenerates in order to maintain balance and health among body systems, involves conservation and restoration of energy, the digestion and absorption of nutrients, body repair and healing, sexual reproduction, and excretion of waste (56).

Homophobia   Unreasonable fear or hatred of gay or lesbian people (6).

Hypertonia   Excessive muscle tension in a muscle (55).

Hypothalamic-Pituitary-Adrenal Axis (HPA)   Also referred to as the limbic-hypothalamic-pituitary-adrenal axis (LHPA), a pathway that describes connections between brain structures and the organ responsible for the production of cortisol (56).

Hypothalamus   Brain structure in the diencephalon section of the brain, oversees the autonomic nervous system, receives input from multiple regions of the brain, including the cerebral cortex and limbic system, to provide both internal and external sources of information that are necessary to regulate the internal environment of the human body (56).

Hypotonia   Decrease in a muscle's resistance to stretch as the joint is moved through the range of motion, client's inability to recruit adequate force to move against gravity (55).

Ideation   Conceptualizing an action; knowing what to do (59).

Impairment   Any problem with a normal psychological or physiological function, such as concentration or respiration, or with a body structure such as a limb, joint, or organ (5).

Incompetence   Acting without appropriate knowledge, skill, or ability (39).

Incoordination   Extraneous, uneven, or inaccurate movements (55).

Indemnity Plans   Insurance plans that pay for costs associated with a medical condition or injury; associated with fee-for-service method of payment (69).

Independence   Measure of performance indicating the ability to perform a task independently with or without adaptive equipment (46). Ability to participate in self-directed, necessary, and preferred occupations in a satisfying manner irrespective of the amount or kind of external assistance desired or required (OTPF-II).

Independent Living Movement   Organized approach by those with disability that incorporates ideas about managing their personal life, participating in community life, fulfilling social roles, sustaining self-determination; and minimizing physical or psychological dependence on others; emphasizes a person being physically located in a community setting and participating in community activities with consumer direction and control (19).

Indirect Selection   Also called scanning; the user uses a switch to choose from subsets of all options, which are offered sequentially in a scanning array (61).

Individual Controls   Physical, cognitive, and social skills and performance of the workers; safe, efficient job design depends on coordination of all aspects of the system (51).

Individual Education Program (IEP)   Written plan for the delivery of educationally related services to children ages 3–21 years with disabilities, as mandated by IDEA (39, 50).

Individual Family Service Plan (IFSP)   Written plan for the delivery of services to children with disabilities ages birth through 2 years; prepares children with disabilities to enter the educational system at age 3 years (39).

Individual Variation   Differences among individuals in their attributes (e.g., range, standard deviation) (30).

Individuals with Disabilities Education Act (IDEA)   Federal law that mandates that educational services must be provided to a child with a disability from birth to age 21 years (39).

Information Processing   The processing of information that includes registration of sensory information, perception or interpretation of the data, identification or memory, and cognition (59).

Inhibition   Release of a neurotransmitter at the synapse makes it less likely that the postsynaptic neuron will reach threshold (signal level) required for an action potential to occur and therefore for the sensory or motor information to be transmitted (59).

Inner Drive   Motivation and self-direction that come from within a child to develop sensory integration (59).

Institutional Bias   Financial support for institutional care, nursing home care, or other segregated settings rather than community-based settings (17).

Instrumental ADLs (IADLs)   Activities to support daily life within the home and community that often require more complex interactions than self-care used in ADLs (OTPF-II).

Integrated Practitioner   Considers the best scientific evidence while simultaneously attending to the humanistic aspects of the client's narrative and lived experience (27).

Interagency Model of Fieldwork   Development of a new role for occupational therapy by collaborating with a community agency or industry to create a fieldwork experience for students (26).

Interdependence   Mutual dependence, people's reliance on each other as a natural consequence of living (OTPF-II).

Interests   What one finds enjoyable or satisfying to do (44).

Internalized Role   Incorporation of a socially and/or personally defined status and a related cluster of attitudes and actions (44).

International Classification of Function [ICF]   Model proposed by the World Health Organization that describes a person's level of ability along a continuum of impairment to participation (55).

Interoception   Sensation originating from inside the body; perception of visceral sensations arising from internal organs (59).

Intervention   Process and skilled actions taken by occupational therapy practitioners in collaboration with the client to facilitate engagement in occupations related to health and participation. The intervention process includes the plan, implementation, and review (OTPF-II).

Isokinetic Exercise   Exercise in which speed of the muscle contraction is controlled and maximum exertion occurs at the end of the range; contraction can be eccentric or concentric (54).

Isometric Exercise   Exercise involving a muscle contraction in which there is no lengthening or shortening of a muscle (54).

Isotonic Exercise   Exercise in which the muscles actively lengthen and shorten during the contraction (54).

Job Analysis   Formal methodology that details the interaction between the worker and the equipment of a system (51).

Job Description   Defines the essential functions of the job and how the job relates to other jobs and to the workplace (51).

Joint Protection   Techniques to reduce stress on joints, pain and inflammation, and deformity during performance of daily tasks (54).

Just-Right Challenge   A task that is manageably demanding; promotes central nervous system integration (59).

Least Restrictive Environment (LRE)   Environment that provides maximum interaction with nondisabled peers and is consistent with the needs of the child/student (50).

Leisure   Nonobligatory activity that is intrinsically motivated and engaged in during discretionary time (OTPF-II).

Level I Fieldwork   Experiences designed to enrich didactic course work through directed observation and participation in selected aspects of the occupational therapy process (26).

Level II Fieldwork   In-depth experience in delivering occupational therapy services to clients, focusing on the application of purposeful and meaningful occupation, as integral to the academic program's curriculum design (26).

Life World   Phenomenological spatiotemporal context of human experience (8).

Limbic System   Cluster of brain structures that are responsible for emotion formation and emotional behavior as well as complex cognitive thought processing (e.g., memory) (56).

Low Registration   High thresholds and a passive self-regulation strategy. People with a low registration pattern

of sensory processing do not detect sensory input that others notice readily (59).

Malpractice   Misconduct on the part of a professional that results in harm to a client (39).

Managed Care   Comprehensive health care system that provides a variety of health services and facilities with a focus on controlling costs (69).

Management   Process of guiding a work unit by planning for future work obligations, organizing employees into functional units, directing employees in the process of completing daily work tasks, and controlling work processes and systems to ensure adequate quality of work output (67).

Marginal Functions   Tasks that are not essential to the specific job or tasks that could, if necessary, be completed by another worker (51).

Measurement   Process of assigning numbers to represent quantities of a trait, attribute, or characteristic or to classify objects (47).

Memory   Ability to register, retain, and recall past experience, knowledge, and sensation (57).

Mental Status Examination   Formal procedure to examine and diagnose mental functioning, including a general description of a person, notation of emotional expression, identification of perceptual disturbances, and exploration of thought processes and thought content (57).

Metacognitive   Cognitive processes in which one thinks about one's own thinking (32).

Modification   Changes in the form or character of a task (35)

Motor Control   Ability to direct the movement (static or dynamic) of the body through conscious or unconscious motor and sensory processes (55).

Motor Learning   Set of processes associated with practice or experience leading to permanent changes in the capability for skilled acts (54, 55).

Motor Planning   Ability to carry out a skilled, nonhabitual motor activity (57). Process that bridges ideation and motor execution to enable an adaptive response (59).

Motor Program   Abstract representation that prescribes the movements required to perform a given motor task (55).

Motor Skill   Learned and goal directed movement requiring some degree of precision and accuracy (55).

Movement   Motor action that is reflexive and/or controlled (55).

Multimedia   Mode of communication using a computer and requiring human interaction (41).

Muscle Strength   Ability to produce movement or resist an external force (54).

Myth   An unfounded or poorly founded belief that is given uncritical acceptance by members of a group (6).

Negligence   Failing to do something that ought to be done to prevent harm to a client (39).

Nervous System Thresholds   Amount of excitatory input necessary to activate neurons; thresholds for responding occur along a continuum rather than at extremes; may be lower thresholds for some inputs and higher thresholds for other inputs (59).

Neural Map   Sensory information "stored" as a consequence of active movement, with more variations of movement enabling the development of more accurate "maps" (59).

Neurohormone   Hormone that influences brain (neural) structures (56).

Neuroplasticity   Brain's ability to reorganize itself by forming new neural connections throughout life; in development, it entails the activity-dependent shaping of connections at synapses where information is transferred from one nerve cell to another; is influenced profoundly by sensory experience during childhood (59).

New Poor   Unexpected poverty with inability to meet most basic needs; major factors contributing to growing numbers of new poor are job layoffs, family breakdown, and sudden illness (7).

Norepinephrine (noradrenaline)   Another catecholamine (see *Epinephrine*) produced by both the adrenal glands and neurons in the sympathetic nervous system neurons; Although similar in structure and influence to epinephrine, norepinephrine has its own receptor sites on the same and sometimes different organs (56).

Normative Expectations   Activities or occupations that are viewed as standard behavior expected of other people in the same circumstances; may be encouraged by members of the community (3).

Objective Observation   Measurement or compilation of data in ways that others can easily replicate (53).

Occupation   Ordinary and extraordinary things people do in their day-to-day lives that occupy time, modify the environment, ensure survival, maintain well-being, nurture others, contribute to society, and pass on cultural meanings and through which people develop skills, knowledge, and capacity for doing and fulfilling their potential (5). Personal activities that individuals choose to engage in and the ways in which each individual experiences them (35). An activity that has three inextricably linked properties: (a) active involvement of the person, (b) meaning to the person, and (c) a process with a product that may be either tangible or intangible (45). Meaningful, purposeful activity (51).

Occupation-Based Intervention   A client-centered intervention in which the occupational therapy practitioner and client collaboratively select and design activities that have specific relevance or meaning to the client and support the client's interests, needs, health, and participation in daily life (OTPF-II).

Occupational Activities   Tasks that are directly related to the individual's preferred occupational role. Such tasks must have personal meaning and occupational relevance; the individual must be the primary actor in the activity (45).

Occupational Adaptation   Constructing a positive occupational identity and achieving occupational competence over time in the context of one's environment (44). Normative process, internal to the person, by which competence in occupational functioning develops (45).

Occupational Adaptation Model of Professional Development   Conceptualizes three classes of adaptive response behaviors—primitive, transitional, and mature—that are typically demonstrated among all students; students tend to revert to lower-level behaviors when faced with situations that they perceive as too difficult or too unfamiliar (26).

Occupational Adaptation Process   Normative internal process that is activated by the individual when approaching and adapting to challenges in life (45).

Occupational Analysis   Analysis of an occupation that is relevant to an individual within the actual context of performance (35).

Occupational Apartheid   Separation between those who have meaningful, useful occupations and those who are deprived of, isolated from, or otherwise constrained in their daily life occupations (7, 27).

Occupational Challenge   What the individual experiences when circumstances create significant difficulty in carrying out his or her occupational roles (45).

Occupational Competence   Degree to which one is able to sustain a pattern of occupational participation that reflects one's occupational identity (44).

Occupational Deprivation   Situations in which people's needs for meaningful and health-promoting occupations go unmet or are systematically denied (27).

Occupational Engagement   Clients' doing, thinking, and feeling under certain environmental conditions in the midst of or as a planned consequence of therapy (44).

Occupational Environment   One of the three primary elements in the theory of occupational adaptation. In contrast with other environments, the occupational environment calls for an occupational response from the individual in the context of either work, play/leisure, or self-maintenance. The contexts are shaped by unique physical, social, and cultural influences (45).

Occupational Identity   Composite sense of who one is and who one wishes to become as an occupational being generated from one's history of occupational participation (44).

Occupational Justice   Concept to guide humans as occupational beings who need and want to participate in occupations in order to develop and thrive and the political, social, economic, and cultural factors that may influence such participation (7). Right of every individual to be able to meet basic needs and to have equal opportunities and life chances to reach toward her or his potential but specific to the individual's engagement in diverse and meaningful occupations (20).

Occupational Orchestration   The capacity of individuals to enact their occupations on a daily basis to meet their needs and those in their social world; rhythmic, harmonious composition of daily life (35).

Occupational Participation   Engagement in work, play, or activities of daily living that are part of one's sociocultural context and that are desired and/or necessary to one's well-being (44).

Occupational Performance   Doing a task related to participation in a major life area (44).

Occupational Profile   A summary of the client's occupational history and experiences as described by the client; includes the client's patterns of living, interests, values, and needs relative to the current situation (39).

Occupational Readiness   A term that characterizes interventions that are designed to affect the individual's sensorimotor, cognitive, and/or psychosocial deficits (e.g., strengthening, endurance, and ROM activities; memory training; stress management) (45).

Occupational Response   Outcome; the observable by-product of the adaptive response; the individual's action or behavior in response to an occupational challenge (45).

Occupational Role   The occupations that an individual assigns to particular roles (35).

Occupational Role Expectations   Product of both the individual's personal desires for performance and demands that stem from the occupational environment and its respective physical, social, and cultural influences; the internal and external expectations shape the uniqueness of the challenge the person experiences (45).

Occupational Science   A basic science concerned with the study of occupation and human life, particularly related to health, well-being, and social participation (1).

Occupational Therapist (OTR)   Graduate of an accredited occupational therapy program who has completed fieldwork and passed the certification examination administered by the National Board for Certification of Occupational Therapy (NBCOT); also referred to as a certified occupational therapist or registered occupational therapist (25).

Occupational Therapy Aide   An individual who is assigned by a certified occupational therapist to perform delegated, selected, skilled tasks in specific situations under intense close supervision by an occupational therapy practitioner (25).

Occupational Therapy Assistant (OTA)   Graduate of an accredited occupational therapy assistant program who has completed fieldwork and passed the certification examination by the National Board for Certification of Occupational Therapy; also referred to as a certified occupational therapy assistant (COTA) (25).

Occupational Therapy Practitioner   Occupational therapist or occupational therapy assistant (25).

Occupational Therapy Process   Problem-solving method used by occupational therapy practitioners to help clients improve their occupational performance; consists of theory selection, evaluation, problem definition, intervention planning, intervention implementation, and reevaluation (46).

Office of the Surgeon General   The Surgeon General is the chief health educator in the United States, giving Americans the best scientific information available on how to improve their health and reduce the risk of illness and injury (17).

Open Skills   Motor skills that are performed in a constantly changing environment, have high information-processing demands, and are attention demanding (55).

Operational Definition   Clear description of a concept or term that contains sufficient detail to enable uniform interpretation of the concept or term by many individuals (48).

Organizing   Designing workable units, determining lines of authority and communication, and developing and managing patterns of coordination (67).

Orientation   Awareness of self in relation to time, place, and identification of others (57).

Orthotic   Relatively permanent device worn to substitute for impaired or lost muscle function (54).

Outcome   Result(s) or consequence(s) of occupational therapy intervention (46).

Oxytocin   Primarily a neurohormone produced in the hypothalamus and released into the bloodstream by the pituitary gland; primary role is regulation of social emotions and reproductive behavior; supports caregiving behavior, including stimulating milk production for breast-feeding; released during orgasm; measured through blood and cerebral spinal fluid samples (56).

Parasympathetic Branch of the Autonomic Nervous System (PNS)   System that is mostly concerned with generalized homeostasis (56).

Participation   Taking part in any occupation, whether by oneself or as part of a group, regardless of the reason for taking part, involvement in life situations, which encompasses all aspects of human functioning that involve learning and applying knowledge, completing tasks, communication, mobility, self-care, domestic life, interpersonal relationships, major life areas such as education and employment, and community, social, and civic life (5).

Passive Range of Motion (PROM)   Arc of motion through which the joint passes when moved by an outside force (54).

Peer Supervision   Oversight provided by another professional who does not have any formal authority to provide supervision but participates in providing feedback or sharing knowledge with another professional with the intent of influencing the other person's practices to improve client outcomes (68).

Perception   Integration of impressions from the different sensory sources into psychological, meaningful information (55). Meaning that the brain gives to sensory input; consists of "maps" of every part of our body that are stored in the nervous system as the sensations from the skin, muscles, joints, and gravity and movement receptors are organized and sorted during the person's daily activities (59).

Performance Capacity   Underlying mental and physical abilities and how they are used and experienced in performance (44). Ability for doing things provided by the status of underlying objective physical and mental components and corresponding subjective experience (46).

Performance Discrepancy   Performance problems that occur when performance demands exceed a person's capacities (46).

Performance Parameters   Variables or characteristics of task performance that can be observed and/or measured, such as independence, pain, and satisfaction (46, 48).

Perseveration   Unnecessary and prolonged repetition of a word, phase, or movement (57).

Person-Environment-Occupation Fit   The goodness of fit or congruence in the relationship that exists between the person, his or her occupation, and the environment in which the occupation is being performed (60).

Personal Causation   Individual's sense of competence and effectiveness (44).

Personal Factors   Aspects of the human condition such as body structures and body functions (53).

Personal Meaning   Satisfaction of conscious or unconscious needs and/or attribution of benefits derived from activities (52).

Personal Theory   Private understanding based on experience (42).

Phases of Group Development   Theoretical, predictable periods in the life cycle of a group (37).

Phenotype   Appearance of an individual that has a relationship to genotype but not a direct correspondence because it reflects variation in expression of alleles (6).

Physical Agent Modality (PAM)   Treatment that uses energy in the form of heat, light, sound, cold, electricity, or mechanical devices (54).

Physical Environment   Includes human-made environments, natural environments, equipment, and technology (60).

Place   Space or location that is given meaning through habitation and the accumulation of location-based life experiences (8).

Plan of Care   A written document that that describes the client's occupational therapy goals and how those goals will be achieved; also be called a care plan, intervention plan, or treatment plan (39).

Planning   Process of deciding what to do by setting performance objectives and identifying the activities needed to accomplish these objectives (67).

Play   Any spontaneous or organized activity that provides enjoyment, entertainment, amusement, or diversion (OTPF-II).

Point of Service Plans   Managed care option consisting of a hybrid of an HMO and a PPO plan (69).

Policies   Written statements of direction and responsibility (39).

Political Activities of Daily Living   Adoption by mainstream therapists of concepts and practices related to occupational justice, such as political action to resolve occupational injustice, including understanding the political nature of human relations and societies (27).

Population   Group of people who collectively possess the specific traits or characteristics of interest for a particular study or intervention (47).

Population Health   Health outcomes of a group of individuals, including the distribution of such outcomes within the group (18).

Portfolio   Archive of self-assessment processes, learning plans, evidence of engagement in selected learning methods, reflection on the learning process, and outcomes of the application of learning to practice (25).

Postural Adaptation   Ability of the body to maintain balance automatically and remain upright during alterations in positions and challenges to stability (55).

Postural Alignment   A bodily position in which the center of gravity of each body segment is over the supporting base of the body (55).

Postural Control   Controlling or regulating the body's position in space to maintain stability and orientation (55, 59).

Posture   Composite of the positions of all the joints of the body at any given time (55).

Power   Ability to force compliance with one's wishes through coercion despite resistance (67).

Praxis   Engaging in a new or nonhabitual motor act; in addition to executing the motor act, praxis requires the cognitive ability to come up with the idea for action (ideation) and the ability to plan the action to be performed (59).

Precautions   Actions to prevent harm to an individual (39).

Preferred Provider Organization (PPO)   Flexible form of managed care consisting of a group of health care providers and hospitals that the consumer can choose to access health services at a reduced cost (69).

Present Levels of Educational Performance   Information from the special education evaluation that describe a student's current school performance; includes how the student's disability affects involvement and progress in the general education curriculum (50).

Prevention   Measures not only to prevent the occurrence of disease such as risk factor reduction, but also to arrest its progress and reduce its consequences once established. Prevention can also apply to injury prevention (18).

Primary Health Care   Essential health care made accessible at a cost a country and community can afford, with methods that are practical, scientifically sound, and socially acceptable (18).

Primary Prevention   Aimed at preventing the disease or injury from ever occurring (18).

Primary Reflexes   Innate motor reactions that do not require cognitive processing and are elicited automatically in response to a stimulus (55).

Problem Definition   Component of the occupational therapy process describing the performance problem to be addressed by occupational therapy interventions (46).

Procedures   Written statements that describe how policies should be implemented (39).

Professional Development   Process involving planning and achievement of excellence or establishing expertise in seeking a change in responsibilities or when assuming more complex professional roles (25).

Professional Practice Supervision   Supervision of others in the same profession, undertaken with an understanding of the profession's values, standards, and ethics aimed at providing support, training, and evaluation of the supervisie's professional performance (68).

Professional Reasoning   Process used by practitioners to plan, direct, perform, and reflect on client care. Includes processes by supervisors, fieldwork educators, and occupational therapy managers as they conceptualize occupational therapy practice (32).

Progress Notes   Any note written about a client that explains what the client did in occupational therapy. It may be written in a narrative (paragraph form), SOAP, or other format (39).

Project-Focused Fieldwork   Managing a project, such as developing new programs or resources or evaluating an existing program, including conducting a needs assessment/analysis, proposal preparation, and development of reporting structures and timelines (26).

Projective Identification   Experiencing a feeling or experience in common and disavowing it while at the same time displacing the feeling onto another individual (37).

Proportional Controls   Linking direction and speed within the same controller such as a joystick or in an option for setting up a mouse (61).

Proprioception   Sensations derived from movement (i.e., speed, rate, sequencing, timing, and force) and joint position; Derived from stimulation to muscle and, to a lesser extent, joint receptors, especially from resistance to movement (59).

Prosthesis   Device that substitutes for a lost body part (54).

Psychometrics Properties   Estimates of aspects of a test or the outcomes of a test score, such as reliability or validity, that provide evidence that it measures what it is intended to measure in a consistent and stable manner for a specific purpose (47).

Public Health   Science and art of promoting health, preventing disease, and prolonging life through the organized efforts of society (18). Dealing with the protection and improvement of community health through organized efforts of preventive medicine, as well as environmental and social sciences (19).

Punishment   A response to an undesired behavior (36).

Purposeful Activities   Goal-directed behaviors leading to an occupation that are designed or graded to help a client develop, recover from an impairment, or learn an adaptive approach (35).

Random Practice   Schedule of practice that involves nonsystematic but repetitive practice of the same set of tasks (54).

Range of Motion (ROM)   Arc of motion through which a joint moves (54).

Reaction Time Time from when a stimulus is given to the time when a movement begins in reaction to the stimulus (55).

Reading Level Grade level at which an individual reads; academic level and reading level are often not equivalent (41).

Reductionism Whole is understood in terms of its parts. In occupational therapy, reductionism means focusing intervention on the parts of the person (physical, emotional, or cognitive) or parts of the occupation (2).

Regulations Rules or laws issued by a government that guide conduct (70).

Reinforcement Something that causes a behavior to be strengthened and performed again (36).

Related Services In a school setting, services that help a child with a disability to benefit from special education, such as those provided by occupational or physical therapy practitioners, school nurse, psychologist, or social worker or special transportation services (39).

Reliability Consistency and repeatability of the outcome of administration of a test across time, parallel forms of the test, and raters. It also refers to the consistency of the internal structure of the test (47).

Religion Corporate beliefs with its attendant practices (9).

Requisite Managerial Authority The level of control and discretion that a manager must have to be fairly held responsible for the outcomes of work groups (67).

Response The reaction to the stimulus (36).

Response to Intervention (RtI) An integrated approach to service delivery that includes both general and special education and includes high-quality instruction, interventions matched to student need, frequent progress monitoring, and data-based decision making (50).

Responsiveness Evidence Research findings that test the quality of progress-monitoring procedures (30).

Rigidity Simultaneous increases of muscle tone in the agonist and antagonist muscle that result in increased resistance to passive motion in any direction (55).

Risk Factors Characteristics associated with individuals who have a health condition that may include demographic variables, behavioral risk factors, and environmental factors (19).

Rituals Highly symbolic actions with a strong affective component and representative of a collection of events that are performed at regular intervals or on specific occasions (OTPF-II).

Role Normative models shaped by the culture (35). Set of behaviors expected by society, shaped by culture and further conceptualized and defined by the individual (OTPF-II).

Role-Emerging Supervision Occurs in a placement where there is no occupational therapist on-site with opportunities for students to be more autonomous and independent, promoting increased professional growth (26).

Role Lock Fixed perceptions of others' view of someone's position and function in a group (37).

Routines Patterns of behavior that are observable, regular, and repetitive and that provide structure for daily life; may be satisfying, promoting, or damaging; require momentary time commitment; and are embedded in cultural and ecological contexts (OTPF-II).

Safety Measure of task performance indicating that a person can perform a task without risk to himself or herself or to the task environment (46).

Same Site Model of Fieldwork Entails students completing a Level I and Level II fieldwork experience at the same training site (26).

Sample A group of individuals selected to represent the theoretical population (47).

Satisfaction with Experience Overall feelings and perceptions related to experience (52).

Scaffolding Providing help or support to an individual to enable task completion (35, 59).

Scapegoating Individuals displacing common feelings and attitudes, usually negative, onto someone else in a group (37).

Screening Obtaining and reviewing data that are relevant to a potential client to determine the need for further evaluation and intervention (39).

Secondary Prevention aimed at changing unhealthy lifestyles or behaviors to reduce risk (18).

Self-Appraisal Examination of competencies and client outcomes in order to make decisions about how best to learn; once learning is implemented, selecting the evidence of learning that best indicates achievement of the competency statement (25).

Self-Assessment Provides the means to assess performance, abilities, and skills; to analyze demands and resources of the work environment; to interpret information about clients' outcomes; to reassess current learning goals; and to develop goals and plans for professional growth and continuing competence and competency (25).

Self-Determination Combination of skills, knowledge, and beliefs that enable a person to engage in goal-directed, self-regulated, autonomous behavior and to make choices and control one's life (OTPF-II).

Self-Efficacy Beliefs of individuals in their capabilities to organize and execute the courses of action required to deal with prospective situations (OTPF-II).

Self-Regulation Ability to adapt emotional expression, behavioral activity level, and attention/arousal level effectively in response to the contextual demands of the environment (56, 59).

Self-Regulation Strategies Strategies that individuals use to control the amount of sensory input they receive, whereas other people are passive, letting things happen and then responding. Self-regulation also occurs along a continuum rather than as only active or passive responding (58, 59).

Sensation Avoiding Low thresholds and an active self-regulation strategy. People with a sensation avoiding pattern of sensory processing actively work to limit the sensory input that they have to encounter throughout the day (59).

Sensation Seeking High thresholds and an active self-regulation strategy. People with a sensation seeking pattern of sensory processing create more sensory input for themselves, and derive pleasure from sensation (59).

Sensory Defensiveness Fight-or-flight reaction to sensation that most others would consider nonnoxious (59).

Sensory Detection Sensory registration; first step of sensory processing within the central nervous system (59).

Sensory Discrimination Discerning the qualities, similarities and differences of stimuli (59).

Sensory Integration and Praxis Tests A battery of 17 tests designed to evaluate several aspects of praxis as well as some aspects of somatosensory and visual discrimination and postural control in children 4 through 8 years of age with mild to moderate learning or motor difficulties; contributes to understanding a child's difficulties and planning intervention (59).

Sensory Modulation The ability to regulate and organize reactions to sensory input in a graded and adaptive manner; the balancing of excitatory and inhibitory inputs and adapting to environmental changes (59).

Sensory Processing Functions related to sensation occurring in the central nervous system; includes reception, modulation, integration, and organization of sensory stimuli; also includes the behavioral responses to sensory input (59).

Sensory Registration Noticing sensory stimuli in the environment (59).

Sensory Sensitivity Represents low thresholds and a passive self regulation strategy. People with a sensory sensitivity pattern of sensory processing notice many sensory experiences around them, and detect details of sensory input that others might not notice (58).

Serial Tasks Several discrete movements performed in a structured sequence (55).

Service Coordinator The person responsible for managing a student's IFSP or IEP (39).

Services on Behalf of the Child Includes supports for parents and school personnel that can include specialized training that helps them to work more effectively with the child (50).

Shaping A strategy to develop closer and closer approximations of behavior (36).

Shear Parallel but opposing forces that injure soft tissue (61).

Sheltered Workshop Noncompetitive employment setting that is intended to provide many of the positive benefits of a work atmosphere for individuals with disabilities (51).

Skill Observable, goal-directed action that a person uses while performing (44).

Skill Acquisition Process of learning a skill (55).

SOAP (Subjective, Objective, Assessment, Plan) A type of progress note written in a standard format so that specific information is easy to find (39).

Social Determinants of Health Factors that go beyond inherited biology and access to health care services but still exert a major influence on human health and well-being, including income and social status, social support networks, education and literacy, social and physical environment, personal health practices and coping skills, discrimination, and social exclusion; also used to describe a branch of public health and epidemiology (7).

Social Gradient Concept that higher standing in the social hierarchy leads to improved health status (7).

Social Inequality Unequal rewards and opportunities that accrue to different individuals and groups, particularly rewards and opportunities that are judged to be unfair, unjust, avoidable, and unnecessary; often linked to unequal distribution of economic assets and power within a society (7).

Social Justice Ethical distribution and sharing of resources, rights, and responsibilities between people recognizing their equal worth as citizens (OTPF-II).

Social Mobility The degree to which, in a given society, an individual's social status can change throughout the life course or the degree to which that individual's offspring and subsequent generations move up and down the class system (7).

Socioeconomic Position Includes both resource-based and prestige-based measures as linked to both childhood and adult social class position; gives greater weight to the

role of material resources in shaping life chances, including health, as compared to socioeconomic status (7).

Socioeconomic Status (SES) Status- or prestige-based measure of place in the social hierarchy; measurement of SES includes occupational attainment, education, and income (7).

Somatodyspraxia A relatively severe form of sensory-integrative-based dyspraxia characterized by difficulty with both easy (feedback-dependent) and more difficult (feedforward-dependent) motor tasks; thought to be based in poor processing (59).

Spasticity Velocity-dependent resistance to muscle stretch as the joint is moved through the range of motion (55).

Special Education Educational services that are designed to help a child with a disability learn in a way that is consistent with that child's unique needs; provided with no cost to parents (39, 50).

Specially Designed Instruction Instruction that has been individualized to meet the unique needs of a student in order to receive free and appropriate education in the least restrictive environment (50).

Spirituality A deep experience of meaning by engaging in occupations that involve the enacting of personal ideologies, reflection, and intention within a supportive contextual environment (9). Personal quest for understanding answers to ultimate questions about life, about meaning, and about relationship with the sacred or transcendent, which may (or may not) lead to or arise from the development of religious rituals and the formation of community (OTPF-II).

Splint Temporary device that is used to facilitate recover from an injury or to enhance function (54).

Stability Ability to maintain the body in equilibrium (synonym: *Balance*) (55).

Standardized Test Measurement instrument that has been developed in a rigorous, scientific manner for a defined construct and population with a prescribed process of administration and scoring and with demonstrated psychometric properties (47).

Stimulus Something that prompts a behavior (36).

Stress Heightened state of action or arousal in the mind and body; can be positive (e.g., falling in love) or negative (e.g., a state of wear and tear on the body), as well as physical (e.g., exercise) and psychological (e.g., a state of worry) (56).

Subgrouping Dyads or clusters of members who consciously or unconsciously band together in a group for the purpose of avoiding something displeasing (37).

Subjective Experience State of mind with which activities are approached and affective experience of engaging in them (53).

Sundowning Increased confusion or disorientation that occurs at the end of the day; typically seen in people with Alzheimer's disease or other dementias (57).

Supervision Process of guiding an organization through the authoritative control of others completed by the governing body of the organization (67). Providing support, training, and evaluation of a supervisee's professional performance and development (68).

Supplemental Aids and Services Aids and services, in addition to specially designed instruction or related services, that are provided for a student in order to receive free and appropriate education in the least restrictive environment (50).

Supported Employment Competitive work in an integrated work environment consistent with the individual's strengths, resources, priorities, concerns, abilities, capabilities, interests, and informed choice (51).

Suppression Ability to dampen some stimuli so that other stimuli are easier to detect; ability to filter through all the input to the brain to determine which stimuli warrant attention and which stimuli can be ignored safely (59).

Surveillance Zone Space within the visual field of a person's residence (8).

Sympathetic Branch of the Autonomic Nervous System (SNS) Drives the fear, flight, or fight responses with increased respiration, cardiac activity, and metabolic activity, among others (56).

Synaptic Activity Transfer of information from one cell to another at a synapse, which can be facilitated if the firing of the presynaptic cell increases the likelihood that the postsynaptic cell will reach threshold and fire an action potential (excitatory synapse) or inhibited if the firing of the presynaptic cell reduces the likelihood of the postsynaptic cell firing (inhibitory synapse) (59).

Synaptic Function Entails the transfer of information from one cell (presynaptic neuron) to another (postsynaptic neuron) at the synaptic cleft; commonly referred to as synaptic transmission (59).

Synergy Functional coupling of groups of muscles constrained to act as a unit (55).

Systems Approach Views the properties of the whole, or system, as arising from interactions and relationships among the parts (51).

Tactile Defensiveness A sensory integrative dysfunction in which tactile sensations cause excessive emotional reactions, hyperactivity, or other behavior problems (59).

Target Condition   The public health or disease outcome that the preventive care intervention avoids (primary prevention) or identifies early (secondary prevention) or treats effectively (tertiary prevention) (19).

Task Analysis   Systematic process of determining task demands (51).

Task Demands   Action requirements that a task puts on people (46).

Terminal Device   Prosthetic hand or hook that is attached to the wrist unit of a prosthesis (54).

Tertiary Prevention   Aimed at reducing the effect of a disease or injury or preventing the person from becoming more ill or dying (18).

Third-Party Payer   Private company or government agency (such as Medicare) that provides payment for medical expenses (48).

Tone   Amount of tension within a muscle (55).

Transaction   As used in reference to the person-task-environment transaction, the balance or equilibrium achieved between person (client) and task and environment factors that optimally supports occupational performance (46). Process that involves two or more individuals or elements that reciprocally and continually influence and affect one another through an ongoing relationship (OTPF-II).

Transference   Negative and positive feelings, attitudes, and responses to others based on an individual's psychological and social history (37).

Transition Planning   Preparation of the student to leave the school setting and enter employment; education and rehabilitation team involved in this preparation (51).

Underresponsiveness   A type of sensory modulation response pattern characterized by fewer or flattened overt responses to sensation compared to the responses of people with normal sensory modulation (59).

Unilateral Neglect   Lack of awareness of stimuli presented to the side opposite the cerebral lesion in individuals who do not have primary sensory or motor impairments (57).

Universal Design   Design of environments and products to be usable by all people to the greatest extent possible without the need for special arrangements or adaptations (19). The intent of universal design is to simplify life for everyone by making products, communications, and the built environment more usable by as many people as possible at little or no extra cost (60, 61).

Validity   Evidence from theory and scientific study that supports the meaning, utility, and appropriateness of inferences and actions resulting from test scores, congruent with the defined purposes of the test (47).

Values   What one finds important and meaningful to do (44).

Vasopressin   Hormone produced in the hypothalamus and released by the pituitary gland; regulates water and salt concentrations in the blood, as well as blood pressure; also believed to play a key role in the regulation of social behavior; measured in blood and cerebral spinal fluid (56).

Vestibular   Sensation derived from stimulation to the vestibular mechanism in the inner ear that occurs through movement and position of the head; contributes to posture and the maintenance of a stable visual field (59).

Visitability   Home construction practices offering specific features that make the home easier for people with a mobility impairment to visit (e.g., zero-step entrance, 32-inch doorways, main floor bathroom) (19). Movement to change home construction practices so that new homes, whether or not designated for residents who currently have disabilities, offer a few specific features that make the home easier for people who develop a mobility impairment to live in and visit (60).

Visual Perceptual   Cognitive process of obtaining and interpreting visual information from the environment; includes discrimination, memory, spatial relationships, form constancy, sequential memory, figure-ground, and closure (59).

Volition   Pattern of thoughts and feelings about oneself as an actor in one's world that occur as one anticipates, chooses, experiences, and interprets what one does (44).

Well-Being   Extent to which individuals experience a sense of vitality and satisfaction with their life and circumstances; subjective perceptions of occupational performance, rather than objective measurements of the frequency or extent of participation in valued occupations (5).

Wellness   Process of taking responsibility for realizing one's maximum health potential (51).

Work   Exertion or effort directed to produce or accomplish something (51).

Work Conditioning   Emphasizes physical conditioning; addresses issues of strength, endurance, flexibility, motor control, and cardiopulmonary function (51).

Work Hardening   Highly structured, goal-oriented, individualized treatment program designed to maximize the individual's ability to return to work (51).

Work Integration Programs   Coordination of the clinical features of the injured worker into the organizational and ergonomic aspects of the system (56).

Working Poor   People who maintain full-time jobs but remain in relative poverty according to government-established poverty standards; may have negative net worth and lack the ability to escape their situations (7).

World Federation of Occupational Therapists (WFOT)
Key international representative for occupational therapy
and the official international organization for the promo-
tion of occupational therapy (23, 24).

Xenophobia   An unreasonable fear or hatred of those who
are different from oneself (6).

Index
Page numbers in *italics* denote figures; those followed by a t denote tables; those with an n denote footnotes.
